Clonal evolution (e.g., to myelodysplasia and acute leukemia) occurs in 10 to 20% of patients with acquired aplastic anemia survivors and up to 40% of children and adults with dyskeratosis congenita and FA. This complication likely evolves through a process of clonal selection and adaptation and for that reason is seen less commonly in completely responsive patients than in those with less than complete responses (who therefore have ongoing suppression of hematopoiesis). This suggests that more effective strategies of immunosuppressive therapy may better control ongoing marrow damage and decrease the incidence of clonal evolution.

PROGNOSIS

Acquired Idiopathic Aplastic Anemia

The severity of aplastic anemia and age are key determinants of long-term survival. Both these factors influence the choice of therapy (see Table 168-4). Early intervention is associated with a better prognosis, which should inform the pace of diagnostic evaluation. Matched sibling donor transplants are associated with higher response rates, lower relapse rates, long-term survival rates approximating 80%, and a lower incidence of clonal evolution. Immunosuppressive therapy is associated with long-term (10-year) survival rates of 70 to 75% in responders. Infection represents the most common cause of death in patients of any age treated with either immunosuppression alone or stem cell transplantation.

Inherited Bone Marrow Failure Syndromes

Patients with dyskeratosis congenita and FA will not respond to immunosuppressive therapy. Stem cell transplantation with nonmyeloablative approaches has the potential of curing the marrow failure component of these diseases. There are good theoretical reasons for anticipating that successful transplantation will reduce the likelihood of clonal evolution to myelodysplasia and acute leukemia. Unfortunately, the decision to transplant is influenced by other key factors, as described earlier. In light of these complexities, no clear-cut when-to-transplant rule can be applied to all patients with these diseases. Taking these difficult issues into account, all patients should be evaluated early in an experienced transplantation center, and family members should be screened by hematologists, geneticists, and genetic counselors using specialty laboratories.

In patients with dyskeratosis, small case series report good outcomes after fludarabine-containing nonmyeloablative conditioning regimens, but studies of sufficient size are not available to permit concrete recommendations except that patients should be referred to an experienced center. In patients with FA, with proper conditioning regimens, matched sibling donor transplant recipients have expected 3-year survival rates of about 85% and matched unrelated recipients (when fludarabine containing nonmyeloablative approaches are used) have 3-year survival rates of 50%. In patients with Diamond-Blackfan anemia, sibling donor transplant recipients have 3-year survival rates of about 80%, but disease-free survival rates after matched unrelated donor transplants have been poor (20 to 30%).

Future Treatments

For patients with acquired aplastic anemia, studies designed to selectively target the T-cell clones responsible for hematopoietic suppression may provide more effective and less toxic strategies for immunosuppressive therapy. For all patients with aplastic anemia, further improvements in matched unrelated transplantation should make this modality more widely available for patients who are not now considered optimal candidates. GVHD control will continue to improve. For children with nonsevere aplastic anemia, the 10-year progression-free survival rate is only about 25%, suggesting that prospective trials of early intervention are warranted. For patients with inherited bone marrow failure syndromes, the genes for which have been largely identified, the possibility of stem cell gene therapy holds enormous theoretical promise.

POLYCYTHEMIAS, ESSENTIAL THROMBOCYTHEMIA, AND PRIMARY MYELOFIBROSIS

AYALEW TEFFERI

DEFINITION

Polycythemia vera (PV), essential thrombocythemia (ET), and primary myelofibrosis (PMF) are categorized as myeloproliferative neoplasms (MPNs) in the 2008 World Health Organization (WHO) classification system for hematologic malignancies (Table 169-1). These disorders represent hematopoietic bone marrow stem cell–derived clonal myeloproliferations with a propensity to evolve into acute myeloid leukemia (also called blast-phase MPN). These three clinicopathologic entities, together with

TABLE 169-1 2008 WORLD HEALTH ORGANIZATION CLASSIFICATION OF MYELOID NEOPLASMS

1. Myeloproliferative neoplasms (MPNs)
   - 1.1. Chronic myelogenous leukemia, *BCR-ABL1* positive (CML)
   - 1.2. Polycythemia vera (PV)
   - 1.3. Essential thrombocythemia (ET)
   - 1.4. Primary myelofibrosis (PMF)
   - 1.5. Chronic neutrophilic leukemia (CNL)
   - 1.6. Chronic eosinophilic leukemia, not otherwise specified (CEL-NOS) (Chapter 173)
   - 1.7. Mast cell disease (MCD) (Chapter 263)
   - 1.8. MPN, unclassifiable (MPN-U)
2. Myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, or *FGFR1* (Chapter 173)
3. Myelodysplastic syndromes (MDS)/MPN
   - 3.1. Chronic myelomonocytic leukemia (CMML) (Chapter 190)
   - 3.2. Juvenile myelomonocytic leukemia (JMML)
   - 3.3. Atypical chronic myeloid leukemia, *BCR-ABL1* negative (aCML) (Chapter 190)
   - 3.4. MDS/MPN, unclassifiable
4. Myelodysplastic syndromes (MDS) (Chapter 188)
5. Acute myeloid leukemia (AML) and related neoplasms (Chapter 189)

chronic myelogenous leukemia (Chapter 190), used to be referred to as *myeloproliferative disorders*. Because chronic myelogenous leukemia is invariably linked to the Philadelphia translocation (i.e., *BCR-ABL1*), PV, ET, and PMF are operationally labeled *BCR-ABL1–negative MPNs*.

EPIDEMIOLOGY

Incidence figures for *BCR-ABL1*–negative MPNs are estimated at 0.2 to 2.5 per 100,000 for ET, 0.4 to 1.5 per 100,000 for PMF, and 0.8 to 2.6 per 100,000 for PV. The median age at diagnosis for all three MPNs is usually reported as 60 years, but population-based studies report a substantially older age. Family studies suggest a five- to seven-fold increased risk of MPN among first-degree relatives of patients with *BCR-ABL1*–negative MPN; the possibility of there being a hereditary component to disease susceptibility has been further supported by *JAK2* haplotype studies. ET appears to be more common in young women, but this gender imbalance is not as clear in other age groups. PMF has been associated with exposure to ionizing radiation (e.g., in Hiroshima survivors), heavy exposure to petroleum derivatives, and thorium dioxide (Thorotrast) contrast medium, but in the vast majority of cases there is no such exposure history.

PATHOBIOLOGY

The clonal nature of PV, ET, and PMF was established between 1976 and 1981 using glucose-6-phosphate dehydrogenase isoenzyme analysis. These diseases are now believed to derive from a genetically transformed bone marrow stem cell resulting in either monoclonal or oligoclonal myeloproliferation. In 2005, a *JAK2* gain-of-function mutation (*JAK2*V617F) was reported in *BCR-ABL1*–negative MPN, and subsequent studies using sensitive assays have revealed the presence of this mutation in approximately 95% of patients with PV and 60% of those with ET or PMF. Most of the remaining 5% of patients with PV carry another *JAK2* mutation (*JAK2* exon 12), whereas approximately 5 to 15% of *JAK2*V617F-negative patients with ET or PMF carry a *MPL*W515 mutation. All these mutations relate to the JAK-STAT intracellular signaling pathway in hematopoietic cells. The JAK-STAT pathway is normally activated by the occupancy of hematopoietic growth factor receptors (the receptor and the thrombopoietin receptor, also known as MPL) by their respective ligands (erythropoietin [Epo], thrombopoietin). Both *JAK2* and *MPL* mutations are also seen, albeit much less frequently, in other myeloid neoplasms. More recently, additional mutations have been described in PV, ET, and PMF and involve *TET2*, *ASXL1*, *CBL*, *IDH*, *IKZF1*, and *LNK* (Table 169-2). Most of these mutations originate at the progenitor cell level, but they do not necessarily represent the primary clonogenic event, are not mutually exclusive, and do not follow a predictable hierarchy.

The aforementioned molecular alterations in *BCR-ABL1*–negative MPN induce biologic changes that are demonstrated in animal models or ex vivo. For example, *JAK2* or *MPL* mutations induce PV-, ET-, or PMF-like diseases in mice by experimental manipulation of the mutant allele burden. These mutations are also believed to contribute to the growth factor independence or hypersensitivity of erythroid or megakaryocyte colony-forming progenitor cells and the accumulation of anti-apoptotic proteins such as Bcl-X_L. Bone marrow fibrosis, osteosclerosis, and angiogenesis in PMF are currently believed to be reactive and mediated by cytokines; that is, fibroblast proliferation in the bone marrow of patients with PMF is not a primary part of the clonal process.

TABLE 169-2 NOVEL MUTATIONS IN POLYCYTHEMIA VERA, ESSENTIAL THROMBOCYTHEMIA, PRIMARY MYELOFIBROSIS, AND BLAST-PHASE MYELOPROLIFERATIVE NEOPLASM

MUTATION	CHROMOSOME LOCATION	APPROXIMATE MUTATIONAL FREQUENCY (%)	PATHOGENETIC RELEVANCE
*JAK2*V617F exon 14 (Janus kinase 2)	9p24	PV: 96 ET: 55 PMF: 65 Blast-phase MPN: 50	Believed to contribute to myeloproliferation and progenitor cell growth factor hypersensitivity
JAK2 exon 12	9p24	PV: 3 ET: rare PMF: rare Blast-phase MPN: ?	Believed to contribute to primarily erythroid myeloproliferation
MPL exon 10 (myeloproliferative leukemia virus oncogene; encodes for thrombopoietin receptor)	1p34	PV: rare ET: 3 PMF: 10 Blast-phase MPN: ?	Believed to contribute to primarily megakaryocytic myeloproliferation
TET2 (mutations occur across several of the gene's 12 exons; TET oncogene family member 2)	4q24	PV: 16 ET: 5 PMF: 17 Blast-phase MPN: 17	Might contribute to epigenetic modulation of transcription (TET1 catalyzes conversion of 5-methylcytosine to 5-hydroxymethylcytosine)
ASXL1 exon 12 (Additional Sex Combs-Like 1)	20q11.1	PV: ? ET: ? PMF: ? Blast-phase MPN: 19	Believed to affect regulation of transcription and RAR-mediated signaling
CBL exons 8 and 9 (Casitas B-lineage lymphoma proto-oncogene)	11q23.3	PV: rare ET: rare PMF: 6 Blast-phase MPN: ?	Believed to alter the regulatory function of wild-type CBL against kinase signaling because of defective ubiquitylation of oncoproteins
IDH1/IDH2 exon 4/exon 4 (isocitrate dehydrogenase)	2q33.3/15q26.1	PV: rare ET: rare PMF: 4 Blast-phase MPN: 20	Induces accumulation of 2-hydroxyglutarate, a possible oncoprotein
IKZF1 (mostly deletions, including intragenic; IKAROS family zinc finger 1)	7p12	PV: rare ET: rare PMF: rare Blast-phase MPN: 19	Not clear at this point
LNK exon 2 (encodes a membrane-bound adaptor protein)	12q24.12	PV: rare ET: rare PMF: rare Blast-phase MPN: 10	Wild-type is a negative regulator of JAK2 signaling

ET = essential thrombocythemia; MPN = myeloproliferative neoplasm; PMF = primary myelofibrosis; PV = polycythemia vera; RAR = retinoic acid receptor.

TABLE 169-3 CLINICAL AND LABORATORY FEATURES OF POLYCYTHEMIA VERA

Persistent leukocytosis
Persistent thrombocytosis
Microcytosis secondary to iron deficiency
Increased leukocyte alkaline phosphatase
Splenomegaly
Generalized pruritus (usually after bathing)
Unusual thrombosis (e.g., Budd-Chiari syndrome)
Erythromelalgia (acral dysesthesia and erythema; see Fig. 169-1)

CLINICAL MANIFESTATIONS

Polycythemia Vera

Table 169-3 lists the typical clinical and laboratory features of PV. Increased red cell mass in PV might result in blood hyperviscosity, which leads to a plethora of symptoms and signs. Headaches are frequent, but blurry vision, altered hearing, mucous membrane bleeding, shortness of breath, and malaise are also observed. At least two thirds of PV patients have splenomegaly. Thrombosis occurs in about 40% of patients, most commonly arterial thrombosis. As in ET, venous thrombosis can occur in unusual sites, such as mesenteric or hepatic vessels, and hepatic vein thrombosis (Budd-Chiari syndrome) or portal vein thrombosis (Chapter 145) may be the presenting manifestation before the full hematologic picture of PV has emerged. Bleeding, especially gastrointestinal, is seen in PV, but it is less common than thrombosis. Pruritus is common in PV and may be provoked by warm water ("aquagenic"). Erythromelalgia (described later under Essential Thrombocythemia) may trouble some patients with PV, as do other vasomotor symptoms such as paresthesias and headaches.

Essential Thrombocythemia

At presentation, microvascular and vasomotor symptoms are found in 25 to 50% of ET patients. Major thrombosis is seen in 11 to 25% of patients at diagnosis and in 10 to 22% during follow-up; major hemorrhage is observed in 2 to 5% at diagnosis and in 1 to 7% during follow-up. Vasomotor disturbances (e.g., headaches, lightheadedness, visual symptoms such as blurring and scotomata, palpitations, chest pain, erythromelalgia, distal paresthesias) are not infrequent in ET and might be the result of abnormal platelet-endothelium interactions. Erythromelalgia (Fig. 169-1) is the most dramatic vasomotor symptom, characterized by erythema, warmth, and pain in the distal extremities; this symptom is rare but not entirely specific for ET. Splenomegaly is found in about 40% of patients with ET, but it is usually not prominent. Life-threatening complications of ET include large-vessel thrombosis (both arterial and venous), hemorrhage, and transformation of the disease into either a fibrotic phase resembling PMF or acute myeloid leukemia. Venous thrombosis in ET occurs both in sites common to other thrombotic diatheses (e.g., pulmonary embolism, lower extremity deep vein thrombosis) and in more unusual sites (e.g., cerebral sinus thrombosis, retinal vein thrombosis, hepatic and portal vein thrombosis).

Major hemorrhage in ET is most common in the gastrointestinal tract and may be precipitated by aspirin or other nonsteroidal anti-inflammatory drugs. Hemorrhage also occurs in the central nervous system and the retina, but such events are, fortunately, uncommon. Paradoxically, patients with extreme thrombocytosis may be at special risk for bleeding, in part related to the development of an acquired von Willebrand syndrome (Chapter 176) that is thought to be related to the adsorption of large multimers of von Willebrand protein from plasma onto the large number of abnormal circulating platelets. Fibrotic and leukemic transformations of ET are rare events (<5% of patients) during the first 10 years after diagnosis, but the risk increases with time.

Primary Myelofibrosis

Most patients with PMF present with anemia and marked splenomegaly. The anemia of PMF is multifactorial. Contributing factors include ineffective hematopoiesis and hypersplenism. Spleen and liver enlargement in PMF is secondary to extramedullary hematopoiesis (EMH) and may be associated with hypercatabolic symptoms including profound fatigue, weight loss, night sweats, and low-grade fever. Patients also experience peripheral edema, diarrhea, early satiety, and, occasionally, complications of portal hypertension, including variceal bleeding and ascites.

FIGURE 169-1. Erythromelalgia—a painful red discoloration of the hands or toes.

Splenomegaly in PMF may be complicated by splenic infarction that manifests with left upper quadrant abdominal pain and referred left shoulder pain. Computed tomography in such cases may be unremarkable, or it may show wedge-shaped or rounded low-attenuation lesions in the spleen. EMH occurs in many sites throughout the body. Besides the spleen and liver, common sites include the lymph nodes, skin, pleura, peritoneum, lung, and paraspinal and epidural spaces, where lesions may be found incidentally on imaging or may produce mass effects. The latter may result in spinal cord and/or nerve root compression, which is a medical emergency requiring corticosteroids to reduce edema and immediate radiation therapy.

DIAGNOSIS

At present, the 2008 WHO criteria are used for the diagnosis of ET, PV, and PMF (Table 169-4). These criteria are based on morphology and cytogenetic or molecular studies (Fig. 169-2). Almost all patients with PV carry a *JAK2* mutation (*JAK2*V617F or *JAK2* exon 12 mutation). Therefore, the absence of a *JAK2* mutation makes a diagnosis of PV unlikely. *JAK2*V617F is not specific to PV, however; it is also found in ET (≈55% of cases), PMF (≈65% of cases), and other myeloid neoplasms (usually <5% of cases). *JAK2* exon 12 mutations are relatively specific to *JAK2*V617F-negative PV and occur in approximately 3% of all patients with PV. Thus, the presence of a *JAK2* mutation excludes secondary myeloproliferation (e.g., secondary polycythemia or reactive thrombocytosis; see later), and its absence makes a diagnosis of PV very unlikely. The value of *MPL* and other MPN-associated mutations as diagnostic markers is undermined by their low prevalence in ET and PMF.

At present, neither red cell mass measurement nor bone marrow examination is essential for the diagnosis of PV (see Fig. 169-2). However, bone marrow examination with cytogenetic studies is often necessary for the accurate diagnosis of ET and PMF and is especially useful in distinguishing ET from prefibrotic PMF. Bone marrow fibrosis associated with *JAK2*V617F, trisomy 9, or del(13q) is highly suggestive of PMF. Figure 169-3 shows the typical peripheral blood smear seen in PMF, and the corresponding bone marrow histology is illustrated in Figure 169-4. Bone marrow morphology in ET also provides additional clues for distinguishing clonal from reactive thrombocytosis (Fig. 169-5).

Erythrocytosis (Polycythemias)

Polycythemia refers to either a real (true polycythemia) or a spurious (apparent polycythemia) perception of an increase in red blood cell mass. True polycythemia may represent either a clonal myeloproliferative disorder (PV) or a nonclonal increase in red blood cell mass that is often mediated by Epo (secondary polycythemia). Apparent polycythemia results from a decrease in plasma volume without an actual increase in red cell mass (relative polycythemia). Occasionally, a true increase in red blood cell mass may be masked by a normal-appearing hematocrit because of a concomitant increase in plasma volume, often accompanied by marked splenomegaly (inapparent polycythemia).

Most conditions that cause an acute depletion of plasma volume (i.e., relative polycythemia) are clinically obvious (e.g., severe dehydration, diarrhea, vomiting, use of diuretics, capillary leak syndrome, severe burns) and do not require specialized tests to confirm the diagnosis. Conversely, the existence

TABLE 169-4 2008 WORLD HEALTH ORGANIZATION DIAGNOSTIC CRITERIA FOR POLYCYTHEMIA VERA, ESSENTIAL THROMBOCYTHEMIA, AND PRIMARY MYELOFIBROSIS

CRITERIA	POLYCYTHEMIA VERA*	ESSENTIAL THROMBOCYTHEMIA*	PRIMARY MYELOFIBROSIS*
Major criteria	1 Hb >18.5 g/dL (men), >16.5 g/dL (women) or Hb/Hct >99th percentile of reference range or Hb >17 g/dL (men) or >15 g/dL (women) if associated with sustained increase of ≥2 g/dL from baseline, not otherwise explained or Elevated red cell mass >25% above mean normal predicted value	1 Platelet count ≥450 × 10^9/L	1 Megakaryocyte proliferation and atypia† accompanied by either reticulin or collagen fibrosis or In the absence of fibrosis, megakaryocyte changes accompanied by increased marrow cellularity and granulocytic proliferation
	2 Presence of *JAK2*V617F or similar mutation	2 Megakaryocyte proliferation with large and mature morphology; no or little granulocyte or erythroid proliferation	2 Not meeting WHO criteria for CML, PV, MDS, or other myeloid neoplasm
		3 Not meeting WHO criteria for CML, PV, PMF, MDS, or other myeloid neoplasm	3 Demonstration of *JAK2*V617F or other clonal marker or No evidence of reactive marrow fibrosis
		4 Demonstration of *JAK2*V617F or other clonal marker or No evidence of reactive thrombocytosis	
Minor criteria	1 Bone marrow trilineage myeloproliferation		1 Leukoerythroblastosis
	2 Subnormal serum Epo level		2 Increased serum LDH
	3 EEC growth		3 Anemia
			4 Palpable splenomegaly

*Diagnosis of PV requires meeting either both major criteria and one minor criterion or the first major criterion and two minor criteria. Diagnosis of essential thrombocythemia requires meeting all four major criteria. Diagnosis of PMF requires meeting all three major criteria and two minor criteria.
†Small to large megakaryocytes with an aberrant nuclear-to-cytoplasmic ratio and hyperchromatic and irregularly folded nuclei and dense clustering.
CML = chronic myelogenous leukemia; EEC = endogenous erythroid colony; Epo = erythropoietin; Hct = hematocrit; Hb = hemoglobin; LDH = lactate dehydrogenase; MDS = myelodysplastic syndrome; PMF = primary myelofibrosis; PV = polycythemia vera; WHO = World Health Organization.

of chronic contraction of the plasma volume, such as that postulated to occur in Gaisböck's syndrome or stress polycythemia, is controversial. Accurate reference to the race- and sex-adjusted normal laboratory values should minimize the inappropriate use of the term *apparent polycythemia* in physiologically normal persons with hematocrit values in the upper percentiles of the normal range. In such instances, the performance of costly diagnostic tests, including the measurement of red blood cell mass, is unwarranted.

Table 169-5 provides a comprehensive list of causes of erythrocytosis (polycythemia), including acquired forms (both clonal and secondary) and congenital forms. In each of these, the serum Epo level is helpful in

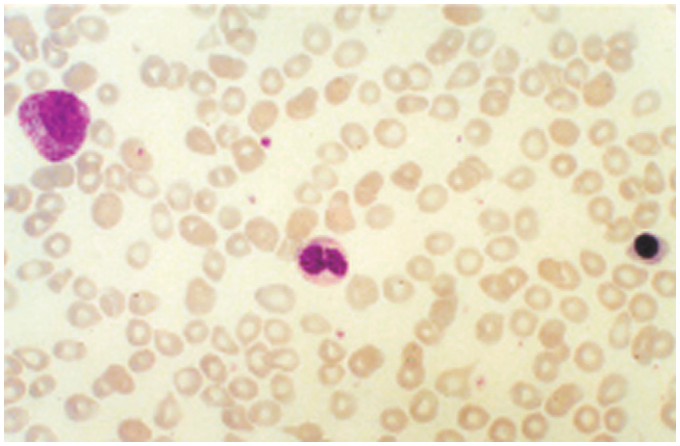

FIGURE 169-3. Myeloproliferative disorder. A peripheral blood smear from a patient with agnogenic myeloid metaplasia shows a leukoerythroblastic picture. The characteristic findings are teardrop-shaped red blood cells (dacryocytes), nucleated red blood cells (erythroblasts), and immature granulocyte precursors.

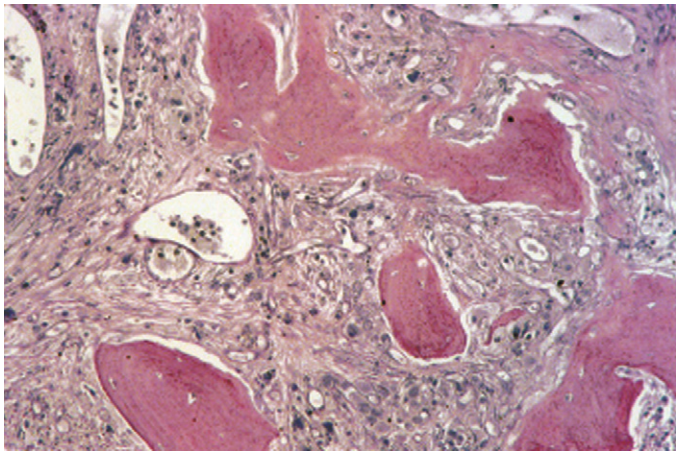

FIGURE 169-4. Bone marrow biopsy specimen from a patient with primary myelofibrosis shows reticulin fibrosis, osteosclerosis, and intrasinusoidal hematopoiesis.

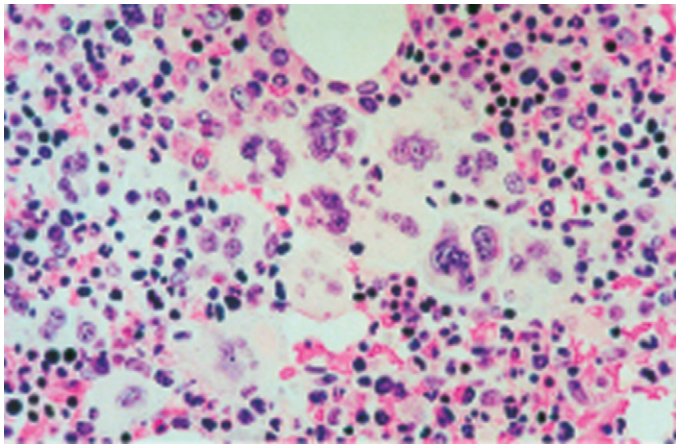

FIGURE 169-5. Myeloproliferative disorder. Bone marrow shows megakaryocytic clusters, seen in essential thrombocythemia and other conditions associated with clonal thrombocytosis.

TABLE 169-5 CLASSIFICATION OF ERYTHROCYTOSIS

I. Acquired erythrocytosis
  A. Clonal (polycythemia vera)
  B. Secondary
    1. Hypoxia driven
      a. Chronic lung disease
      b. Right-to-left cardiopulmonary shunts
      c. High-altitude habitat
      d. Tobacco use, carbon monoxide poisoning
      e. Sleep apnea–hypoventilation syndrome
      f. Renal artery stenosis
    2. Hypoxia independent
      a. Use of androgen preparations, erythropoietin injection
      b. Post renal transplant
      c. Cerebellar hemangioblastoma, meningioma
      d. Pheochromocytoma, uterine leiomyoma, renal cysts, parathyroid adenoma
      e. Hepatocellular carcinoma, renal cell carcinoma
II. Congenital erythrocytosis
  A. Associated with reduced p50 (partial pressure of oxygen at which 50% of hemoglobin is saturated with oxygen)
    1. High-oxygen-affinity hemoglobinopathy (usually autosomal dominant)
    2. 2,3-bisphosphoglycerate deficiency (usually autosomal recessive)
    3. Methemoglobinemia (Chapter 161)
  B. Associated with normal p50
    1. *VHL* mutations, including Chuvash polycythemia (usually autosomal recessive)
    2. *PHD2* mutations
    3. *HIF2α* mutations
    4. *EPOR* mutations (usually autosomal dominant)

From Patnaik MM, Tefferi A. The complete evaluation of erythrocytosis: congenital and acquired. *Leukemia.* 2009;23:834-849.

establishing the differential diagnosis. Epo is a 35-kD glycosylated protein synthesized in response to tissue hypoxia, mainly by the peritubular capillary endothelial cells of the renal cortex by means of an intricate oxygen-sensing mechanism. Acquired secondary polycythemia is usually associated with increased Epo production that is either hypoxia driven or hypoxia independent. In the former instance, the hypoxic stimulus is usually central, with cardiopulmonary conditions most commonly responsible. Other causes of central hypoxia include high-altitude habitat and carbon monoxide poisoning. Hypoxia in peripheral tissues is exemplified by the acquired polycythemia associated with renal artery stenosis. In both central and peripheral hypoxia-driven secondary polycythemia, the serum Epo level is initially elevated but may fall to within the normal range after the hemoglobin level has stabilized at a higher level. In contrast, in Epo-mediated, hypoxia-independent secondary polycythemia, the serum Epo level often remains elevated despite the rise in hemoglobin. Hypoxia-independent elevation of Epo with an elevated hemoglobin level is associated with malignant or benign tumors of the liver, kidney, uterus, and cerebellum (see Table 169-5). Exogenous administration of drugs such as androgen preparations or Epo itself also causes acquired secondary polycythemia.

Congenital polycythemia can be associated with increased, normal, or decreased serum Epo levels. For example, the serum Epo level is usually increased or normal in the autosomal dominant, high-oxygen-affinity hemoglobinopathies (e.g., 2,3-diphosphoglycerate mutase deficiency) and the autosomal recessive Chuvash polycythemia that is endemic in Russia and is associated with a von Hippel-Lindau (*VHL*) gene mutation. Conversely, the serum Epo level is low in patients with an activating mutation of the Epo receptor gene.

The diagnostic approach to congenital polycythemia should start with measurement of the serum Epo level. The presence of a subnormal serum Epo level in the absence of PV suggests the presence of a germline mutation of the Epo receptor. If the serum Epo level is normal or elevated, the next step is to measure the p50 (the oxygen tension at which hemoglobin is 50% saturated). Decreased p50 suggests the presence of either a high-oxygen-affinity hemoglobinopathy or 2,3-bisphosphoglycerate deficiency. If the p50 is normal, the possibility of *VHL* mutations (usually associated with increased serum Epo levels) should be considered first because they constitute the most frequent mutations in congenital polycythemia.

Thrombocytosis

Table 169-6 outlines the different causes of thrombocytosis, and Figure 169-6 provides an algorithmic approach to the differential diagnosis. By far, the most common cause of thrombocytosis in general medical populations is a reactive or secondary process. Also, the degree of elevation in the platelet count does not clearly differentiate clonal from reactive thrombocytosis. Figure 169-7 illustrates the value of examining the peripheral blood smear

in cases of thrombocytosis; the finding of Howell-Jolly bodies indicates a post-splenectomy or asplenic state as the cause of secondary (reactive) thrombocytosis.

Bone Marrow Fibrosis (Myelofibrosis)

Other causes of bone marrow fibrosis (myelofibrosis) are outlined in Table 169-7. The diagnosis of post-PV or post-ET myelofibrosis requires full documentation of a previous morphologic diagnosis of PV or ET, respectively.

TREATMENT

Polycythemia Vera and Essential Thrombocythemia

Drug therapy in PV or ET does not improve survival or prevent disease transformation into post-ET or post-PV myelofibrosis or blast-phase MPN. Instead, the main objective of specific therapy is to prevent thrombosis in high-risk patients (i.e., those older than 60 years or with a history of thrombosis) or to alleviate non-life-threatening symptoms, including microvascular disturbances (e.g., headaches, acral paresthesia, erythromelalgia), pruritus, or symptomatic splenomegaly. Microvascular symptoms are usually effectively treated with low-dose aspirin (81 mg/day). The cause of MPN-associated

TABLE 169-6 CAUSES OF THROMBOCYTOSIS IN UNSELECTED COHORTS OF CONSECUTIVE PATIENTS

	Platelet Count (Approximate % of Patients)	
CONDITION	**ADULTS, >500,000/μL**	**>1 MILLION/μL**

TABLE 169-8 RISK STRATIFICATION AND RISK-ADAPTED THERAPY IN ESSENTIAL THROMBOCYTHEMIA, POLYCYTHEMIA VERA, AND PRIMARY MYELOFIBROSIS

	Management			
RISK GROUPS FOR PV AND ET	**ET**	**PV**	**PMF**	**IPSS RISK GROUPS FOR PMF**
Low risk (age <60 yr and no thrombosis history)	Low-dose aspirin	Low-dose aspirin + phlebotomy*	Observation	Low risk (no risk factors†)
Low risk with extreme thrombocytosis‡	Low-dose aspirin§	Low-dose aspirin§ + phlebotomy	Conventional management‖	Intermediate-1 risk (1 risk factor†)
High risk (age ≥60 yr or thrombosis history)	Low-dose aspirin + hydroxyurea¶	Low-dose aspirin + phlebotomy + hydroxyurea¶	Allo-SCT if age <65 yr, or experimental therapy	Intermediate-1 risk with transfusions or unfavorable karyotype
			Allo-SCT if age <65 yr, or experimental therapy	Intermediate-2 risk (2 risk factors†)
			Allo-SCT if age <65 yr, or experimental therapy	High-risk (≥3 risk factors†)

*In the presence of aspirin therapy, the hematocrit target can range between 38 and 50% and is set at a level that maintains best performance status.
†The IPSS uses five risk factors for inferior survival: age >65 years, hemoglobin <10 g/dL, leukocyte count >25 × 10^9/L, circulating blasts ≥1%, and presence of constitutional symptoms.
‡Extreme thrombocytosis is defined as a platelet count >1000 × 10^9/L.
§Clinically significant acquired von Willebrand syndrome (ristocetin cofactor activity <30%) should be excluded before using aspirin in patients with extreme thrombocytosis.
‖Androgen preparations or thalidomide with prednisone for anemia; hydroxyurea for symptomatic splenomegaly.
¶In hydroxyurea-intolerant or -resistant cases, interferon-α (age <60 years) or busulfan or pipobroman (age >60 years) can be used.
Allo-SCT = allogeneic stem cell transplantation; ET = essential thrombocythemia; IPSS = International Prognostic Scoring System; PMF = primary myelofibrosis; PV = polycythemia vera.
From Tefferi A, Vainchenker W. Myeloproliferative neoplasms: molecular pathophysiology, essential clinical understanding, and treatment strategies. *J Clin Oncol.* 2011;29:573-582.

pruritus is poorly understood, but its dramatic response to JAK inhibitor therapy suggests a causal relationship with cytokines that use JAK-STAT signaling. Other therapies for MPN-associated pruritus include antihistamines, selective serotonin re-uptake inhibitors, interferon-α (IFN-α), and phototherapy. Symptomatic splenomegaly is usually managed with hydroxyurea (starting dose 500 mg orally twice a day).

Preventive cytoreductive therapy for thrombosis is indicated only in the presence of high-risk disease (see Prognosis later; Table 169-8). In this regard, randomized studies have demonstrated the value of low-dose aspirin (40 to 100 mg/day) in PV[100] and hydroxyurea (starting dose 500 mg orally twice a day) in high-risk ET. Hydroxyurea is a nonalkylating DNA synthesis inhibitor and a myelosuppressive agent. Based on noncontrolled but prospective evidence, most experts agree that low-dose aspirin therapy (81 mg/day) should also be considered for ET and hydroxyurea therapy for high-risk PV (see Table 169-8). In addition, phlebotomy is required for all patients with PV, and the target hematocrit in aspirin-treated individuals should be less than 50%—preferably around 45%. In high-risk patients with ET in whom cytoreductive therapy is indicated, a platelet target of less than 400 × 10^9/L is reasonable and supported by data from retrospective studies.

High-risk PV or ET patients (see Prognosis) who cannot tolerate or are resistant to hydroxyurea are effectively managed by IFN-α or busulfan. IFN-α is the preferred second-line drug, at least for younger patients. Two recent studies of pegylated IFN-α (≈90 μg by weekly subcutaneous injection) in PV and ET patients reported hematologic remissions of approximately 80%, accompanied by decreases in the *JAK2*V617F allele burden (complete molecular remission rate of 5 to 10%). A controlled study is needed before IFN-α is recommended as first-line therapy in either PV or ET. For older patients, busulfan is started at 4 mg/day; it is withheld in the presence of platelets less than 100 × 10^9/L or a white blood cell count less than 3 × 10^9/L, and the dose is reduced to 2 mg/day if the corresponding levels are less than 150 × 10^9/L and 5 × 10^9/L.

There is unsubstantiated fear among primary caregivers regarding the leukemogenicity of hydroxyurea and busulfan; no controlled studies in either PV or ET have shown this to be the case. The most recent randomized study in this regard found no difference in leukemia risk among patients receiving either hydroxyurea or anagrelide. Similarly, the two largest noncontrolled studies in ET and PV, as well as long-term studies of patients receiving hydroxyurea for sickle cell disease, do not support the concern that leukemia might be caused by the use of hydroxyurea. The evidence for busulfan's leukemogenicity in the context of treatment for PV or ET is equally weak and inappropriately extrapolated from older patients with advanced disease who were exposed to multiple cytoreductive drugs. Similarly, the safety and efficacy of busulfan treatment in ET were underlined by a more recent long-term study of 36 patients older than 60 years in whom no instances of acute myeloid leukemia or other malignancies were documented after a median follow-up of 72 months.

Anagrelide is a cyclic adenosine monophosphate phosphodiesterase III inhibitor that relatively selectively reduces the platelet count by acting on platelet production in the bone marrow. A large randomized study compared anagrelide with hydroxyurea, both in combination with aspirin, in high-risk patients with ET and demonstrated hydroxyurea's overall superiority.[101] Hydroxyurea was better tolerated and was associated with significantly less risk of arterial thrombosis, major hemorrhage, and fibrotic transformation. In contrast, anagrelide displayed better activity against venous thrombosis. A more recent but smaller randomized study found no difference between hydroxyurea and anagrelide in terms of the incidence of ET-related events, but the treatment discontinuation rate was higher in the anagrelide arm. Other treatment options in PV and ET include pipobroman (not available in the United States) and radiophosphorus. The latter has been associated with a delayed risk of leukemic transformation in patients with PV, and its use is currently limited to patients older than 65 years.

ET is associated with an increased risk (approximately 35% vs. 15% in the control population) of spontaneous abortion in the first trimester of pregnancy. There is no association between the increased risk of spontaneous abortion and the degree of thrombocytosis. Low-risk pregnant patients with ET or PV are managed the same way as their nonpregnant counterparts, and the use of low-dose aspirin has been associated with a decreased prevalence of first trimester miscarriages in retrospective studies. High-risk pregnant women with ET (i.e., those with previous thrombosis) require cytoreductive therapy, just like other high-risk patients. In such patients, there is anecdotal evidence of the safety of using IFN-α and the potential teratogenicity of hydroxyurea.

Major bleeding occurs in less than 10% of ET patients. Extreme thrombocytosis (i.e., platelet count >1 million/μL) appears to be a risk factor for bleeding, in part because of the acquired von Willebrand syndrome (Chapter 176). One approach is to measure ristocetin cofactor activity in patients with extreme thrombocytosis and withhold aspirin therapy if the value is less than 30%.

Primary Myelofibrosis

Drug therapy does not modify the natural history of PMF, although survival has improved in recent years. Patients with PMF who are considered low risk, as determined by the International Prognostic Scoring System (IPSS), can be observed without any therapeutic intervention. IPSS high-risk or intermediate-2-risk patients should be considered for investigational drug therapy or allogeneic stem cell transplantation (Chapter 181). Intermediate-1-risk patients who are transfusion dependent or have an unfavorable karyotype are managed as high-risk patients.

Conventional therapy for PMF is largely palliative and does not improve survival. Anemia and symptomatic splenomegaly are the main indications for treatment. Conventional drugs used to treat PMF-associated anemia include androgen preparations (e.g., oral fluoxymesterone 10 mg twice daily), danazol (400 to 600 mg/day), prednisone (30 to 40 mg/day), and erythropoiesis-stimulating agents. Prostate cancer screening is required in men treated with androgen preparations. Response rates to prednisone, androgen preparations, or danazol are about 20%, and response durations average about 1 to 2 years. Erythropoiesis-stimulating agents may exacerbate PMF-associated splenomegaly and are usually ineffective in transfusion-dependent patients.

Thalidomide and thalidomide-like drugs such as lenalidomide may be effective in the treatment of anemia in PMF. Thalidomide as a single agent (50 to 200 mg/day) is not as effective as its combination with prednisone (30 mg/day), with reported response rates ranging from 20 to 62% for anemia, 25 to 80% for thrombocytopenia, and 7 to 30% for splenomegaly. Response rates with lenalidomide are similar, but the drug works best in the presence of a del(5q) cytogenetic abnormality. The occurrence of peripheral neuropathy with thalidomide and severe pancytopenia with lenalidomide therapy has limited their use in most patients.

The drug of choice for symptomatic splenomegaly in PMF is hydroxyurea (starting dose 500 mg twice daily). Hydroxyurea-refractory cases are often

managed by splenectomy because the value of other conventional drugs in this regard is limited. Indications for splenectomy in PMF include mechanical discomfort, symptomatic portal hypertension (i.e., associated with ascites or variceal bleeding), and frequent red blood cell transfusions. The perioperative mortality of splenectomy in PMF is between 5 and 10%. Post-splenectomy complications occur in approximately 50% of patients and include bleeding, thrombosis, hepatomegaly, extreme thrombocytosis, leukocytosis, and an increase in circulating blasts. Prophylactic therapy with hydroxyurea is advised to prevent post-splenectomy thrombocytosis. A transjugular intrahepatic portosystemic shunt might be considered to alleviate symptoms of portal hypertension.

EMH is the main cause of hepatosplenomegaly in PMF and post-PV or post-ET myelofibrosis. Nonhepatosplenic EMH also occurs in PMF and might involve the vertebral column (causing cord compression), lymph nodes, lung (causing pulmonary hypertension), pleura (causing effusion), small bowel, peritoneum (causing ascites), urogenital tract, skin, and heart. Diagnosis is usually tissue based, but imaging studies are sometimes used; myelofibrosis-associated pulmonary hypertension is confirmed by technetium-99m sulfur colloid scintigraphy, which shows diffuse pulmonary uptake.

Radiation therapy is an attractive treatment option in both hepatosplenic and nonhepatosplenic EMH. Splenic irradiation (100 to 500 cGy in 5 to 10 fractions) induces a transient reduction in spleen size but might be associated with life-threatening pancytopenia. More recent studies suggest the relative safety and value of lower-dose treatment (100 cGy total dose in four daily fractions of 25 cGy). Radiation therapy works best for nonhepatosplenic EMH. Single-fraction (100 to 400 cGy) involved-field therapy has also been shown to benefit patients with myelofibrosis-associated pulmonary hypertension or extremity pain.

Symptoms in myelofibrosis that affect quality of life include profound fatigue, night sweats, weight loss, pruritus, bone pain, and nonproductive cough. In an international survey of 1179 patients, standardized fatigue metrics of the Functional Assessment of Cancer Therapy–Anemia (FACT-AN) and Brief Fatigue Inventory (BFI) were used to demonstrate that patients with PV, ET, and PMF suffer from anemia-independent fatigue exceeding that expected in age-matched controls. In a subset analysis of 458 patients with myelofibrosis, more than 50% suffered from moderate to severe fatigue, night sweats, pruritus, and symptomatic splenomegaly, whereas a smaller proportion listed bone pain, weight loss, and fever as additional symptoms. The study also documented the inadequacy of conventional therapy in the management of these symptoms. Recent studies of JAK inhibitor therapy in PMF or post-PV or post-ET myelofibrosis suggest major benefits in terms of constitutional symptoms and cachexia (see later).

Experimental Drug Therapy in Myeloproliferative Neoplasms

Because of the association between MPN and JAK-STAT–relevant mutations (e.g., *JAK2* and *MPL* mutations), several anti-JAK2 small-molecule drugs are currently undergoing clinical trials. One or more of these drugs have demonstrated remarkable activity against splenomegaly and constitutional symptoms, including pruritus, and resolution of leukocytosis and thrombocytosis, as well as reduction in the *JAK2*V617F allele burden. Side effects so far have included gastrointestinal symptoms; anemia; thrombocytopenia; reversible increases in transaminases, amylase, or lipase; and the phenomenon of "cytokine rebound." This phenomenon is seen in some patients receiving JAK2 inhibitors with particularly strong activity in suppressing pro-inflammatory cytokines and consists of the acute and immediate reappearance of symptoms on drug discontinuation.

Allogeneic Stem Cell Transplantation

The largest study of allogeneic stem cell transplantation in PMF was conducted by the Center for International Bone Marrow Transplant Research (CIBMTR) and included 289 subject with a variety of donor types and conditioning regimens. Five-year disease-free survival and treatment-related mortality were 33 and 35% for matched related transplants and 27 and 50% for unrelated transplants, respectively. Outcome was not favorably affected by reduced-intensity conditioning (Chapter 181). In another reduced-intensity conditioning transplant study from the Chronic Leukemia Working Party of the European Group for Blood and Marrow Transplantation, 103 patients (median age, 55 years) with PMF or post-PV or post-ET myelofibrosis were prospectively studied, and 5-year disease-free survival was estimated at 51%. Chronic graft-versus-host disease (Chapter 181) occurred in 49% of these patients, and relapse (29%) was predicted by high-risk disease and prior splenectomy. The chronic graft-versus-host disease and relapse rates for matched related transplants in the CIBMTR study were 40 and 32%, respectively, and a history of splenectomy did not affect outcome.

Considering the lack of effective drug therapy for PMF, the risk of transplant-related complications might be justified in patients whose median survival is expected to be less than 5 years and whose leukemia risk is greater than 20%. Using the age-adjusted dynamic prognostic model, this group includes high- or intermediate-2-risk patients, as well as those with either red cell transfusion dependence or an unfavorable karyotype (see Prognosis). In general, post-transplant outcome is poor in the presence of high-risk disease, advanced age, unrelated donor, or human leukocyte antigen (HLA) mismatch. More studies are needed to clarify the impact of pretransplant *JAK2*V617F presence or allele burden on transplant outcome, but the persistent presence of the mutation after transplantation predicts clinical relapse.

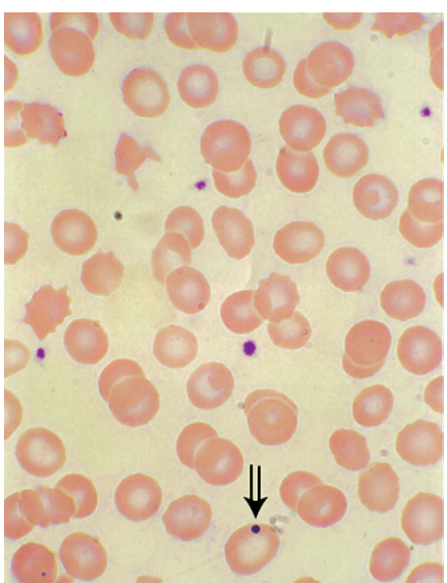

FIGURE 169-7. Peripheral smear showing Howell-Jolly bodies (arrow) in red blood cells. This finding is typical of surgical or functional hyposplenism.

PROGNOSIS

Essential Thrombocythemia and Polycythemia Vera

Neither ET nor PV is presently a curable disease, and current therapy has not been rigorously shown to prolong survival. Fortunately, a normal life expectancy is possible in most patients. Recent studies suggest a median survival that approaches 20 years in both diseases. Fibrotic or leukemic transformation in ET or PV is relatively infrequent (a combined rate of <10% in the first 15 years of disease).

Current risk stratification in PV and ET is designed to estimate the risk of thrombosis (see Table 169-8). Age 60 years or older and history of thrombosis are the two risk factors used to classify patients with PV or ET into low-risk (no risk factors) and high-risk (one or two risk factors) groups. In addition, because of the potential risk for bleeding, low-risk patients with extreme thrombocytosis (platelet count >1000 $\times$ 10^9/L) are considered separately. The presence of cardiovascular risk factors is currently not taken into consideration during formal risk stratification.

Primary Myelofibrosis

The prognosis of PMF is worse than that of ET or PV. Median survival is approximately 6 years and appears to have improved in recent years. The IPSS uses five independent predictors of inferior survival: age older than 65 years, hemoglobin less than 10 g/dL, leukocyte count greater than 25 $\times$ 10^9/L, circulating blasts 1% or higher, and constitutional symptoms. The presence of zero, one, two, or three or more adverse risk factors defines low-, intermediate-1-, intermediate-2-, and high-risk disease, respectively, with corresponding median survivals of approximately 11.3, 7.9, 4, and 2.3 years. A dynamic prognostic model that uses the same variables but can be applied at any time during the disease course was recently published. In addition, red cell transfusion dependency, a platelet count less than 100 $\times$ 10^9/L, and an unfavorable karyotype carry an IPSS-independent prognostic value, and their presence warrants assignment to the high-risk category regardless of IPSS score.

170 LEUKOCYTOSIS AND LEUKOPENIA

NANCY BERLINER

The normal peripheral white blood cell count (WBC) ranges between 4500/μL and 10,000/μL, with a mean of 7500/μL and is composed of neutrophils, lymphocytes, monocytes, basophils, and eosinophils. Because neutrophils usually represent about 60% of the peripheral WBC, derangement in the WBC usually reflects elevation or reduction in the absolute neutrophil count. Leukocytosis, an elevated WBC, and leukopenia, a depressed WBC, may be secondary to an underlying disease or exposure, or they may be manifestations of a primary hematologic disorder. This chapter outlines both the primary and secondary causes of leukocytosis and leukopenia, focusing particularly on neutrophilia and neutropenia.

NORMAL NEUTROPHIL DYNAMICS

To understand the pathogenesis of a high or low WBC, one must understand normal neutrophil dynamics. Neutrophils arise from multipotent progenitor cells in the bone marrow that also give rise to erythrocytes, megakaryocytes, eosinophils, basophils, and monocytes. Neutrophil precursors in the marrow mature over 6 to 10 days to form a storage pool of mature neutrophils (Fig. 170-1). Together the marrow populations make up about 95% of the body's total granulocyte mass (20% neutrophil precursors, 75% mature bands and neutrophils). The circulating neutrophil pool thus represents only the remaining approximately 5% of the body's total neutrophils, just over half of which at any given time are adherent to the vascular endothelium and the spleen, a phenomenon termed *margination*. These marginated neutrophils are poised for immediate release into the circulation during times of stress. The remaining neutrophils circulate freely in the blood, where they can survive for 6 to 12 hours, or migrate into tissues, where they can survive for 1 to 4 days. In general, then, neutrophilia can occur as the result of increased marrow production, increased release of neutrophils from the storage pool, or mobilization of neutrophils from the marginated pool. Neutropenia, on the other hand, may be due to decreased marrow production, increased margination with or without sequestration by the spleen, or increased destruction of peripheral cells.

NEUTROPHILIA

Most cases of neutrophilia are reactive or secondary to an underlying inflammatory process. This includes neutrophilia due to infection, chronic inflammation, stress, drugs, nonhematologic malignancy, marrow stimulation (as in hemolysis or idiopathic thrombocytopenic purpura), or splenectomy. Primary causes of neutrophilia may be congenital, including hereditary neutrophilia, Down syndrome, and leukocyte adhesion deficiency (LAD), or acquired as in the case of chronic myelogenous leukemia and other myeloproliferative neoplasms (Table 170-1).

Secondary Causes of Neutrophilia

Infection

Many acute bacterial infections can present with a modest leukocytosis with a "left shift," referring to the circulation of more immature myeloid cells. This left shift most commonly is restricted to release of an increased number of band forms; however, in severe stress, one may see circulating metamyelocytes and even earlier cells (see Fig. 170-1) in the peripheral blood. Leukocytosis occurs within hours of infection owing to release of neutrophils from both the marrow and marginated pools. Examination of these neutrophils on peripheral smear may reveal evidence of toxic granulation (see Fig. 160-18 in Chapter 160), Döhle bodies (see Fig. 160-19 in Chapter 160), and cytoplasmic vacuoles. Certain infections (e.g., *Clostridium difficile* or tuberculosis in particular) are known to cause elevations in the WBC to greater than 30,000/μL in about one fourth of infected patients and may result in a *leukemoid reaction*, defined as a WBC of greater than 50,000/μL with a pronounced left shift (Fig. 170-2).

Chronic Inflammation

Leukocytosis due to chronic inflammation results from increased leukocyte (specifically neutrophil and monocyte) production as opposed to altered neutrophil distribution. Mature neutrophil pools become depleted with ongoing inflammation, and the myeloid compartment of the marrow expands to increase neutrophil production. A myriad of cytokines, including tumor necrosis factor-α (TNF-α), granulocyte colony-stimulating factor (G-CSF),

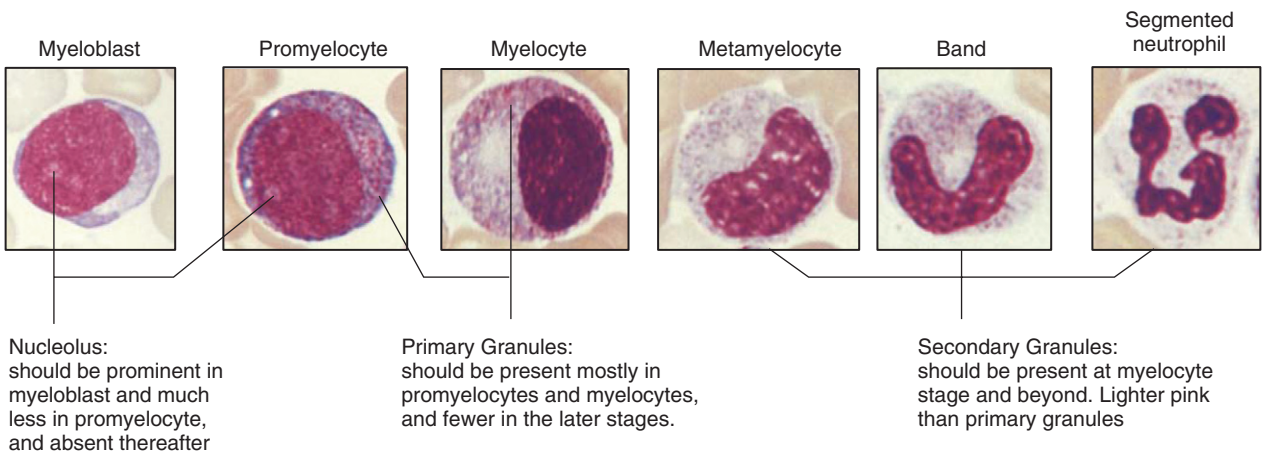

FIGURE 170-1. Myeloid maturation in the bone marrow. Nucleoli are prominent in myeloblasts, much less frequent in promyelocytes, and absent in more mature forms. Primary granules are present in the cytoplasm of promyelocytes and myelocytes, and secondary granules predominate beyond the myelocyte stage.

TABLE 170-1 DIFFERENTIAL DIAGNOSIS OF NEUTROPHILIA

I. Primary hematologic etiologies
  a. Congenital neutrophilia
    i. Hereditary neutrophilia
    ii. Chronic idiopathic neutrophilia
    iii. Down syndrome
    iv. Leukocyte adhesion deficiency (LAD)
      1. LAD I
      2. LAD II
  b. Acquired hematologic neoplasms
    i. Myeloproliferative disease
      1. Chronic myelogenous leukemia
      2. Polycythemia vera
II. Secondary to other disease entities
  a. Infection
    i. Acute via release from marginated and storage pools
    ii. Chronic via increased myelopoiesis (e.g., tuberculosis, fungal infection, chronic abscess, other chronic infections)
  b. Chronic inflammation
    i. Rheumatic disease: juvenile rheumatoid arthritis, rheumatoid arthritis, Still's disease, and others
    ii. Inflammatory bowel disease
    iii. Granulomatous disease
    iv. Chronic hepatitis
  c. Cigarette smoking
  d. Stress
  e. Drug induced
    i. Corticosteroids
    ii. β-agonists
    iii. Lithium
    iv. Recombinant cytokine administration
  f. Nonhematologic malignancy
    i. Cytokine-secreting tumors (lung, tongue, kidney, urothelial tumors)
    ii. Marrow metastasis (myelophthisis)
  g. Marrow stimulation
    i. Hemolytic anemia, immune thrombocytopenia
    ii. Recovery from marrow suppression
    iii. Recombinant cytokine administration
  h. Postsplenectomy

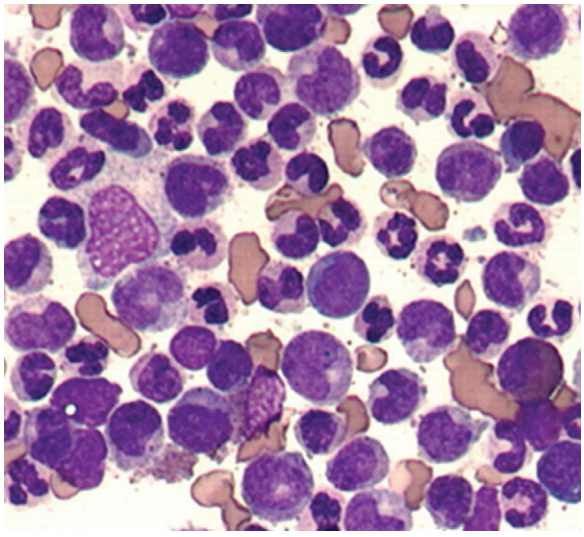

FIGURE 170-2. Peripheral blood from a patient with leukemoid reaction. From this smear, it would be impossible to distinguish this from chronic-phase chronic myelogenous leukemia (Chapter 190). Distinction would depend on determination of presence or absence of *BCR-ABL* fusion.

granulocyte-macrophage colony-stimulating factor (GM-CSF), macrophage inflammatory protein-1 (MIP-1), interleukin-1 (IL-1), IL-6, and IL-8, have been implicated in this marrow stimulation (Chapter 159). Chronic inflammatory conditions that are particularly associated with leukocytosis and neutrophilia include juvenile rheumatoid arthritis, rheumatoid arthritis, Still's disease, Crohn's disease, ulcerative colitis, granulomatous infection, and chronic hepatitis. The WBC and neutrophil elevation in these cases is typically more modest than that seen in acute infection or inflammation.

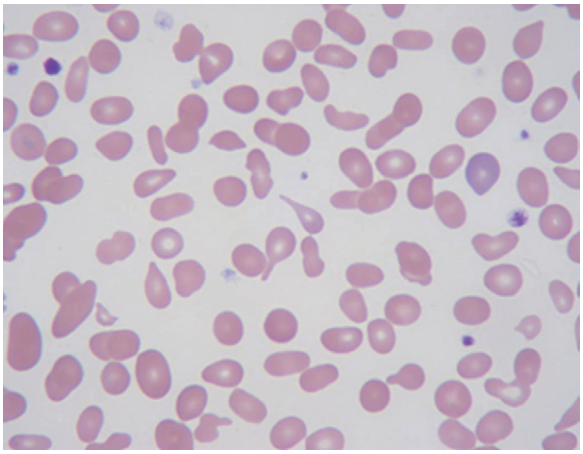

FIGURE 170-3. Myelophthisic changes in erythrocyte morphology. Note prominent teardrop forms. (From Rose M, Berliner N. Disorders of red blood cells. In Andreoli TE, Benjamin IJ, Griggs RC, et al, eds. *Andreoli and Carpenter's Cecil Essentials of Medicine,* 8th ed. Philadelphia: Saunders, 2010:522, Fig. 49-2.)

Cigarette Smoking

Cigarette smoking can cause a leukocytosis and neutrophilia in about 25 to 50% of chronic smokers that can persist for even up to 5 years after quitting smoking. The mechanism by which this occurs is unknown.

Stress

Within minutes of exercise, surgery, or stress, one can see an elevation in circulating neutrophils. This is presumed to be due to the effects of catecholamines on marginated neutrophils, with release of neutrophils into the circulation. Some cases of stress-induced neutrophilia can be prevented by pretreatment with β-adrenergic antagonists (e.g., propranolol), supporting the role of catecholamines in the process. Exercise-induced neutrophilia, however, is not blocked by propranolol, suggesting that it may instead be due to flow and mechanical perturbation of neutrophils in the lungs. An elevated WBC has also been noted in the setting of acute myocardial infarction, but whether this is a risk factor for cardiac ischemia or a result of inflammation is unclear.

Drug Induced

Probably the most well-known and widely used drugs associated with leukocytosis are corticosteroids. Other drugs that are associated with elevations in WBC and neutrophil count in particular include β-agonists and lithium. Lithium causes neutrophilia by increasing the production of endogenous colony-stimulating factors (CSFs).G-CSF or GM-CSF treatment likewise may result in neutrophilia, and although this is the desired effect, the neutrophilia can be quite pronounced if not appropriately monitored.

Nonhematologic Malignancy

Leukocytosis can be seen in a number of nonhematologic malignancies. Some tumors (lung, tongue, kidney, bladder) are thought to secrete G-CSF themselves as an ectopic hematopoietic growth factor. Other tumors (lung, stomach, breast), when metastasized to the bone and bone marrow, can cause a *leukoerythroblastic reaction*, characterized by left-shifted leukocytosis, thrombocytosis, and red cell abnormalities including nucleated and teardrop-shaped red blood cells (Fig. 170-3). The presence of nonhematopoietic entities invading the bone marrow (metastatic cancer, fibrosis, granulomatous disease) is termed *myelophthisis*.

Marrow Stimulation

Peripheral destruction of red cells and platelets, as seen with hemolytic anemia and idiopathic thrombocytopenic purpura, can result in stimulation of the bone marrow and a "spillover" leukocytosis. Recovery of cell counts following marrow suppression, as in the case of chemotherapy, can result in a rebound leukocytosis that may last several weeks.

Primary Causes of Neutrophilia

Hereditary Neutrophilia

Hereditary neutrophilia is an autosomal dominant genetic disease that is characterized by an elevated WBC in the 20,000 to 100,000/μL range with

splenomegaly and widened diploe of the skull. The neutrophils in this disorder appear to function normally, and patients have no increased risk for bacterial infection or other sequelae.

Chronic Idiopathic Neutrophilia

Chronic idiopathic neutrophilia is a condition marked by leukocytosis in the 11,000 to 40,000/μL range with a normal bone marrow biopsy. In one series with a 20-year follow-up, patients with this condition had no medical sequelae from this elevated WBC.

Pelger-Huet Anomaly

Patients with the Pelger-Huet anomaly (PHA) are often misdiagnosed as having a left-shifted WBC because many of their mature neutrophils are misinterpreted as band forms. Although these patients do not actually have leukocytosis, the anomaly often raises suspicion for an acute infection or inflammatory process because of this apparent left shift. PHA is due to a mutation in the lamin B receptor gene and manifests with mature neutrophils and condensed, clumped chromatin within a bilobed nucleus (see Fig. 160-20 in Chapter 160). These neutrophils, however, function normally. A number of drugs can reversibly induce pseudo-PHA, including colchicine, sulfonamides, ibuprofen, taxoids, and valproate. Pseudo-PHA is also seen in some patients with myelodysplasia (Chapter 188). Vitamin B_{12} or folate deficiency can cause increased nuclear lobation of neutrophils in patients with PHA, perhaps leading a missed diagnosis. With correction of the vitamin deficiency, however, the aberrant neutrophil nuclear morphology returns.

Down Syndrome

Up to 10% of patients with Down syndrome develop transient myeloproliferative disorder (TMD) related to peripheral blood leukocytosis with blasts in association with an accumulation of megakaryoblasts in the blood, liver, and marrow. Similar reactions have also been reported in patients with trisomy 21 mosaicism who are phenotypically normal. TMD resolves spontaneously in most patients but can progress to acute megakaryoblastic leukemia (AMKL) in 23 to 30% of affected patients. This fascinating disorder is attributable to acquisition of mutations in the *GATA1* gene, which encodes a key transcription factor for hematopoietic regulation, leading to loss of normal GATA-1 expression and expression of a truncated GATA-1 protein. Evidence supports that these mutations are acquired during fetal life, and patients present in early infancy with TMD. The pathogenesis of progression to AMKL presumably requires additional genetic events and is the focus of intense study.

Leukocyte Adhesion Deficiency

Patients with LAD have persistent leukocytosis, defects in stimulus-dependent activation of neutrophils, recurrent infections, and delayed separation of the umbilical cord. LAD is an abnormality of leukocyte adhesion reflecting the loss of surface adhesion molecules. LAD I is due to absence or marked reduction in the common β chain of β_2 integrins, resulting in loss of expression of leukocyte function-associated antigen 1 (LFA-1), the C3bi receptor, and GP150;95. This results in a failure to ingest and kill microbes opsonized by C3bi. In LAD II, neutrophils lack sialyl Lewis X, the ligand for L-selectin expressed on endothelial cells. Neutrophils appear morphologically normal but are defective in chemotaxis, adherence, and phagocytosis.

Familial Cold Urticaria

Familial cold urticaria is marked by episodic fevers, leukocytosis, urticaria, rash, conjunctivitis, and muscle and skin tenderness with cold exposure. The rash is composed of infiltrating neutrophils. The syndrome appears to be related to decreased levels of C1-esterase inhibitor and is associated with mutations in the *CIAS1* gene on chromosome 1q.

Chronic Myelogenous Leukemia and Other Myeloproliferative Disorders

Chronic myelogenous leukemia (CML) and the other myeloproliferative neoplasms (namely polycythemia vera [PV] and essential thrombocythemia [ET]) are discussed in detail in Chapters 190 and 169, respectively. They are the principal acquired primary hematologic disorders associated with neutrophilia. They are marked by clonal expansion of myeloid precursors and increased release of both immature and mature myeloid cells into the peripheral blood. CML on presentation often has to be distinguished from a leukemoid reaction. In contrast to a leukemoid reaction, CML is characterized by the presence of abnormalities of other blood cell lines ("panmyelosis") and by the presence of specific abnormalities. Therefore, the peripheral blood smear in CML (but not leukemoid reaction) demonstrates increased numbers in all cells of the neutrophilic series, classically with a greater proportion of myelocytes to metamyelocytes, and may display concomitant basophilia, eosinophilia, anemia, and thrombocytosis. CML is characterized by the diagnostic presence of the Philadelphia chromosome [t(9;22)], which can be identified in the peripheral blood by the detection of the *BCR-ABL* translocation by fluorescence in situ hybridization (FISH) or reverse transcriptase–polymerase chain reaction (RT-PCR). PV and ET, on the other hand, are notable for a marked increase in red cell mass and a marked thrombocytosis, respectively, which is often accompanied by leukocytosis. Both PV and ET are associated with activating mutations in the *JAK2* gene (95 to 97% and 23 to 75% for PV and ET, respectively).

The leukocyte alkaline phosphatase (LAP) score was historically used in the laboratory evaluation of granulocytosis as a diagnostic marker for myeloproliferative disease. The LAP score is very low (usually 0) in the setting of CML and elevated in PV. The LAP score has a very wide normal range and in practical terms was only definitively helpful in the setting of CML because "high" LAP scores can also be seen in infectious and inflammatory settings. With the availability of direct molecular genetic diagnosis of CML by assay for the *BCR-ABL* fusion gene, it can no longer be recommended as a diagnostic test.

Postsplenectomy

Patients develop leukocytosis following splenectomy, and this may be long-standing, reflecting the loss of a major site of neutrophil margination. This is of no clinical importance, except insofar as it leads to unnecessary evaluation for other pathology.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

As outlined previously, acquired leukocytosis is most commonly the result of acute or chronic infection or inflammation. When it occurs in the absence of fever, aberrations in acute phase reactants, effusions and edema, or other signs and symptoms of inflammation, it still may be secondary to drugs or an underlying nonhematologic malignancy. As such, it should be seen as the sign of a healthy hematopoietic system responding to an outside stress. Bone marrow evaluation is therefore rarely indicated. However, persistence of leukocytosis in the absence of signs and symptoms of inflammation or infection, nonhematologic malignancy, and offending drugs should prompt an evaluation for a primary myeloproliferative disease or clonal hematologic neoplasm, particularly when there is evidence of a leukoerythroblastic reaction. CML and PV can be ruled out by molecular diagnosis on the peripheral blood as described previously. In this setting, bone marrow examination is indicated to evaluate for marrow infiltration by infection, tumor, or fibrosis and should include cultures for tuberculosis and fungal infection as well as cytogenetics and flow cytometry (Fig. 170-4).

Leukocytosis Due to Expansion of Other Cell Lines

Monocytosis and lymphocytosis can also lead to elevations of the WBC. Monocytosis is defined by an absolute monocyte count of greater than 500/μL and usually occurs in the setting of chronic inflammation resulting from infections like tuberculosis, syphilis, or subacute bacterial endocarditis, autoimmune or granulomatous disease, and sarcoidosis. It can also be seen in malignancies, such as preleukemic states, nonlymphocytic leukemia including acute myelomonocytic and monocytic leukemia, histiocytosis, Hodgkin's disease, non-Hodgkin's lymphoma, and various carcinomas. Finally, it can be seen in the setting of chronic neutropenia, after splenectomy, and in the setting of recovery from marrow suppression (Table 170-2).

Lymphocytosis is defined by an absolute lymphocyte count of more than 5000/μL. The most common causes of an elevated lymphocyte count are viral infections such as Epstein-Barr virus and the hepatitis viruses. Although most bacterial infections cause neutrophilia, pertussis and cat-scratch disease due to *Bartonella henselae* can cause an impressive lymphocytosis. Other infections that may cause a secondary lymphocytosis include toxoplasmosis and babesiosis. Hypersensitivity reactions due to drugs or serum sickness may also be associated with lymphocytosis. Primary disorders that cause a lymphocytosis include chronic lymphocytic leukemia (CLL) and monoclonal B-cell lymphocytosis (Table 170-3; see also Table 190-2 and Chapter 190).

Eosinophilia is defined by an absolute eosinophil count of more than 400/μL. Eosinophils proliferate under the influence of IL-5 and play a role in phagocytosis and modulating toxicity due to mast cell degranulation in

hypersensitivity reactions. Eosinophilia is therefore most often seen in the setting of drug reactions, allergy, atopy, and asthma. A variety of infections, particularly parasitic infections and, to a lesser degree, fungal infections, can be associated with an increased number of circulating eosinophils. Eosinophilia can also be the result of autoimmune and inflammatory conditions, as in Churg-Strauss vasculitis. Atheroembolic disease and adrenal insufficiency may also cause eosinophilia. There are a number of cancers that have been associated with polytypic expansion of eosinophils, including lymphomas and solid tumors. There are also a number of clonal disorders of eosinophils that occur in the setting of some leukemias. Finally, there is a heterogeneous group of disorders termed *hypereosinophilic syndromes*. A *FIP1L1-PDGFRA* fusion gene has confirmed that some of these are primary clonal disorders of eosinophils; the clonality of other hypereosinophilic syndromes can be difficult to establish (see Table 173-1 in Chapter 173).

NEUTROPENIA

Neutropenia may reflect low numbers of circulating neutrophils with either low or normal neutrophil reserves. The risk for infection in the setting of neutropenia is therefore highly dependent on the size of the neutrophil storage pool. Although neutropenia is defined by an absolute neutrophil count of less than 1500/μL, patients with neutrophil counts below this number may have different risks and rates of infection depending on the cause of neutropenia. For instance, patients who are neutropenic owing to chemotherapy, marrow failure, or marrow exhaustion experience infection at much higher rates than those with chronic neutropenic syndromes and immune-mediated neutropenia. Neutropenia may be congenital or acquired. The following sections first discuss congenital neutropenic disorders, the study of which has provided critical insights into normal myelopoiesis, and then the secondary causes of neutropenia (Table 170-4).

Primary Causes of Neutropenia

Ethnic and Benign Familial (Constitutional) Neutropenia

The normal range of the neutrophil count is genetically determined and can be variable. A number of racial and ethnic groups have been observed to have a relatively large proportion of members who are neutropenic by comparison to the published normal range, usually based on young, largely white individuals. This is termed *constitutional neutropenia* and is seen among a variety of ethnic groups, including African Americans, Yemenite Jews, Falasha Jews, and African Bedouins. Single nucleotide polymorphisms in the gene for the Duffy antigen receptor for chemokine (DARC) have been shown to associate with race and are a postulated candidate to explain racial and ethnic differences in neutrophil counts. There is also an autosomal dominantly inherited

TABLE 170-5 CONGENITAL NEUTROPENIA SYNDROMES

SYNDROME	INHERITANCE PATTERN	GENE
SCN	Autosomal dominant	ELANE (~60%)
	Autosomal recessive	HAX1 (~5%)
	X-linked	WASP (~5%)
	Autosomal recessive	G6PC3 (~2%)
	Autosomal dominant	Gfi1 (rare)
	Autosomal dominant	G-CSFR (rare)
Cyclic Neutropenia	Autosomal dominant	ELANE
Other Congenital Syndromes		
Shwachman-Diamond syndrome	X-Linked	SBDS
Fanconi anemia	Autosomal recessive	FANCA-FANCO
Dyskeratosis congenita	Variable	Telomerase and related genes
Glycogen storage disease type 1b	Autosomal recessive	G-6-PT
Myelokathexis	Autosomal dominant	CXCR4
Chédiak-Higashi Syndrome	Autosomal recessive	LYST
Griscelli syndrome type 2	Autosomal recessive	RAB27A
Hermansky-Pudlak syndrome type 2	Autosomal recessive	AP3B1

ELANE = neutrophil elastase; G6PC3 = glucose-6-phosphatase catalytic subunit 3; G-6-PT = glucose-6-phosphatase translocase; G-CSFR = granulocyte colony-stimulating factor receptor; LYST = lysosomal trafficking regulatory gene; SBDS = Shwachman-Bodian-Diamond syndrome; SCN = severe congenital neutropenia; WASP = Wiskott-Aldrich syndrome protein.

condition called *benign familial neutropenia* that is characterized by neutrophil counts in the 800 to 1400/μL range. Both ethnic and benign familial neutropenia have been shown to be associated with *no* increased risk for infection.

Severe Congenital Neutropenia

First described by Rolf Kostmann in 1956, severe congenital neutropenia (SCN) is a disorder of severe neutropenia with neutrophil counts of less than 500/μL, presenting in the neonatal period with recurrent bacterial infections. These infections can occur as early as the first months of life and often include omphalitis and perirectal abscesses. There is often an increase in other myeloid cell lines, including monocytes and eosinophils. Bone marrow biopsy in SCN patients reveals a "maturation arrest" with an absence of mature neutrophil elements. SCN can follow autosomal dominant and recessive and X-linked patterns of inheritance and has been shown to be associated with mutations in a variety of genes, as summarized in Table 170-5.

Neutrophil elastase (ELA2, now ELANE) is a serine protease that is synthesized at high levels in the promyelocyte stage of neutrophil maturation and is packaged in primary granules. It was originally hypothesized that mutations in ELANE led to its defective cellular trafficking and cytoplasmic accumulation, subsequently triggering neutrophil apoptosis. Newer evidence, however, supports a mechanism by which accumulation of the mutant neutrophil elastase in the endoplasmic reticulum activates the unfolded protein response, leading to apoptosis. SCN due to these mutations is inherited in an autosomal dominant fashion. Hax-1 is a mitochondrial protein with weak homology to bcl-2, and its absence results in mitochondrial-dependent apoptosis. It is the mutated protein implicated in the original autosomal recessive cases of SCN described by Kostmann. Although all SCN cases were originally referred to as *Kostmann's syndrome*, that term is now reserved for this subgroup of autosomal recessive SCN. Wiskott-Aldrich syndrome protein (WASP) regulates actin polymerization in hematopoietic cells, and deficiency in this protein results in the Wiskott-Aldrich syndrome, characterized by small platelets in low number, sinopulmonary infections, and eczema. Another phenotype of mutated WASP, however, is X-linked thrombocytopenia and neutropenia. Mutations in glucose-6-phosphatase catalytic subunit 3 (*G6PC3*) are the most recently discovered cause of a subset of SCN patients; homozygous loss of this metabolic enzyme also appears to lead to activation of the unfolded protein response and increased apoptosis of neutrophil precursors.

SCN was formerly a disease of infancy and early childhood because few, if any, patients survived to adulthood. However, the advent of the availability of recombinant G-CSF and the observation that G-CSF is able to raise neutrophil counts and prevent infection in most patients have allowed these children to survive. Some patients require very high doses of G-CSF, but responses are seen in 80 to 90% of individuals. Increased survival led to the emerging realization that SCN predisposes to the development of myelodysplasia and acute leukemia (MDS/AML), with the development of MDS/AML at a rate of approximately 2% per year, and a cumulative risk of about 30% over 10 years. Patients refractory to G-CSF appear to have a higher risk for leukemic transformation. As discussed later, development of MDS/AML is often associated with the acquisition of a mutation in the gene encoding for the G-CSF receptor. Considerable controversy exists concerning the potential contribution of G-CSF administration to the risk for malignant transformation in children with SCN who receive lifelong treatment with G-CSF (see later under Treatment).

Two classes of G-CSF receptor mutations have been associated with SCN and either hyper-responsiveness or hyporesponsiveness of the receptor. Initial studies aimed at demonstrating that SCN was caused by mutation of the G-CSF or G-CSF receptor gene did not implicate such mutations in the pathogenesis of a significant number of patients with SCN. However, a small number of patients have been shown to have mutations in the G-CSF receptor gene that block ligand binding and produce a G-CSF-resistant form of SCN. More important, however, the studies identified an acquired missense mutation that introduces a stop codon and leads to the deletion of the distal intracellular domain of the receptor known to be responsible for differentiation signaling. This has been hypothesized to cause proliferation of hematopoietic progenitors at the expense of maturation and to be associated with hypersensitivity to G-CSF, suggesting that this mutation may play an important role in the development of MDS/AML in the setting of SCN. However, whether this mutation is in fact of pathogenetic importance to the

development of MDS/AML and whether G-CSF influences the risk of developing the mutation and influencing leukemic transformation remain subjects of significant controversy.

Cyclic Neutropenia

Cyclic neutropenia is defined as periods of neutropenia (≤200/μL) lasting 3 to 5 days and occurring at approximately 21-day intervals. These periods of neutropenia can be marked by recurrent fevers, mouth sores, and infections of the skin, upper respiratory tract, and ears. The disorder can be dominantly inherited or sporadic. Congenital cyclic neutropenia has also been shown to be associated with mutations in the gene for neutrophil elastase in all cases tested to date. The diagnosis formerly required demonstration of transient neutropenia through blood counts every 2 to 3 weeks over a course of 6 weeks but now can be established by sequencing of the neutrophil elastase gene. It is successfully treated with G-CSF and is not associated with an increased risk for leukemic transformation. Rare cases of cyclic neutropenia acquired in adulthood have been associated with systemic diseases such as large granular lymphocytosis or T-cell lymphoma.

Other Congenital Syndromes with Associated Neutropenia

A number of other congenital syndromes are associated with neutropenia as one of the constellation of disease-associated abnormalities. These include Shwachman-Diamond syndrome, Fanconi anemia, dyskeratosis congenita, glycogen storage disease Ib, myelokathexis, Chédiak-Higashi syndrome, Griscelli syndrome II, and Hermansky-Pudlak syndrome II.

Shwachman-Diamond syndrome usually begins as an isolated neutropenia but progresses to marrow failure and is also associated with pancreatic dysfunction and skeletal abnormalities. The responsible gene has been identified, the Shwachman-Bodian-Diamond syndrome gene (*SBDS*), and is involved in the regulation of ribosomal RNA. These patients carry an increased risk for leukemic transformation.

Fanconi anemia is due to mutations in genes involved in DNA repair, and as such, it takes more time for marrow failure to develop in these patients (median age, 7 years). Patients with Fanconi anemia often have, in addition to marrow failure, short stature with upper limb anomalies and hyperpigmented cafe au lait spots, although about one third have no physical abnormalities. Screening is done by chromosomal fragility testing following exposure to diepoxybutane or mitomycin C as well as direct assessment for known Fanconi gene mutations. Stem cell transplantation is curative but carries a high risk for morbidity and mortality.

Dyskeratosis congenita is a syndrome of nail dystrophy, leukoplakia, and skin pigmentation abnormalities with associated neutropenia or aplastic anemia, or both. It can be inherited in an autosomal dominant or recessive or X-linked fashion and has been shown to be associated with mutations in several genes that are implicated in telomere maintenance. It typically does not present until the second decade of life.

Glycogen storage disease Ib is inherited in an autosomal recessive fashion and characterized by intermittent neutropenia due to defects in the neutrophil respiratory burst with subsequent apoptosis of circulating neutrophils. Hepatomegaly and metabolic crises are also the hallmarks of this disease and are due to mutations in the gene for the glucose-6-phosphatase translocase enzyme.

The neutropenia of *myelokathexis* is due to retention of mature neutrophils in the bone marrow despite a low peripheral neutrophil count. During infection, however, patients with myelokathexis typically have a sudden rise in their neutrophil count, which makes their clinical course relatively more benign. There is an association between this condition and hypogammaglobulinemia and warts, the WHIM syndrome (*w*arts, *h*ypogammaglobulinemia, *i*mmunodeficiency, and *m*yelokathexis). It has been shown to be caused by heterozygous mutations in the gene encoding chemokine receptor CXCR4.

Chédiak-Higashi syndrome, Griscelli syndrome II, and *Hermansky-Pudlak syndrome II* are all syndromes of albinism and neutropenia due to defects in vesicular trafficking. Chédiak-Higashi syndrome is due to mutations in a lysosomal trafficking regulatory gene (*LYST*) and is characterized by oculocutaneous albinism, bleeding, progressive neurologic disease, and increased susceptibility to hemophagocytic syndrome. Patients with Griscelli syndrome II also have an increased susceptibility to hemophagocytic syndrome as well as albinism and periodic neutropenia; Griscelli syndrome II is caused by mutations in the gene encoding the small guanosine triphosphatase RAB27A, which is involved in the release of myeloperoxidase from the primary granules of neutrophils. Finally, Hermansky-Pudlak syndrome II is due to mutations in the *AP3B1* gene, which encodes a part of a protein transport complex that is involved in vesicular trafficking in many cell types and appears to be involved in the trafficking of neutrophil elastase. It is also marked by albinism, platelet abnormalities, and pulmonary fibrosis.

Secondary Causes of Neutropenia

Infection-Related Neutropenia

Several viral infections have been shown to cause a transient neutropenia that typically resolves as the viremia abates. These include varicella, measles, rubella, hepatitis A and B, Epstein-Barr virus, influenza, parvovirus, and cytomegalovirus. The mechanisms are diverse and can involve redistribution, decreased production, and immune destruction of neutrophils. Human immunodeficiency virus and acquired immunodeficiency syndrome can likewise cause leukopenia and neutropenia, perhaps through splenomegaly with increased sequestration as well as through immune-mediated destruction by antineutrophil antibodies. A myriad of atypical infections like *Mycobacterium tuberculosis*, ehrlichiosis, rickettsia, tularemia, brucellosis, and some staphylococcal infections can cause a moderate neutropenia. Any infection leading to overwhelming sepsis can cause neutropenia, but this is usually through consumption of the marrow neutrophil reserve and is typically seen in newborns and elderly patients and not in individuals with an otherwise healthy and mature marrow. There is also increased margination of neutrophils during sepsis due to systemic activation of complement, exacerbating the neutropenia.

Drug-Induced Neutropenia and Neutropenia Due to Marrow Injury

Drug-induced neutropenia is the most common cause of neutropenia. Multiple drugs have been implicated in neutropenia and agranulocytosis, in both predictable and idiosyncratic patterns. The mechanism of leukopenia is predominantly one that occurs within the marrow compartment, but certain drugs are also associated with increased destruction or clearance of peripheral neutrophils. Within the marrow compartment, many drugs cause direct dose-dependent marrow suppression, whereas others incite immune-mediated destruction. The typical pattern of drug-induced neutropenia is neutropenia that occurs after about 1 to 2 weeks of exposure to the drug with a recovery that begins within days of stopping the drug. However, atypical cases can present long after drug initiation, and others may be associated with a longer interval before recovery of the neutrophil count (Fig. 170-5). Patients with drug-induced agranulocytosis may present with acute sepsis, and it is associated with a significant risk for acute mortality. Recovery is often preceded by the appearance of monocytes and immature neutrophil forms. The more hypercellular the marrow is at diagnosis, the earlier marrow recovery may occur. Some common drugs known to cause neutropenia, in addition to antineoplastic, antiviral, and immunosuppressive agents, include clozapine, the thioamides, and sulfasalazine. Neutrophil recovery is speeded by G-CSF, although there are no definitive data that this improves survival.

Radiation can also result in marrow injury leading to an acute or chronic marrow failure state; in high doses, it is also a risk factor for the development of myelodysplasia and leukemia. These malignant hematopoietic diseases can themselves cause marrow failure because the malignant cells proliferate within the marrow-occupying space and can cause marrow fibrosis, both of which lead to cytopenias. These diseases are discussed in greater detail in Chapters 188 and 189, respectively. Likewise, metastatic carcinoma to the bone can also cause marrow failure because the marrow becomes increasingly occupied by the metastatic cells.

Immune Neutropenia

Infection and drugs cause immune-mediated neutrophil destruction. However, immune neutropenia can also occur as an isolated phenomenon (primary immune neutropenia) or as a manifestation of an underlying systemic autoimmune disease (secondary immune neutropenia). Primary autoimmune neutropenia is a disease of children younger than 4 years; median age of onset is 6 to 12 months. Although infectious risk is increased, treatment is restricted to prophylactic antibiotics, with G-CSF reserved for acute infectious episodes. Ninety-five percent of patients undergo spontaneous remissions within 2 years. Nearly all of these patients have antineutrophil antibodies directed against antigens derived from the FcγIIIb receptor; these antibodies mediate neutrophil destruction by either sequestration in the spleen or complement-mediated neutrophil lysis.

Secondary autoimmune neutropenia is a disease of adults and can be seen in association with hyperthyroidism, Wegener's granulomatosis, rheumatoid

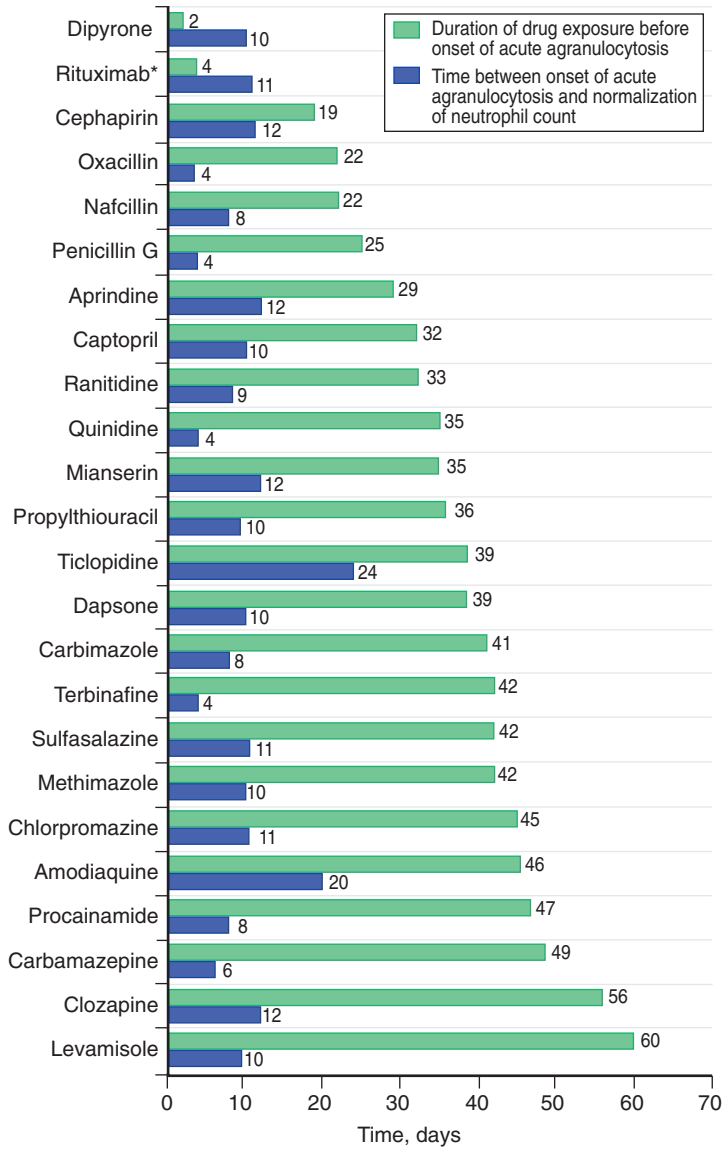

FIGURE 170-5. Median duration of treatment and neutropenia. Only drugs with more than three definite or probable reports of the time between onset of acute agranulocytosis and normalization of neutrophil count and the duration of treatment before onset of acute agranulocytosis were considered. (From Andersohn F, Konzen C, Garbe E. Systematic review: agranulocytosis induced by nonchemotherapy drugs. *Ann Intern Med.* 2007;146: 657-665.)

arthritis, and systemic lupus erythematosus (SLE). The role of antineutrophil antibodies in these patients is less clear. More than 50% of patients with SLE, for example, have antineutrophil antibodies, but many have normal neutrophil counts, and there is a poor correlation between the presence of the antibodies and neutrophil number.

Felty's syndrome and *large granular lymphocyte syndrome* deserve separate mention. Felty's syndrome occurs in association with long-standing rheumatoid arthritis (RA) (Chapter 272), and is characterized by splenomegaly and profound neutropenia. Large granular lymphocyte syndrome often occurs in the setting of RA but can also occur as an isolated phenomenon. Both Felty's syndrome and large granular lymphocyte syndrome are associated with a proliferation of large granular lymphocytes, with a characteristic surface phenotype ($CD3^+$, $CD8^+$, $CD16^+$, and $CD57^+$). In the setting of RA, these two syndromes were originally thought to be separate diseases, with Felty's syndrome being polyclonal and large granular lymphocyte syndrome representing a monoclonal proliferation of larger granular lymphocytes, but with increasing sensitivity of detection of monoclonal populations of lymphocytes, this distinction has become blurred. Finally, it has been observed that more than 90% of RA patients with either syndrome are human leukocyte antigen (HLA)-DR4-positive, leading to the postulate that the two entities represent the extremes of a single spectrum of disease. This HLA restriction is not found among non-RA patients with large granular lymphocytes. Both

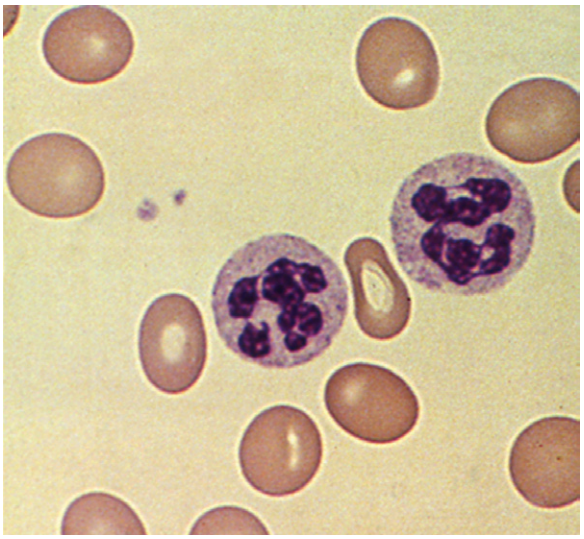

FIGURE 170-6. Peripheral blood with macrocytosis and hypersegmented neutrophils in megaloblastic anemia.

syndromes cause immune-mediated neutrophil destruction by a wide array of mechanisms, including antineutrophil antibodies and cell-mediated destruction. Some patients may also have G-CSF resistance mediated by inhibitory G-CSF antibodies.

There are other rare forms of immune neutropenia. Isoimmune neonatal neutropenia is a moderate to severe neutropenia of the newborn due to transplacental passage of maternal immunoglobulin G antibodies against alleles inherited from the father, resulting in neutropenia in a manner similar to the development of anemia in Rh hemolytic disease. Pure white cell aplasia is a rare disease associated with severe pyogenic infections, and also with thymoma in more than two thirds of cases. It has also occurred following ibuprofen therapy. There is a complete absence of myeloid precursors on bone marrow examination. It is immune-mediated, but removal of the thymoma in thymoma-associated cases may not be sufficient for remission. Adjuvant therapy with cyclophosphamide, corticosteroids, cyclosporine, and intravenous immunoglobulin may be needed.

Neutropenia Due to Increased Margination and Hypersplenism

Complement activation can result in both acute and chronic neutropenia as a result of increased margination of the circulating neutrophil pool. This is attributed to the fact that C5a renders neutrophils more adherent and thereby prone to aggregation within the pulmonary vasculature. This has been seen in patients suffering from burns and transfusion reactions. Complement activation may also lead to neutrophil destruction, as in paroxysmal nocturnal hemoglobinuria. The circulating neutrophil pool can also be diminished in association with hypersplenism, although this is typically less common and less pronounced than the anemia and thrombocytopenia seen in patients with an enlarged spleen.

Neutropenia Due to Nutritional Deficiency

Several vitamin and mineral deficiencies, particularly B_{12}, folate, and copper, are associated with neutropenia. Deficiencies in these vitamins and minerals result in ineffective myelopoiesis, maturation arrest, and megaloblastic changes with nuclear-cytoplasmic dyssynchrony. The characteristic finding in the setting of megaloblastic anemia is hypersegmentation of the neutrophil (Fig. 170-6).

Chronic Idiopathic Neutropenia

Chronic idiopathic neutropenia in adults (CINA) is perhaps the most puzzling form of neutropenia. Patients present with chronic neutropenia that is often an incidental finding on routine blood tests, making it impossible to know how long the neutropenia has been present. They have no evidence of autoimmune disease, nutritional deficiency, or myelodysplasia. The syndrome is heterogeneous, with a wide range of neutrophil counts. A group of these patients from Greece has been studied by Papadaki and colleagues, who reported increased production of transforming growth factor-β (TGF-β) and consequent marrow suppression, leading them to posit an undiagnosed underlying inflammatory disease. These patients, however, tend to have very

mild neutropenia, with an absolute neutrophil count (ANC) that is rarely less than 800. It seems likely that these patients have an ethnic predisposition to neutropenia, and indeed the neutropenia has been demonstrated to be linked to a genetic polymorphism in the TGF-β locus. It seems likely, however, that these patients should be distinguished from other CINA patients, many of whom have an ANC below 200. The etiology of neutropenia in these patients is completely unknown. However, the natural history of CINA, even in the face of very low neutrophil counts, is generally benign. Most patients require no therapy, although those with very low counts must be treated with G-CSF when they develop fever in the setting of infections. Some patients with recurrent infections or troublesome aphthous ulcers require chronic G-CSF treatment. These patients typically respond to fairly low doses of G-CSF, and there is no reported increase in the development of MDS/AML.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Neutropenia by itself is not associated with many clinical signs and symptoms other than those of the condition that may be causing it. It becomes clinically evident, however, when it results in infection. Although patients with an ANC below 1000/μL do have a slightly increased risk for infection, the risk is substantially increased once the neutrophil count falls below 500/μL. Given the lack of neutrophils, the signs and symptoms of infection may be attenuated; as such, pneumonia may be present with minimal infiltrate on chest radiograph, or a urinary tract infection may yield only a very mild pyuria. Given this, fever in any neutropenic patient must be considered an emergency with prompt acquisition of cultures and administration of empirical antibiotic therapy.

When fever, infection or sepsis, and neutropenia present concomitantly for the first time, it can be difficult to determine whether the neutropenia predated the infection or, rather, is the result of the infection. Examination of the peripheral blood smear can be helpful in this regard because an elevation of band forms and evidence of toxic granulation suggest the latter.

Because drug-induced neutropenia is the most common cause of acquired neutropenia, a careful inventory of all drug and toxin exposures is warranted. Likewise, there should be a careful evaluation for underlying malignant and inflammatory conditions as the precipitant of neutropenia. The time course of the neutropenia and infections can provide clues to the etiology of the neutropenia (acute versus chronic, persistent versus cyclic, neonatal versus childhood versus adult onset). Attention should be paid to the skin, bones, appendages, and nails because abnormalities in these may point toward one of the congenital neutropenia syndromes. Evaluation of the complete blood count, peripheral blood smear, and vitamin B_{12} and folate levels should also be performed.

When the neutropenia is not severe and is associated with anemia and thrombocytopenia, one should consider the possibility of hypersplenism. In many cases, the diagnosis can be made by the finding of palpable splenomegaly. However, especially in obese patients, abdominal imaging should be used to evaluate spleen size. Abdominal ultrasound allows the assessment of portal venous flow with Doppler studies. If splenic enlargement is confirmed, the etiology of the splenomegaly (Chapter 171) should be determined. It may reflect congestive splenomegaly secondary to portal hypertension (as a result of cirrhosis, fatty liver, or congestive heart failure, among others) or infiltrative splenomegaly due to a benign or malignant process; Felty's syndrome should be considered in the setting of RA.

In patients with chronic neutropenia in the absence of a history of infection or drug or toxin exposure or an evident B_{12} or folate deficiency, bone marrow examination should be performed to rule out myelodysplasia, with assessment of morphology, flow cytometry for large granular lymphocyte syndrome, and cytogenetics. Once a normal marrow has been obtained, further bone marrow examination is not indicated in patients with CINA (Fig. 170-7).

TREATMENT AND MANAGEMENT

Rx

The management of neutropenia (Chapter 289) is dependent on the etiology of the depressed neutrophil count as well as its severity and the presence or absence of fever or infection. Neutropenia with fever is a clinical emergency because these patients are at risk for hemodynamic collapse and septic shock. Therefore, these patients should be evaluated thoroughly and cultured promptly, and antibiotics should be administered within 30 to 60 minutes of presentation before obtaining the results of the cultures. The timely empirical administration of a combination of antipseudomonal antibiotics in patients with neutropenia at the onset of fever resulted in significant clinical benefit,

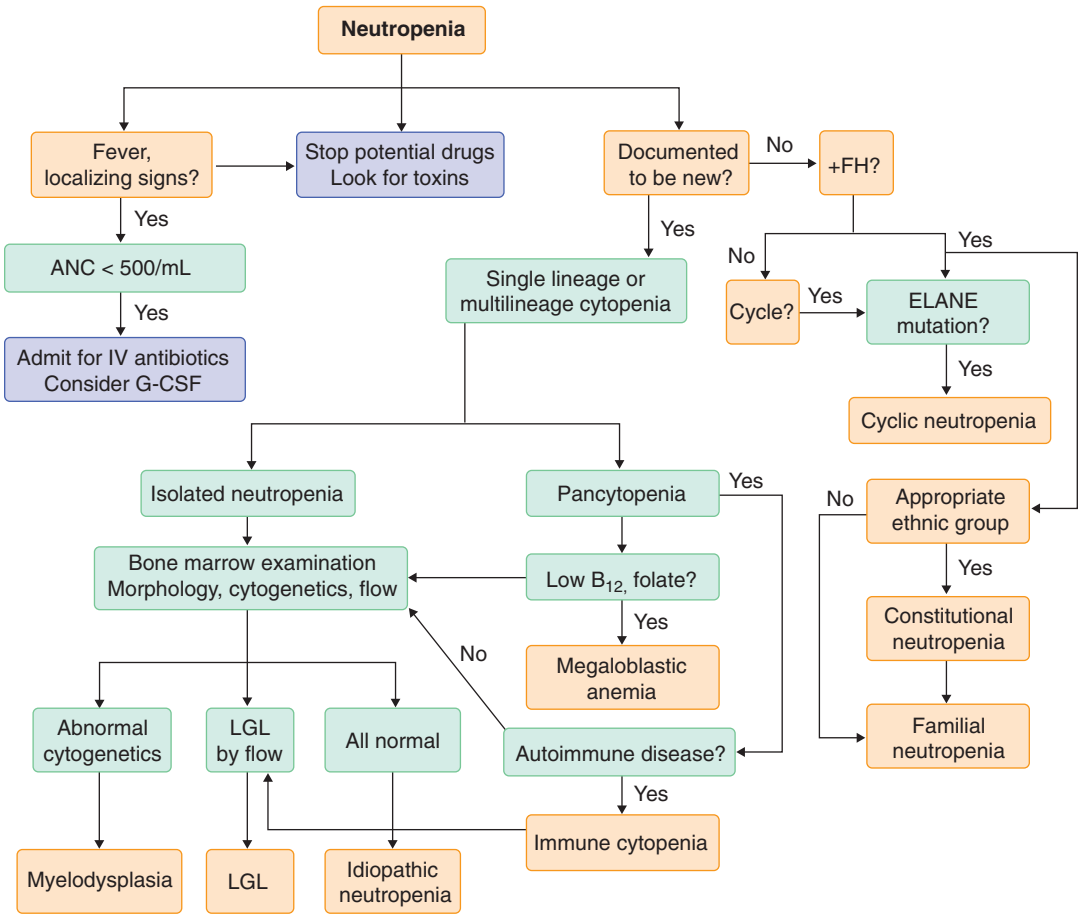

FIGURE 170-7. Diagnostic approach to neutropenia. ANC = absolute neutrophil count; ELANE = neutrophil elastase gene, FH = family history; G-CSF = granulocyte colony-stimulating factor; IV = intravenous; LGL = large granular lymphocyte syndrome.

both with respect to response and survival. With the advent of newer-generation cephalosporins, studies have shown that monotherapy with a third- or fourth-generation cephalosporin at the onset of fever may be sufficient. The addition of a second antipseudomonal agent, vancomycin, or antifungal agent is warranted in patients considered at risk for resistant pseudomonal infection, resistant gram-positive infection, or fungal infections, respectively, or in the face of a failure to defervesce within 3 to 5 days of antibiotic administration. These considerations are discussed in more detail in Chapter 289.

How to manage the uninfected and afebrile neutropenic patient is more nuanced and dependent on the etiology of the neutropenia. Patients with immune-mediated neutropenia are typically treated with immunosuppressive therapy, including steroids, antithymocyte globulin, or cyclosporine, or a combination of these, aimed primarily at treatment of the underlying autoimmune disease. Patients usually respond to G-CSF, although in the setting of RA, this may induce a flare of joint symptoms. Patients with large granular lymphocyte syndrome often respond to therapy with low-dose methotrexate, cyclosporine, or low-dose cyclophosphamide.

Patients with congenital neutropenia, including idiopathic, severe congenital, or cyclic neutropenia, are usually successfully managed with G-CSF for years. Before the use of G-CSF, the mean age of death for these patients was 2 to 3 years. Since the advent of G-CSF, however, life expectancy has been extended by decades into adulthood. Therapy is daily and chronic, with doses varying by the type of neutropenia and the individual responsiveness to therapy. It is usually well tolerated, although accelerated bone loss has been observed. Growth and development do not appear to be affected. Patients with SCN typically require the highest doses, whereas those with idiopathic neutropenia require the lowest, and patients with cyclic neutropenia fall somewhere in between. An increased rate of MDS/AML has been reported with the use of G-CSF in patients with SCN, but this has occurred coincidentally with improved survival. The increased incidence of MDS/AML may then be due to the fact that patients are living longer with a disease whose natural history includes a risk of developing MDS or AML. Certainly, the observation that acquired mutations in the G-CSF receptor are present in 65 to 80% of patients with SCN who develop MDS or AML suggests a potential mutagenic pathway towards leukemogenesis, but whether this is enhanced or accelerated by the administration of G-CSF has yet to be determined. Patients with idiopathic and cyclic neutropenia do not develop MDS or AML, despite therapy with G-CSF. However, recent evidence suggests that the risk for MDS/AML in SCN patients is much higher in those requiring high doses of G-CSF (>10 µg/kg/day), and patients with idiopathic and cyclic neutropenia are usually responsive to much lower G-CSF doses.

In patients with CINA, G-CSF should be reserved for acute febrile episodes unless the patient has recurrent infections. Patients with CINA treated with G-CSF may experience significant side effects, including fever, gastrointestinal symptoms, and splenomegaly. Consequently, in patients with CINA requiring chronic G-CSF administration, the cytokine should be administered at the lowest dose necessary to prevent infections; it is usually sufficient to treat to maintain the ANC higher than 500.

For patients with an inflammatory, infectious, or drug-induced neutropenia, the recommendation is to treat the underlying condition or stop the offending agent. This, however, is not always immediately possible, as in the cases of HIV-infected patients with opportunistic infections or on antiretroviral therapy, solid organ and bone marrow transplant recipients on immunosuppression and antiviral prophylaxis and treatment, and cancer patients undergoing chemotherapy. Prophylactic use of G-CSF in these patients has been shown to be effective in improving the ANC and decreasing rates of infection and febrile neutropenia, but has not been associated with a proven or consistent survival advantage.[1] In light of these findings, many oncologic professional society guidelines recommend the use of prophylactic G-CSF in patients receiving chemotherapy who have a 20% or greater risk of developing febrile neutropenia based on age, comorbid illness, disease characteristics, and myelotoxicity of the chemotherapy regimen. In addition, it is recommended for use during hematopoietic stem cell transplantation, for patients receiving chemotherapy for non-Hodgkin's lymphoma or dose-dense chemotherapy, and for patients with a history of febrile neutropenia receiving further chemotherapy.

The use of prophylactic antibiotics has also been investigated, predominantly in neutropenic patients receiving chemotherapy. Early studies in the 1980s and 1990s demonstrated an improvement in infection-related outcomes but not in infection-related or overall survival. Most recently, several randomized trials of prophylactic quinolones in patients receiving chemotherapy demonstrated an improvement in rates of infection and febrile neutropenia.[2,3] A meta-analysis of studies investigating the use of prophylactic quinolones in patients receiving chemotherapy was the first to document an overall survival benefit as well, although most of these patients had hematologic as opposed to solid tumor malignancies. The current Infectious Diseases Society of America guidelines do not recommend the use of prophylactic antibiotics in cancer patients undergoing myelosuppressive chemotherapy, with the exception of trimethoprim-sulfamethoxazole in patients at risk for *Pneumocystis jirovecii* pneumonia. Antibiotic prophylaxis is not generally used outside of the stem cell transplantation setting. The use of antibiotics to prevent infection in patients with neutropenia due to other causes has not been extensively studied but is typically not recommended and should be based on clinical context.

Stem cell transplantation (Chapter 181) can be curative for a number of the congenital neutropenia and bone marrow failure syndromes. It is, however, not without risk and should therefore be reserved for patients with severe neutropenia complicated by recurrent infection definitively shown to be due to marrow failure.

Leukopenia Due to Deficiency of Other Cell Lines

Lymphocyte production takes place in a variety of anatomic sites, and lymphocyte trafficking from those sites is bidirectional, making it difficult to understand lymphocyte dynamics in the same way that we do for neutrophils. Despite this, the peripheral lymphocyte count seems to be maintained in a narrow range at 2000 to 4000/µL, 20% of which are B cells and 70% of which are T cells. Lymphocytopenia, then, is a total lymphocyte count of less than 1500/µL. It can be the result of decreased production, defective trafficking, or increased loss or destruction. Decreased production can occur as a result of protein and calorie malnutrition; lymphocyte progenitor pool injury secondary to radiation, chemotherapy, or immunosuppressive agents; and congenital immunodeficiency states. Endogenous or exogenous glucocorticoid excess can cause lymphocytopenia by altering lymphocyte trafficking. This can also occur as the result of acute bacterial or fungal infections, certain viral infections, and granulomatous disease. Finally, many viruses can cause direct destruction of lymphocytes, as can antilymphocyte antibodies seen in patients with underlying autoimmune diseases. Lymphocytes can also be lost from intestinal lymphatics in cases of protein-losing enteropathy, primary disease of the gut or intestinal lymphatics, or gut edema secondary to severe heart failure. When lymphocytopenia is discovered, a comprehensive assessment of the immune system should be done, including lymphocyte subtyping, quantitative immunoglobulins, and skin testing to detect deficiencies of cell-mediated immunity. Treatment is typically aimed at the underlying disease, but intravenous immunoglobulin can be administered to patients who are hypogammaglobulinemic, and transplantation can be performed in patients with severe deficiencies of cell-mediated immunity due to impaired lymphocyte production and function.

Monocytopenia, eosinopenia, and basophilopenia can be seen in the setting of bone marrow failure syndromes or as a result of acute infection, malignancy, or severe injury. This is thought to be due to elevations in glucocorticoids, prostaglandins, and epinephrine. A rise in these humoral factors has the greatest impact on eosinophils such that a lack of eosinopenia in any of these settings should prompt suspicion for adrenal insufficiency, a primary myeloproliferative syndrome, parasitic infection, or primary hypereosinophilic syndrome. Monocytopenia is less frequently seen, probably owing to the diverse roles monocytes play in normal human physiology; prolonged and extreme monocytopenia may not be compatible with life.

171 APPROACH TO THE PATIENT WITH LYMPHADENOPATHY AND SPLENOMEGALY

JAMES O. ARMITAGE

LYMPHADENOPATHY

Physiology and Anatomy

Lymph nodes are found throughout the body along the course of the lymphatics, strategically located to allow the filtering of lymphatic fluid and the interdiction of microorganisms and abnormal proteins. Lymphatic fluid enters the node in afferent lymphatic vessels that empty into the subcapsular sinus. The fluid then transverses the node and exits in a single efferent lymphatic vessel. In doing so, the lymph and its contents are exposed to immunologically active cells throughout the node. Lymph nodes are populated predominantly by macrophages, dendritic cells, B lymphocytes, and T lymphocytes. B lymphocytes are located primarily in the follicles and perifollicular areas, whereas T lymphocytes are found principally in the interfollicular or paracortical areas of the lymph node. These cells function together to provide antigen processing, antigen presentation, antigen recognition, and proliferation of effector B and T lymphocytes as part of the normal immune response to microorganisms or foreign proteins.

Because the normal immune response leads to the proliferation and expansion of one or more cellular components of lymph nodes, it often results in significant lymph node enlargement. In young children, who are continuously being exposed to new antigens, palpable lymphadenopathy is the rule. In fact, the absence of palpable lymphadenopathy would be considered abnormal. In adults, lymph nodes larger than 1 to 2 cm in diameter are generally considered abnormal. However, lymph nodes 1 to 2 cm in diameter in the groin are sufficiently common to be considered normal.

Lymphoid proliferation is a normal response to exposure to foreign antigens. The location of the enlarged lymph nodes often reflects the site of invasion. For example, cervical lymphadenopathy would be typical in a patient with pharyngitis. Generalized immune proliferation and lymphadenopathy can occur with a systemic disorder of the immune system, disseminated infection, or disseminated neoplasia. Malignancies of the immune system might manifest as localized or disseminated lymphadenopathy.

Differential Diagnosis

The differential diagnosis of lymphadenopathy (Table 171-1) is vast, and the underlying causes are responsible for either proliferation of immunologically active cells or infiltration of the lymph node by foreign cells or substances. In practice, the cause of enlarged lymph nodes is often uncertain even in retrospect; in such cases, unrecognized infectious processes are generally blamed.

Infections by bacteria, mycobacteria, fungi, chlamydiae, parasites, and viruses are the major causes of lymph node enlargement. Lymph nodes in the drainage area of essentially all pyogenic infections can enlarge. In certain infections, such as bubonic plague caused by *Yersinia pestis,* dramatic regional lymph node enlargement with fluctuant lymph nodes (i.e., buboes) can be a hallmark of the disease (Chapter 320). Other bacterial infections have lymph node enlargement as a prominent feature (e.g., cat-scratch disease, Chapter 323) and can mimic lymphoproliferative disorders. Mediastinal lymphadenopathy is seen in inhalational anthrax (Chapter 302). In some parts of the world, cervical lymphadenopathy is a sufficiently frequent manifestation of tuberculosis to lead to the institution of antituberculous therapy rather than biopsy. Disseminated lymphadenopathy can be seen in cases of infection by a variety of organisms such as *Toxoplasma,* Epstein-Barr virus (i.e., infectious mononucleosis), cytomegalovirus, and human immunodeficiency virus (HIV).

A variety of nonmalignant disorders of the immune system can lead to localized or disseminated lymphadenopathy. Autoimmune diseases such as rheumatoid arthritis (Chapter 272) and systemic lupus erythematosus (Chapter 274) often have accompanying lymphadenopathy, which can pose a diagnostic challenge because of the increased incidence of lymphoma in patients with these disorders. In the lymphadenopathy that occurs as a reaction to drugs such as phenytoin, lymph node biopsy findings can sometimes be confused with lymphoma. Benign proliferative diseases of the immune system that can also be confused with lymphoma include Castleman's disease (Chapters 191 and 400; angiofollicular lymph node hyperplasia), sinus histiocytosis with massive lymphadenopathy, and disorders seen more frequently in Asia, such as Kawasaki syndrome (Chapter 447) and Kimura's disease.

All the cells in the immune system can become malignant. Several of these malignancies typically manifest as lymphadenopathy, and it can be seen in all of them. Lymphadenopathy as the initial manifestation is the rule for Hodgkin's disease and non-Hodgkin's lymphoma, and it is common in Waldenström's macroglobulinemia and B-cell chronic lymphocytic leukemia; it is seen only occasionally in the myeloid leukemias (Chapters 189 through 192) and is rare in multiple myeloma. Malignancies of all organ systems can metastasize to the lymph nodes and cause lymphadenopathy, which is usually seen in the drainage area of the primary tumor—for example, axillary lymph nodes in patients with breast cancer, hilar and mediastinal lymph nodes in patients with lung cancer, and cervical lymph nodes in patients with head and neck cancer. However, widespread lymphadenopathy can also occur. Other disorders in which lymphadenopathy may be an initial finding include storage diseases such as Gaucher's disease (Chapter 215), endocrinopathies such as hyperthyroidism (Chapter 233), sarcoidosis (Chapter 95), and dermatopathic lymphadenitis. Amyloidosis (Chapter 194) can cause lymphadenopathy in patients with multiple myeloma, hereditary amyloidosis, or amyloidosis associated with chronic inflammatory states.

Among patients with lymphadenopathy actually seen in practices in the United States, diagnoses are not determined in a high proportion (Table 171-2). In such cases, the lymphadenopathy is usually blamed on infection. When the lymphadenopathy is in the drainage site of a known infection (e.g., cervical lymphadenopathy in a patient with pharyngitis) or the patient has a known infection associated with lymphadenopathy (e.g., infectious mononucleosis; Chapter 385), this infectious assumption is usually correct. Alternatively, if a patient has an immunologic disorder that is known to cause lymphadenopathy, such as rheumatoid arthritis, this disorder is usually an acceptable

TABLE 171-1 CAUSES OF LYMPHADENOPATHY

Infection
Bacterial (e.g., all pyogenic bacteria, cat-scratch disease, syphilis, tularemia)
Mycobacterial (e.g., tuberculosis, leprosy)
Fungal (e.g., histoplasmosis, coccidioidomycosis)
Chlamydial (e.g., lymphogranuloma venereum)
Parasitic (e.g., toxoplasmosis, trypanosomiasis, filariasis)
Viral (e.g., Epstein-Barr virus, cytomegalovirus, rubella, hepatitis, HIV)
Benign disorders of the immune system (e.g., rheumatoid arthritis, systemic lupus erythematosus, serum sickness, drug reactions such as to phenytoin, Castleman's disease, sinus histiocytosis with massive lymphadenopathy, Langerhans cell histiocytosis, Kawasaki syndrome, Kimura's disease)
Malignant disorders of the immune system (e.g., chronic and acute myeloid and lymphoid leukemia, non-Hodgkin's lymphoma, Hodgkin's disease, angioimmunoblastic-like T-cell lymphoma, Waldenström's macroglobulinemia, multiple myeloma with amyloidosis, malignant histiocytosis)
Other malignancies (e.g., breast carcinoma, lung carcinoma, melanoma, head and neck cancer, gastrointestinal malignancies, germ cell tumors, Kaposi's sarcoma)
Storage diseases (e.g., Gaucher's disease, Niemann-Pick disease)
Endocrinopathies (e.g., hyperthyroidism, adrenal insufficiency, thyroiditis)
Miscellaneous (e.g., sarcoidosis, amyloidosis, dermatopathic lymphadenitis)

TABLE 171-2 MOST FREQUENT CAUSES OF LYMPHADENOPATHY IN ADULTS IN THE UNITED STATES

Unexplained
Infection
In drainage area of infection (e.g., cervical adenopathy with pharyngitis)
Disseminated (e.g., mononucleosis, HIV infection)
Immune disorders (e.g., rheumatoid arthritis)
Neoplasms
Immune system malignancies (e.g., leukemias, lymphomas)
Metastatic carcinoma or sarcoma

TABLE 171-3 FACTORS TO CONSIDER IN THE DIAGNOSIS OF LYMPHADENOPATHY

- Associated systemic symptoms
- Patient's age
- History of infection, trauma, medications, travel experience, previous malignancy
- Location: cervical, supraclavicular, epitrochlear, axillary, intrathoracic (hilar vs. mediastinal), intra-abdominal (retroperitoneal vs. mesenteric vs. other), iliac, inguinal, femoral
- Localized vs. disseminated
- Presence of tenderness or inflammation
- Size
- Consistency

TABLE 171-4 METHODS OF LYMPH NODE EVALUATION

- Physical examination
- Imaging
  - Chest radiography
  - Ultrasonography
  - Computed tomography
  - Magnetic resonance imaging
  - Positron emission tomography
- Sampling
  - Needle aspiration
  - Cutting needle biopsy
  - Excisional biopsy

explanation; however, progressive lymphadenopathy in such patients should trigger a biopsy because they are at increased risk for lymphoma. Localized, progressive lymphadenopathy, particularly when associated with fever, sweats, or weight loss, requires biopsy to exclude lymphoma.

Lymph Node Evaluation

Evaluation of a patient with lymphadenopathy includes a careful history, a thorough physical examination, laboratory tests, and sometimes imaging studies to determine the extent and character of the lymphadenopathy. The age of the patient and any associated systemic symptoms might be important clues (Table 171-3). Cervical lymphadenopathy in a child is much less worrisome than equally prominent lymphadenopathy in a 60-year-old adult. The occurrence of fever, sweats, or weight loss raises the possibility of a malignancy of the immune system. The explanation for the lymphadenopathy might become apparent with the identification of a site of infection, a particular medication, a travel history, or a previous malignancy.

Physical examination allows the identification of localized versus widespread lymphadenopathy. The particular sites of involvement can be important hints to the diagnosis because infection and carcinoma are likely to cause lymphadenopathy in the lymphatic drainage of the site of the disorder. In general, tender lymph nodes are more likely to be due to an infectious process, whereas painless adenopathy raises concern for malignancy. Lymph node consistency can also aid in the diagnosis: typically, lymph nodes containing metastatic carcinoma are rock hard, lymph nodes containing lymphoma are firm and rubbery, and lymph nodes enlarged in response to an infectious process are soft.

The larger the lymph node, the more likely it is that a serious underlying cause exists; lymph nodes greater than 3 to 4 cm in diameter in an adult are very worrisome. Physical examination to assess lymph node size is only marginally accurate and reproducible, although it is by far the most widely used method. More precise methods are available with various imaging techniques.

Imaging

Imaging studies, including routine radiographs, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), and positron emission tomography (PET), can be used to assess the extent of lymphadenopathy in the chest and abdomen (Table 171-4). Chest radiographs are the most economical and easiest way to assess mediastinal and hilar lymphadenopathy but are not as accurate as CT of the chest. CT and ultrasonography are the most useful modalities for assessing abdominal and retroperitoneal lymphadenopathy. In most patients, CT is probably the most accurate approach, but ultrasonography has the advantage of being less expensive and not requiring radiation exposure. MRI and PET are not first-line studies for the assessment of lymphadenopathy. PET is frequently positive in patients with Hodgkin's disease and aggressive non-Hodgkin's lymphomas and can be used to assess the presence of active lymphoma in patients with lymphadenopathy and a proven diagnosis; it is especially useful for re-evaluating patients after therapy because lymph nodes do not always regress to normal size after treatment, particularly those in the mediastinum and retroperitoneum, even though the malignancy has been eradicated.

Interventional Evaluation

Lymph node aspiration or biopsy is often necessary for an accurate diagnosis of the cause of lymphadenopathy. Fine-needle aspiration is currently popular and is an accurate means of diagnosing infection or carcinoma involving a lymph node. Although lymphomas can occasionally be diagnosed with this approach, it is inappropriate as an initial diagnostic maneuver for lymphoma. Cutting needle biopsy occasionally provides sufficient material for an unequivocal diagnosis and subtyping of the lymphoma. However, excisional biopsy, which is most likely to provide the pathologist with adequate material to perform histologic, immunologic, and genetic studies, is also most likely to yield the correct diagnosis.

TABLE 171-5 APPROACH TO THE PATIENT WITH LYMPHADENOPATHY

- Does the patient have a known illness that causes lymphadenopathy? Treat and monitor for resolution.
- Is there an obvious infection to explain the lymphadenopathy (e.g., infectious mononucleosis)? Treat and monitor for resolution.
- Are the nodes very large and/or very firm and thus suggestive of malignancy? Perform a biopsy.
- Is the patient very concerned about malignancy and unable to be reassured that malignancy is unlikely? Perform a biopsy.
- If none of the preceding are true, perform a complete blood cell count and, if unrevealing, monitor for a predetermined period (usually 2 to 8 weeks). If the nodes do not regress or if they increase in size, perform a biopsy.

An Approach to the Patient with Lymphadenopathy

Patients with lymphadenopathy (Table 171-5) come to medical attention in several ways. Perhaps most common is a patient who feels a lymph node in the neck, axilla, or groin and seeks a physician's opinion. Lymphadenopathy might also be an unexpected finding on a routine physical examination or as part of an evaluation for another complaint. Finally, patients might be found to have unexpected lymphadenopathy on imaging studies of the chest or abdomen. When the nodes are multiple or larger than 2 to 3 cm, biopsy via mediastinoscopy, a paramediastinal incision, laparoscopy, or laparotomy is often required for diagnosis.

The approach to a patient complaining of newly discovered lymphadenopathy in the neck, axilla, or groin depends on the size, consistency, and number of enlarged lymph nodes and the patient's general health. In most cases, very large or very firm lymph nodes in the presence of systemic symptoms such as unexplained fever, sweats, or weight loss should lead to lymph node biopsy. Patients who have enlarged lymph nodes in the drainage area of a previously treated malignancy (e.g., neck nodes in a patient with a history of head and neck cancer) might be best approached by lymph node aspiration. Carcinoma can often be diagnosed in this manner, although it is a poor approach for the diagnosis of lymphoid malignancies. For cervical lymph nodes, excisional biopsy should be delayed in a patient in whom head and neck cancer (Chapter 196) is a diagnostic consideration. These patients should initially undergo careful ear, nose, and throat examinations to avoid performing a biopsy that might complicate the patient's subsequent therapy. Some diagnostic possibilities for localized lymphadenopathy are presented in Table 171-6.

In the most common situation—that is, a lymph node is soft and is not larger than 2 to 3 cm and the patient has no obvious systemic illness—observation for a brief period is usually the best approach. Performance of a complete blood cell count and examination of a peripheral smear can be helpful in recognizing a systemic illness (e.g., infectious mononucleosis). These patients are often given antibiotics. If the lymph node does not regress over the course of a few weeks or if it gets bigger, a biopsy should be performed.

TABLE 171-6 SOME DIAGNOSTIC CONSIDERATIONS FOR LOCALIZED LYMPHADENOPATHY

SITE	INFECTIONS	NEOPLASMS	OTHER
Cervical	Pharyngitis, other head and neck infections, mononucleosis, toxoplasmosis, TB	Head and neck cancers, thyroid cancer, lymphoma	
Supraclavicular		Intra-abdominal cancer (particularly left-sided nodes), lung cancer, lymphoma	
Axillary	Cat-scratch disease, distal infections, plague	Breast cancer, melanoma, lymphoma	Silicone implants
Mediastinal	TB, fungal infection, anthrax	Lymphoma, lung cancer, germ cell tumor	Sarcoidosis
Retroperitoneal	TB	Lymphoma, testicular cancer, kidney cancer, upper GI malignancy	Sarcoidosis
Mesenteric	Appendicitis, cholecystitis, diverticulitis, Whipple's disease	Lymphoma, GI cancer	Inflammatory bowel disease, panniculitis
Inguinal	Distal or genital infection, plague, STDs	Lymphoma, melanoma, vulvar cancer	

GI = gastrointestinal; STD = sexually transmitted disease; TB = tuberculosis.

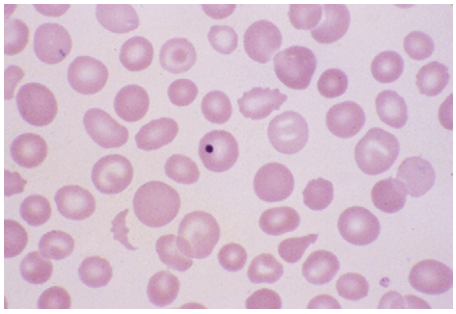

FIGURE 171-1. Howell-Jolly body in an erythrocyte. This is evidence of splenectomy or a nonfunctional spleen.

Part of the care of such patients involves the art of medicine and being responsive to the patient's particular needs. For example, biopsy might be performed more quickly in a patient who is very anxious about malignancy or who needs a definitive diagnosis expeditiously.

SPLENOMEGALY

DEFINITION

The spleen is the largest lymphatic organ in the body and is sometimes approached clinically as though it were a very large lymph node. Although it participates in the primary immune response to invading microorganisms and foreign proteins, the spleen has many other functions. It functions as a filter for the blood and is responsible for removing senescent red blood cells from the circulation, as well as blood cells and other cells coated with immunoglobulins. Blood enters the spleen, filters through the splenic cords, and is exposed to immunologically active cells in the spleen.

The splenic red pulp occupies more than half the volume of the spleen and is the site where senescent red cells are identified and destroyed and red blood cell inclusions are removed by a process known as *pitting*. In the absence of splenic function, basophilic inclusions known as *Howell-Jolly bodies* are seen in circulating red blood cells. The presence of Howell-Jolly bodies (Fig. 171-1) in peripheral blood indicates that the patient has undergone splenectomy or has a process that has rendered the spleen nonfunctional (e.g., sickle cell disease with repeated splenic infarcts, chronic graft-versus-host disease).

The white pulp of the spleen contains macrophages, B lymphocytes, and T lymphocytes; participates in the recognition of microorganisms and foreign proteins; and is involved in the primary immune response. Absence of this splenic function makes individuals particularly susceptible to certain infections, including sepsis with encapsulated organisms such as *Streptococcus pneumoniae*. The risk for overwhelming sepsis is related to the age at the time of splenectomy or other cause of loss of splenic function. Children and young adults are at highest risk. If possible, all patients should undergo vaccination against *S. pneumoniae* and perhaps *Haemophilus influenzae* and *Neisseria meningitidis* before splenectomy. Some physicians have patients take oral penicillin (e.g., phenoxymethyl penicillin 250 mg twice daily) indefinitely if splenectomy has been performed in childhood or adolescence.

TABLE 171-7 CAUSES OF SPLENOMEGALY

- Infection
  - Bacterial (e.g., endocarditis, brucellosis, syphilis, typhoid, pyogenic abscess)
  - Mycobacterial (e.g., tuberculosis)
  - Fungal (e.g., histoplasmosis, toxoplasmosis)
  - Parasitic (e.g., malaria, leishmaniasis)
  - Rickettsial (e.g., Rocky Mountain spotted fever)
  - Viral (e.g., Epstein-Barr virus, cytomegalovirus, HIV, hepatitis)
- Benign disorders of the immune system (e.g., rheumatoid arthritis with Felty's syndrome, systemic lupus erythematosus, drug reactions such as to phenytoin, Langerhans cell histiocytosis, serum sickness)
- Malignant disorders of the immune system (e.g., acute or chronic myeloid or lymphoid leukemia, non-Hodgkin's lymphoma, Hodgkin's disease, Waldenström's macroglobulinemia, malignant histiocytosis)
- Other malignancies (e.g., melanoma, sarcoma)
- Congestive splenomegaly (e.g., portal hypertension secondary to liver disease, splenic or portal vein thrombosis)
- Hematologic disorders (e.g., autoimmune hemolytic anemia, hereditary spherocytosis, thalassemia major, hemoglobinopathies, elliptocytosis, extramedullary hematopoiesis)
- Storage diseases (e.g., Gaucher's disease)
- Endocrinopathies (e.g., hyperthyroidism)
- Miscellaneous (e.g., sarcoidosis, amyloidosis, tropical splenomegaly, cysts)

PATHOBIOLOGY

As with lymphadenopathy, numerous conditions are associated with splenomegaly (Table 171-7). Certain bacterial infections such as endocarditis (Chapter 76), brucellosis (Chapter 318), and typhoid fever (Chapter 316) have splenomegaly as a frequent manifestation. Disseminated tuberculosis (Chapter 332) is often associated with splenomegaly, and splenomegaly can also be seen in cases of disseminated histoplasmosis (Chapter 340) and toxoplasmosis (Chapter 357). Splenomegaly is an almost constant accompaniment of malaria (Chapter 353). Rickettsial disorders such as Rocky Mountain spotted fever are frequently associated with splenomegaly. A wide variety of viral infections typically cause splenomegaly, including infectious mononucleosis associated with Epstein-Barr virus (Chapter 385) and viral hepatitis (Chapters 150 and 151). Splenomegaly can accompany HIV infection. Splenic abscesses, which are usually the result of hematogenous spread of pyogenic organisms, represent an unusual and difficult to diagnose cause of splenomegaly.

Splenomegaly is also seen in a variety of benign disorders of the immune system, including rheumatoid arthritis (Chapter 272); some of these patients have Felty's syndrome and accompanying granulocytopenia. Splenomegaly can be detected in some patients with systemic lupus erythematosus (Chapter 274), certain drug reactions, and serum sickness.

Malignancies of the immune system and nonimmune organs can also lead to splenomegaly. Splenomegaly is usually seen in patients with chronic myeloid leukemia and is frequent in chronic lymphoid leukemia (Chapter 190). It can develop in patients with acute myeloid or lymphoid leukemia, non-Hodgkin's lymphoma, Hodgkin's disease, and Waldenström's macroglobulinemia but is rare in multiple myeloma (Chapter 193). Isolated splenomegaly (i.e., without any enlarged lymph nodes) is characteristic of certain immune system malignancies, including hairy cell leukemia (Chapter 190),

the prolymphocytic variant of chronic lymphocytic leukemia (Chapter 190), and splenic marginal zone lymphoma (Chapter 191). Metastasis of carcinomas and sarcomas to the spleen is unusual except for malignant melanoma; even with melanoma, however, palpable splenomegaly is an unusual finding.

Splenomegaly can develop as a result of increased pressure in the splenic circulation, especially in patients with portal hypertension caused by a variety of hepatic disorders, including alcoholic cirrhosis (Chapter 155). However, it also can be due to splenic or portal vein thrombosis.

Hematologic disorders that can lead to palpable splenomegaly include autoimmune hemolytic anemia, hereditary spherocytosis, and a number of other anemias. In cases of idiopathic myelofibrosis, the spleen is frequently a site of extramedullary hematopoiesis (Chapter 169).

A variety of less common conditions can lead to splenomegaly. The storage disorder Gaucher's disease (Chapter 215) usually manifests as splenomegaly. Splenomegaly can be seen in endocrinopathies such as hyperthyroidism (Chapter 233). Sarcoidosis (Chapter 95) and amyloidosis (Chapter 194) can manifest as splenomegaly. *Tropical splenomegaly* is a term used to describe the palpable spleens found in patients who live in tropical areas, for which there may be numerous causes.

DIAGNOSIS

Evaluation of Spleen Size and Function

Physical Examination

The ability to perform an accurate physical examination and determine the presence of an enlarged spleen (Table 171-8) is an important skill, but it is not easily learned. Physical examination of the spleen can be performed with the patient supine or in the right lateral decubitus position. Inspection, percussion, auscultation, and palpation are all important parts of an accurate assessment. It is rare for a spleen to be so large that it is visible and can be seen to move with respiration. However, in patients with such a condition, it is possible to miss splenomegaly by failing to start palpation sufficiently low to find the edge. Occasionally, percussion of the left upper quadrant helps identify an area of dullness that moves with respiration and can lead to the identification of splenomegaly. Spleen size is generally recorded as the number of centimeters the spleen descends below the left costal margin in the midclavicular line on inspiration. Although auscultation is not usually a regular part of splenic examination, the existence of a splenic rub on inspiration can lead to the diagnosis of splenic infarction. The left kidney is sometimes confused with the spleen on physical examination, but its failure to move with respiration in the manner typical for the spleen usually allows its distinction.

Laboratory Evaluation

Laboratory studies are frequently valuable in assessing splenic function. In patients with an absent or nonfunctional spleen, Howell-Jolly bodies will be seen in circulating red blood cells (see Fig. 171-1). Splenic hyperfunction (a condition often referred to as *hypersplenism*) is associated with cytopenias: the spleen is the normal reservoir for a significant proportion of platelets, and this reservoir function can lead to thrombocytopenia in patients with splenomegaly. Patients with autoimmune hemolytic anemia usually have palpable splenomegaly, but patients with idiopathic (immune) thrombocytopenic purpura usually do not.

The spleen can be imaged with ultrasonography, CT, traditional radionuclide scans, and PET (Fig. 171-2). Ultrasonography can provide an accurate determination of spleen size and is easy to repeat. CT frequently gives a better view of the consistency of the spleen and can identify splenic tumors or abscesses that would otherwise be missed. PET can aid in evaluating focal lesions in the spleen. The technetium-labeled liver-spleen scan can be important in identifying liver disease as the cause of splenomegaly; in patients with cryptogenic cirrhosis who are found to have thrombocytopenia, a technetium liver-spleen scan that shows higher activity in the spleen than in the liver might be the first hint of liver disease.

Because of the spleen's location and its propensity to bleed, needle aspiration or cutting needle biopsy of the spleen is rarely performed. In general, splenic "biopsy" involves splenectomy, which can be performed at the time of laparotomy or via laparoscopy. However, performing splenectomy laparoscopically usually leads to maceration of the organ and can reduce the diagnostic information. In very young children, in whom splenectomy leads to a high risk for serious infections such as pneumococcal septicemia, partial splenectomy can sometimes be performed. Patients who undergo splenectomy at the time of splenic trauma and rupture may have seeding of splenic cells to other sites in the abdomen. Some patients have additional small or accessory spleens. Persistent, functional splenic tissue can be the explanation for recurrent immune thrombocytopenia after splenectomy and might be recognized by the absence of Howell-Jolly bodies in circulating red blood cells.

An Approach to the Patient with Splenomegaly

Patients with splenomegaly (Table 171-9) may come to medical attention for a variety of reasons. Patients may complain of left upper quadrant pain or fullness or early satiety. A splenic infarct, which typically manifests as left upper quadrant pain that sometimes radiates to the left shoulder, can be the first clue to the existence of an enlarged spleen. Rarely, splenomegaly initially manifests with the catastrophic symptoms of splenic rupture. Some patients are found to have splenomegaly as a result of evaluation for unexplained cytopenia. Splenomegaly can also be discovered incidentally on physical examination. In recent years, splenomegaly has frequently been discovered on imaging studies of the abdomen performed for other purposes.

The presence of a palpable spleen on physical examination is almost always abnormal. The one exception to this rule is a palpable spleen tip in a slender young woman. In general, the presence of a palpable spleen should be

TABLE 171-9 APPROACH TO THE PATIENT WITH SPLENOMEGALY

Does the patient have a known illness that causes splenomegaly (e.g., infectious mononucleosis)? Treat and monitor for resolution.
Search for an occult infection (e.g., infectious endocarditis), hematologic disorder (e.g., hereditary spherocytosis), occult liver disease (e.g., cryptogenic cirrhosis), autoimmune disease (e.g., systemic lupus erythematosus), or storage disease (e.g., Gaucher's disease). If found, manage appropriately.
If systemic symptoms are present and suggest malignancy, focal replacement of the spleen is seen on imaging studies, and no other site is available for biopsy, splenectomy is indicated.
If none of the above are true, monitor closely and repeat studies until the splenomegaly resolves or a diagnosis becomes apparent.

considered a serious finding, and an explanation should be sought. It is less clear whether the same rules apply to borderline splenomegaly discovered incidentally on routine imaging studies.

The approach to a patient with an enlarged spleen should focus initially on excluding a systemic illness that could explain the splenomegaly. Infectious mononucleosis, leukemia or lymphoma, rheumatoid arthritis, sarcoidosis, cirrhosis of the liver, malaria, and a host of other illnesses would be reasonable explanations for the splenomegaly. The systemic condition should be treated, and then the spleen should be re-evaluated. If the systemic illness can be treated successfully, the spleen should regress to normal size over time.

Patients with no obvious explanation for an enlarged spleen present a difficult diagnostic problem. Careful follow-up of these patients sometimes reveals occult liver disease or an autoimmune process that initially defied diagnosis. Concerns about malignancy, particularly in patients with systemic symptoms such as fever, sweats, or weight loss or in whom imaging studies show a focal abnormality, are sometimes indications for splenectomy. However, in the absence of such findings, it is generally preferable to monitor patients closely with repeated attempts to establish the diagnosis by approaches other than splenectomy. It is particularly important to avoid splenectomy in a patient with occult liver disease and portal hypertension.

Splenectomy was once performed routinely as part of the staging evaluation for Hodgkin's disease or other lymphomas. Today, this procedure is rarely needed to choose the correct therapy, and it should be avoided. Splenectomy can be an effective therapy for immune thrombocytopenic purpura (Chapter 175) and autoimmune hemolytic anemia (Chapter 163), and it is occasionally an appropriate therapy to relieve cytopenias in other conditions such as advanced myelofibrosis (Chapter 169).

172 DISORDERS OF PHAGOCYTE FUNCTION

MICHAEL GLOGAUER

Neutrophils and monocyte-macrophages are the key phagocytes of the innate immune system. Their principal innate immune role is to recognize and eliminate microorganisms that make their way past primary physical barriers, such as the epithelium and body secretions that protect the external and lining surfaces of the body. Phagocytes identify foreign invaders through a series of pattern recognition receptors, the majority of which belong to the Toll-like receptor family (Chapters 44 and 47). Whereas macrophages carry out sentinel duty looking for microbes in healthy tissue and act as a bridge between the innate and adaptive immune systems, neutrophils appear only in infected or damaged tissue after being recruited by inflammatory mediators released from activated macrophages and endothelial cells or by chemical signals released by invading microorganisms themselves (Table 172-1). After accumulation of these key immune cells at sites of infection, the microbes are eliminated through the process of phagocytosis, which is defined as the engulfment, internalization, and degradation of extracellular material.

NEUTROPHILS

Neutrophils develop in the bone marrow from myeloid precursors, migrate into the circulation, and, if required, make their way into infected or damaged tissue (Fig. 172-1). Their travels are essentially one-way trips because once they leave a compartment, they do not return. After release from the bone marrow compartment, a mature neutrophil has a blood half-life of about 10 hours and may survive up to an additional 48 hours within infected or damaged tissue.

The Bone Marrow Compartment: The Site of Granulopoiesis

Neutrophils are the most abundant white blood cell and account for up to 70% of circulating leukocytes. Neutrophil numbers can increase rapidly by as much as 5- to 10-fold during periods of acute infection. Because these cells have a very short half-life in blood, the bone marrow compartment provides a steady supply of mature neutrophils with the capability to upregulate cell production rapidly during times of infection. Neutrophils originate in the bone marrow from a common population of hematopoietic stem cells through a 10- to 14-day process of proliferation, differentiation, and maturation (Chapter 159).

Steps in Granulopoiesis

The stages of neutrophil granulopoiesis in the bone marrow (Fig. 172-2) are divided and identified by the major transitions from the pluripotent stem cell to the mature neutrophil. The *myeloblast* is the first recognizable progenitor cell committed to granulopoiesis. This proliferating cell is characterized by its large nucleus and agranular cytoplasm. The *promyelocyte* follows and displays the initial development of primary granules. *Myelocytes* occupy the next stage of neutrophil maturation and are characterized by development of the first specific or "secondary" (peroxidase-negative) granules. *Metamyelocytes,* which follow myelocytes, are incapable of further mitosis and are readily identifiable by their now numerous cytoplasmic granules. The functional maturation of metamyelocytes results in the development of *band* cells, which are usually slightly larger than mature neutrophils and have a 15-μm diameter, a horseshoe-shaped nucleus, and a moderate to abundant supply of specific granules. Band cells can be found in the circulation during periods of acute infection. The final mature *neutrophil,* which is released into the circulation, has a diameter of approximately 10 μm with a characteristic nucleus that is segmented and multilobed and occupies about 20% of the cell's volume; the remaining cytoplasm is taken up by granules.

Defects in granulopoiesis are manifested clinically as low circulating levels of neutrophils (neutropenia; Chapter 170). Verification of the stage at which neutrophil developmental arrest occurs can be determined by a bone marrow biopsy to assess the cellularity and characteristics of the neutrophil precursors present in the marrow space.

Regulation of Granulopoiesis

Granulopoiesis is driven by hematopoietic growth factors (Chapter 159). These factors, which are synthesized by a variety of cells, including fibroblasts and endothelial cells, are known to work together with other regulatory molecules, such as cytokines, to regulate hematopoiesis. Hematopoietic growth factors such as *interleukin-3* (IL-3), *granulocyte-macrophage colony-stimulating factor* (GM-CSF), and *granulocyte colony-stimulating factor* (G-CSF) bind to their target cells through specific receptors and are critical for the hematopoietic system to respond rapidly to infection or inflammation by dramatically increasing the production of leukocytes.

G-CSF is a potent cytokine that influences the proliferation, survival, maturation, and functional activation of cells from the neutrophil-granulocyte lineage. In normal individuals, circulating levels of G-CSF are very low (<100 pg/mL). However, in conditions of stress, G-CSF levels can rise to 20 times baseline levels, thereby resulting in a rapid increase in circulating neutrophils. G-CSF may regulate this increased granulopoiesis by increasing the

mitotic pool at the promyelocyte and myelocyte stages and shortening neutrophil transit time in bone marrow.

Neutrophil Granules

One of the major mechanisms used by neutrophils to eliminate bacteria is a remarkable arsenal of antimicrobial proteins that are packed into cytoplasmic granules (Table 172-2). These antimicrobial proteins are securely contained within their respective granules and are released only when granules fuse with phagosomes or directly with the plasma membrane. Granulogenesis begins between the myeloblast and promyelocyte stages of neutrophil development and continues throughout the differentiation and maturation process of the cell. *Azurophilic* granules, which make up 30% of granules in a mature neutrophil, are the first to appear at the promyelocyte stage; they contain hydrolytic enzymes, microbicidal peptides, and myeloperoxidase. The *secondary,* or specific, granules appear later, beginning at the metamyelocyte stage; they are twice as abundant in the cytoplasm as azurophilic granules and contain proteins such as collagenase and lactoferrin. The *gelatinase-containing,* or *tertiary,* granules also appear at the metamyelocyte stage. A fourth category of granules, *secretory vesicles,* appear at the very final stages of neutrophil maturation, immediately before release of the cell into the circulation. All the granule types contain membrane proteins such as CR1, CR3, CD45, CD11c, and fMLP (*N*-formyl-methionyl-leucyl-phenylalanine) receptors, which are rapidly transported to the plasma membrane during activation to enhance neutrophil microbicidal activity.

A number of clinical conditions result from specific defects in granule development and formation. Initial assessment for granule defects can be made by microscopic evaluation of a peripheral blood smear (Chapter 160). Examples of obvious clinical diagnoses made with the peripheral smear include specific granule deficiency, which is characterized by bilobed nuclei in more than 80% of the neutrophils, and a significant decrease in cytoplasmic granularity. Abnormally large cytoplasmic granules are seen in individuals with Chédiak-Higashi syndrome.

The Vascular Compartment

Mature neutrophils are released from the postmitotic bone marrow compartment into the circulation, where they have an approximate lifespan of 8 to 12 hours and either circulate within the center of the blood vessel or attach to its endothelial lining, a process termed *margination*. Marginated neutrophils on the vessel walls are able to detach and reenter the circulation when required. For example, corticosteroids and epinephrine induce a rapid increase in circulating neutrophils by releasing neutrophils from the marginated pool. Neutrophils circulate until they are recruited to a site of infection. The initial phase of recruitment involves changes in the endothelial cell surface receptors lining the capillary beds closest to the site of infection or tissue damage. These critical changes in endothelial cells are mediated by immune regulators released by tissue macrophages, which initially detect the tissue damage or bacterial invasion. Emigration of circulating neutrophils from the vasculature to the site of infection or tissue damage requires three steps (see Fig. 172-1): capture and margination, firm adhesion to the endothelial wall, and diapedesis.

Margination and Capture

The marginated pool of neutrophils consists of neutrophils transiently retained against the walls of pulmonary capillaries and postcapillary venules. In the 20-μm diameter of a postcapillary venule, the smaller and faster circulating red blood cells displace the slower-moving and larger neutrophils, which move to the vessel margins, where a low-affinity molecular interaction occurs between surface adhesion molecules of the neutrophil and the endothelial cells. This interaction results in neutrophil rolling and capture along the vessel walls, an event that requires the specific neutrophil receptors *leukocyte selectin* (L-selectin) and the corresponding endothelial ligand, sLe. L-selectin is constitutively expressed in neutrophils, with highest expression in young circulating neutrophils and gradual decline with a cell's age, probably because previous margination events have depleted the receptor. The endothelial ligand for L-selectin, sLe, is a sialylated carbohydrate linked to a mucin-like molecule that can be upregulated by bacterial lipopolysaccharide or other mediators of inflammation. The selectin-ligand interactions are reversible and serve to promote and maintain accumulation of circulating neutrophils on inflamed endothelium.

Adherence to the Endothelial Wall

Low-affinity, selectin-mediated transient interactions must be replaced by high-affinity, adhesive contacts between neutrophils and endothelial cells. During an acute inflammatory event, mediators derived from bacteria, damaged host cells, complement activation, or other immune cells are released from the site of infection and diffuse to the capillary beds, where they induce an immediate and transient vascular response that results in vascular leakage, which further encourages neutrophil margination. Endothelial cells adjacent to the site of inflammation, as well as the activated neutrophils that are bound to them, express integrin receptors that lead to high-affinity attachments between the neutrophils and endothelial cells. These high-affinity connections occur between neutrophil β2 *integrins* and their endothelial counterparts, the intercellular adhesion molecules (ICAMs). Integrins, which are a receptor family of heterodimeric transmembrane glycoproteins made up of an α- and β-subunit, are integral for cell adhesion. Neutrophil β2 integrins consist of three different α-subunits (CD11a, CD11b, and CD11c) that bind to a common β-subunit (CD18). The cytoplasmic tails of these transmembrane receptors possess phosphorylation sites for attachment of signal transduction and cytoskeletal proteins. The neutrophil integrins that mediate this adhesion step are *macrophage antigen-1* (Mac-1; CD11b/CD18) and *lymphocyte-associated function antigen-1* (LFA-1; CD11a/CD18). The receptors are stored in the neutrophil granule compartments to facilitate quick transfer to the plasma membrane during cell stimulation. The integrins bind to endothelial ICAM-1 and ICAM-2 and *vascular cell adhesion molecule-1* (VCAM-1), which are upregulated on the endothelial cell membranes when a cell is exposed to inflammatory cytokines. L-selectin receptors on neutrophils are concentrated on microvillus projections of the cell membrane, whereas the integrins are restricted to the body of the neutrophil. As a result, soon after initial contact during rolling interactions, the projections retract, thereby allowing integrins to interact with their ligands.

Diapedesis

Firm adherence through the L-selectin and integrin receptors facilitates transendothelial migration, or diapedesis, which marks the "point of no return" in the process of neutrophil recruitment to the site of injury. Unlike rolling and firm adhesion, which require heterophilic interactions between one class of molecules on the neutrophil and another class of molecules on the endothelial cell, diapedesis involves homophilic interactions between the same class of molecules on both cells—the *platelet-endothelial cell adhesion molecule-1* (PECAM-1 or CD31). PECAM-1 is expressed evenly on the surface of neutrophils and concentrated at endothelial cell junctions. Once firmly bound to the endothelial cell surface, neutrophils migrate between the closest tricellular endothelial cell junctions through interactions with PECAM-1 receptors. The neutrophil has now entered the tissue compartment, where it is primed for its final critical role in the elimination of microorganisms and cellular debris.

Laboratory Evaluation of Margination and Firm Adhesion

A defect in neutrophil margination or adhesion to the endothelial lining of the vascular compartment results in neutrophilia (elevated circulating neutrophil levels). This condition is usually associated with leukocyte adhesion deficiency (LAD), which is the result of a lack of CD11/CD18 receptor surface expression in peripheral blood neutrophils. If LAD is suspected, surface expression of these receptors can be measured with a flow cytometer and specific antibodies to CD11, CD18, or CD15 receptors.

The Tissue Compartment

Chemotaxis

Chemotaxis is the directed movement of cells up a chemical concentration gradient of a *chemoattractant*. Chemoattractants are soluble proteins or peptides, including bacterial products, complement factors, and chemokines produced by both inflammatory and noninflammatory cells, that are released from damaged or infected tissue. A concentration difference of 1% at the opposite ends of the neutrophil is sufficient to activate neutrophil chemotaxis. Once a chemoattractant binds to its corresponding neutrophil membrane receptor, a series of cytoplasmic signaling pathways leads to activation of the neutrophil cytoskeleton. This activation results in the neutrophil assuming a polarized state characterized by an actin-rich leading lamella or pseudopod that drives cell motility.

Directional cell crawling, the intrinsic basis of chemotaxis, can be broken down into smaller processes, including extension of the cell membrane, adhesion to the tissue matrix, and contraction of the cell body in an organized and reversible manner. The actin-dependent protrusion of the leading edge, which is a sheetlike structure rich in actin filaments, is critical for normal neutrophil motility. The actin filaments within these lamellar regions are assembled into highly organized structures that push the membrane forward. These structures are formed by different collections of actin-binding proteins under the regulation of specific signal transduction cascades linking chemotactic receptors with cell movement. Defects in actin assembly also result in defects in chemotaxis and recurrent infections.

Actin Assembly Biology

Actin filaments are polar structures, with each end differing in its equilibrium-binding constant for actin monomers (Fig. 172-3). Filaments grow at the high-affinity or barbed end, whereas depolymerization occurs at the low-affinity or pointed end. This difference, generated by the ability of actin to bind and hydrolyze adenosine triphosphate, provides a physical polarity that regulatory proteins use to drive filament dynamics with high temporal and spatial precision. Three classes of proteins regulate the availability of high-affinity actin filament ends: filament-nucleating proteins (e.g., ARP2/3 de novo nucleation), filament-capping proteins (e.g., gelsolin), and filament-severing proteins (e.g., cofilin). Actin-nucleating factors bind actin monomers under conditions otherwise unfavorable for assembly and generate a new filament with a free high-affinity end available for assembly. Actin filament-capping proteins bind to the high-affinity filament end and regulate the addition of monomers by their presence or absence at the end of the filament. Actin-binding proteins are regulated by various second messengers, including calcium. On stimulation, localized changes in the intracellular Ca^{2+} concentration lead to the rapid initiation of actin assembly and disassembly. The changes in actin filament length and the extent of cross-linkage between the filaments may account for the directional extension of actin-rich lamellae and contraction of the tail-like uropod at the other end of the cell. Movement in the neutrophil is therefore the result of lamellar protrusions resulting from the growth of actin filaments. Actin-rich lamellae will continue to be maintained as long as the neutrophil detects the chemoattractant gradient.

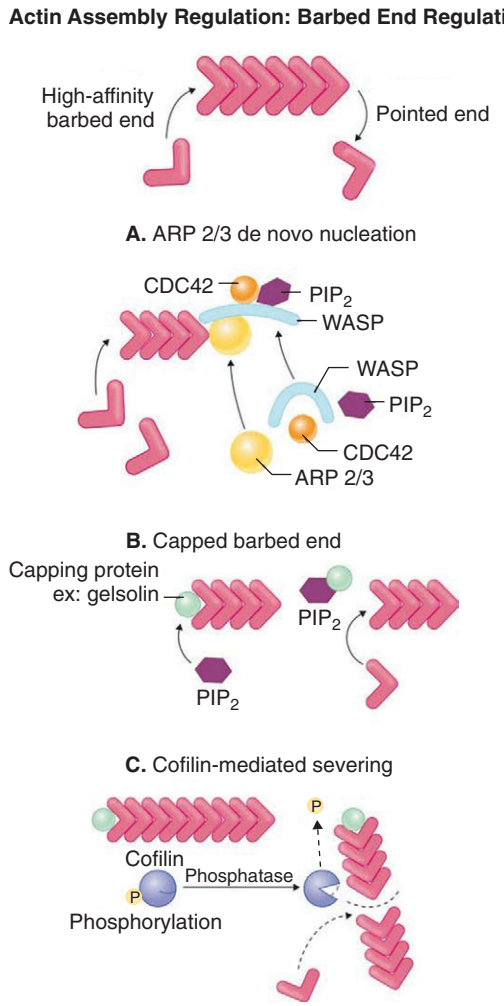

FIGURE 172-3. Regulation of actin assembly through the generation of free barbed ends by actin-binding proteins. A, The components below join together to form a nucleation complex (above). **B,** PIP_2 binds the capping protein, leading to its removal from the high-affinity end, allowing for addition and filament growth. **C,** A phosphatase removes the P from cofilin, thereby allowing it to sever the actin filament and leaving a free high affinity end. PIP_2 = phosphatidylinositol 4,5-biphosphate; WASP = Wiskott-Aldrich syndrome protein.

Laboratory Evaluation of Chemotaxis

A defect in neutrophil chemotaxis can be measured in the laboratory with a Boyden chamber, which uses a porous membrane to separate isolated neutrophils from a chemoattractant. A chemical gradient develops across the porous membrane and activates the neutrophils to crawl through the membrane toward the compartment containing the chemoattractant. Defects in chemotaxis can be determined by a lack of neutrophil transmigration through the membrane compared with control neutrophils from a healthy donor.

Phagocytosis

Phagocytosis is the process whereby neutrophils engulf and internalize invading pathogens into membrane compartments called *phagosomes*. Bacterial targets are "highlighted" or opsonized by antibodies (immunoglobulin G) or products from the classical complement pathway that coat the target and serve to mediate phagocytic adhesion. Neutrophilic phagocytosis involves two separate classes of receptors: *Fcγ receptors* (CD32 and CD16) for antibody-coated targets and *complement receptors* (CR1 and CR3) for complement-coated targets. CD32 and CR3 are functional receptors directly involved in neutrophilic phagocytosis, whereas CD16 and CR1 are coreceptors that assist their mate in completing binding and internalization. Activation of Fcγ receptors brings about phosphorylation of their cytoplasmic *immunoreceptor tyrosine-based activation motifs* (ITAMs) through activation of *Src family kinases;* the result is transduction of signals that induce extension of pseudopods, including signaling to the small Rho family of small guanosine triphosphatases (GTPases). These GTPases are responsible for the assembly of actin filaments, thereby leading to remodeling of the plasma membrane and the formation of actin-rich pseudopods, which are essential for the ingestion of particles and formation of phagosomes.

Laboratory Evaluation of Phagocytosis

Neutrophils can be incubated with fluorescently labeled bacteria after opsonization with serum from either the patient or a control. Phagocytosis is assessed by flow cytometry, which measures the increase in neutrophilic fluorescence after uptake of the fluorescently tagged bacteria.

Bacterial Killing

Phagocytes use two potent mechanisms for killing bacteria within the membrane-bound phagosome. The first involves fusion of the previously described storage granules with the phagosome to deliver microbicidal and lytic enzymes into the membrane compartment that contains the ingested microorganisms. The second mechanism uses a multiprotein enzyme complex to generate microbicidal oxidants through partial reduction of oxygen. The multiprotein enzyme complex known as reduced nicotinamide adenine dinucleotide phosphate (NADPH) oxidase generates oxidants by means of oxygen consumption, hence the term *respiratory burst*.

The NADPH enzyme system is made up of four essential polypeptide subunits that are denoted by their molecular weight (kD) and the superscript phox, which denotes phagocyte oxidase. Within the cytoplasmic membrane, the subunits $p22^{phox}$ and $gp91^{phox}$ bind the electron-carrying components of the oxidase (NADPH, a flavin adenine dinucleotide, and two nonidentical hemes) and form the cytochrome b_{558} redox center of the oxidase complex. Cellular activation by inflammatory mediators results in the addition of two cytosolic components, $p47^{phox}$ and $p67^{phox}$, to the complex along with the Rac small GTPase.

The membrane-bound electron transport chain NADPH oxidase catalyzes the reduction of molecular oxygen to superoxide (O_2^-). The superoxide generated by this process is in turn catalytically converted to hydrogen peroxide and serves as a cosubstrate for myeloperoxidase to oxidize halides and produce hypochlorous acid (HOCl), a very potent antimicrobial agent. These oxidants are able to kill bacteria within the phagosomes by oxidizing their cellular constituents.

Laboratory Evaluation of the Respiratory Burst and Bacterial Killing

Flow cytometry, a rapid and effective method for quantitatively assessing the respiratory burst, measures the fluorescence generated by cytoplasmic fluorescent probes such as dihydrorhodamine, which is converted to rhodamine by H_2O_2. The nitroblue tetrazolium (NBT) test is still used for rapid assessment of the respiratory burst when flow cytometry is not available.

Bacterial killing assays using a patient's neutrophils with either the patient's or control serum and bacteria such as *Staphylococcus aureus* or *Escherichia coli* are a definitive method to determine whether a given patient's neutrophils have an intracellular killing defect. Neutrophils from a healthy control subject phagocytose and kill approximately 95% of the bacteria within 2 hours. In assays in which an intracellular killing defect is present, neutrophils kill less than 10% of bacteria over a 2-hour period. It is necessary to confirm that there is no phagocytic defect before performing the bacterial killing assay to be sure that any defect in bacterial killing is not due to an internalization defect.

Neutrophil Extracellular Traps

It has recently been shown that neutrophils use a newly identified extracellular process to contain and kill bacteria. Neutrophil extracellular traps (NETs) are formed by the release of chromatin and antimicrobial proteins from the neutrophil cytoplasm and granules. The chromatin forms a netlike meshwork that traps the bacteria and brings them in closer proximity to the antimicrobial elements adhered to the chromatin. Activation of NET formation requires simultaneous activation by at least two different receptors and reactive oxygen species are essential to the process. IL-8 has been shown to be a potent activator of NET formation. The importance of NETs was highlighted by work showing that DNase expressing strains of GAS and *Streptococcus pneumoniae* are more virulent than their non-DNase-expressing counterparts because of their ability to escape NETs. The importance of this antibacterial function of neutrophils will become clearer in the years to come.

Clinical Manifestations of Phagocytic Defects

In addition to fever and recurrent infections, the most common findings in patients with phagocytic defects are oral infections resulting in gingival inflammation, periodontal bone loss, mobile or loose teeth, and premature

TABLE 172-3 SYMPTOMS SUGGESTIVE OF A PHAGOCYTIC DISORDER

Recurrent infections that fail to resolve with conventional treatment
Recurrent infections of unusual severity
Recurrent infections in the lung, liver, or bone
Normally nonpathogenic bacteria or fungi identified in cultures from the infection sites
Aphthous ulcers
Severe periodontal diseases, including gingivitis
Lymphadenopathy or hepatosplenomegaly
Severe recurrent cutaneous infections with *Staphylococcus aureus*
Recurrent mycobacterial infections

loss of teeth (Table 172-3). An oral examination should be performed at the initial evaluation, followed by a full dental examination, depending on the findings. The history and laboratory tests can differentiate among the various clinical causes of disordered phagocytosis (Table 172-4).

DEFECTS IN LEUKOCYTE ADHESION

A defect in neutrophil adhesion to the endothelial lining leads to neutrophilia—an accumulation of neutrophils in the circulation, with very few neutrophils at sites of infection. Defects in neutrophil adhesion can be induced by drugs or due to a genetic defect. Drugs such as corticosteroids and epinephrine result in a transient leukocyte adhesive defect that results in an apparent dramatic increase in circulating neutrophils because of release of the marginated neutrophil pool. The major genetic disease that results in an adhesion deficiency is termed *leukocyte adhesion deficiency.*

Leukocyte Adhesion Deficiency

LAD-I

LAD-I is an autosomal recessive inherited disorder in which patients have a mutation in the gene encoding CD18. The result is a deficiency of β2 integrin receptors, which are required for neutrophil migration from the vasculature into the tissues, thereby impairing the binding of neutrophils to C3bi and endothelial ICAM-1 and ICAM-2.

Patients have soft tissue bacterial and fungal infections, delayed wound healing, impaired pus formation, and severe destructive periodontitis with rapid tooth loss. This condition is also characterized by delayed separation of the umbilical cord. Patients usually die during childhood. Flow cytometry is used to measure CD11/CD18 surface expression levels on neutrophils.

Treatment is mainly supportive with prophylactic antibiotics in patients with recurrent infections. In severe cases, bone marrow transplantation is the treatment of choice.

LAD-II AND LAD-III

LAD-II, a variant of LAD-I, is associated with neutrophilia, the Bombay (hh) blood phenotype, dwarfism, and mental retardation. This disorder is due to a mutation in the guanosine diphosphate-fucose transporter gene, which results in impaired expression of CD15s and other selectin ligands. Symptoms are similar to those of LAD-I, and the diagnosis is confirmed by flow cytometry for CD15s. In the most recently described LAD-III, there is a primary activation defect in all three β integrins 1, 2, and 3, and mutations have been found in Kindlin 3, which binds the cytoplasmic tail of integrin.

DEFECTS IN NEUTROPHILIC CHEMOTAXIS

After phagocytes enter the tissue compartment from the vascular pool, they migrate up the concentration gradients of various chemoattractants to the site of focal infection. A number of chemotactic defects result in severe recurrent infections.

Hyperimmunoglobin E Syndrome

Hyperimmunoglobin E syndrome, or hyper-IgE syndrome, also referred to as Job's syndrome, is a group of genetically diverse, multisystem disorders of cytokine signaling. The most common form of the syndrome involves dominant mutations in the gene for signal transducer and activator of transcription 3 (*STAT3*). The neutrophilic disorder is characterized by recurrent skin abscesses, pneumonia, and periodontal diseases. After birth, patients usually have moderate to severe dermatitis, eczematous skin eruptions, nonerythematous abscesses, pneumatoceles, and severe osteoporosis that can result in bone fractures. The organisms most commonly present at infected sites are *S. aureus, Haemophilus influenzae, E. coli,* and *Candida albicans.* Patients have elevated IgE levels and eosinophilia. The defect in neutrophilic chemotaxis is less severe than that in Chédiak-Higashi syndrome (see later). Treatment is prophylactic antibiotics and aggressive treatment of infections. In severe cases, bone marrow transplantation may be considered.

Familial Mediterranean Fever

Familial Mediterranean fever (Chapter 269), also known as recurrent polyserositis, is an autosomal recessive inflammatory disease that is widespread among people of Mediterranean descent, including Arabs, Armenians, and Sephardic Jews. The genetic defect is a missense mutation in the *MEFV* gene, which encodes the protein pyrin. Pyrin is believed to be a transcription factor involved in downregulating inflammation, possibly through an effect on chemotaxis in neutrophils and monocytes. The *MEFV* mutation results in a hyperinflammatory response characterized by abundant neutrophilic infiltration into the peritoneal, pleural, and joint spaces.

The most common findings include acute, self-limited attacks of fever accompanied by pleuritis, peritonitis, arthritis, pericarditis, and erythematous skin lesions. Although first attacks may be observed during infancy, clinical disease commonly occurs in childhood or adolescence.

Leukocytosis has been observed during attacks, but the leukocyte count is normal between episodes. Genetic testing is available for the most common mutations. This disease can be fatal if renal failure develops as a result of amyloidosis (Chapter 194), which occurs in up to 25% of those affected.

The hyperinflammatory attacks can be reduced significantly with 0.6 mg of prophylactic colchicine orally two or three times daily. The prognosis is generally good for most affected individuals maintained with colchicine.

DISORDERS OF NEUTROPHILIC DEGRANULATION

Granules supply key membrane proteins, including receptors required for phagocytosis. Granule-related defects result in profound defects in bacterial killing.

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is a rare autosomal recessive disorder of the *LYST* gene, which encodes a protein responsible for lysosomal trafficking. Defective targeting of granules to the membrane results in large cytoplasmic granules that are unable to target to the plasma membrane in neutrophils, monocytes, and lymphocytes.

Symptoms are recurrent bacterial infections of the skin, mouth, and respiratory tract; partial albinism; peripheral neuropathy; and mild bleeding disorders as a result of a deficiency in serotonin- and adenosine phosphate–containing granules in platelets. Defects in myelopoiesis result in neutropenia. Death usually occurs by 7 years of age because of infection. Advanced disease is characterized by lymphocytic tissue infiltrates and pancytopenia.

Giant cytoplasmic granules are seen in the peripheral blood smear. Neutrophil function testing shows defects in chemotaxis and bacterial killing. Prophylactic antibiotics should be used to prevent infections. Bone marrow transplantation from an HLA-matched donor may be successful if performed before the disease becomes advanced.

Specific Granule Deficiency

Specific granule deficiency is an autosomal recessive disorder that manifests during infancy as the recurrent appearance of deep and superficial skin infections, respiratory infections, and abscesses. Azurophilic granules in neutrophils lack defensins, gelatinase, cytochrome *b,* and vitamin B_{12}. Neutrophils are morphologically altered and have a bilobed rather than a trilobed nucleus. This disorder is characterized by impaired neutrophil chemotaxis, reduced respiratory burst, and a defect in bacterial killing. Infections are commonly caused by *S. aureus, Pseudomonas aeruginosa,* and *C. albicans.* Aggressive treatment of infections is required.

DISORDERS OF OXYGEN-DEPENDENT BACTERIAL KILLING

A genetic defect in any component of the respiratory burst results in delayed or ineffective bacterial killing.

Chronic Granulomatous Disease

PATHOBIOLOGY

Chronic granulomatous disease (CGD) is a genetic disease that occurs in about 1 in 200,000 live births. Neutrophils and macrophages cannot generate

TABLE 172-4 DISORDERS OF PHAGOCYTIC FUNCTION

DISORDER	ETIOLOGY	IMPAIRED FUNCTION	CLINICAL CONSEQUENCE
DEGRANULATION ABNORMALITIES			
Chédiak-Higashi syndrome	Autosomal recessive; disordered coalescence of lysosomal granules Responsible gene found at 1q42-45. The encoded protein (LYST) has structural features homologous to a vacuolar sorting protein	Decreased neutrophilic chemotaxis, degranulation, and bactericidal activity; platelet storage pool defect; impaired NK function; failure to disperse melanosomes	Neutropenia, recurrent pyogenic infections, propensity for the development of marked hepatosplenomegaly in the accelerated phase, partial albinism
Specific granule deficiency	Autosomal recessive; abnormal regulation of various myeloid granule genes by a transacting factor	Impaired chemotaxis and bactericidal activity; bilobed nuclei in neutrophils; reduced content of neutrophil defensins, gelatinase, collagenase, vitamin B_{12}–binding protein, and lactoferrin	Recurrent infections, especially sinopulmonary and skin infections
ADHESION ABNORMALITIES			
Leukocyte adhesion deficiency type 1	Autosomal recessive; absence of CD11/CD18 surface adhesive glycoprotein (β2-integrins) on leukocyte membranes, most commonly arising from failure to express CD18 mRNA	Decreased binding of C3bi to neutrophils and impaired adhesion to ICAM-1 and ICAM-2	Neutrophilia, recurrent bacterial infection associated with lack of pus formation
Leukocyte adhesion deficiency type 2	Autosomal recessive; absence of neutrophil sialyl-Lewis^x	Decreased adhesion to activated endothelium expressing ELAM	Neutrophilia, recurrent bacterial infection without pus
Leukocyte adhesion deficiency type 3	Autosomal recessive; defects in activation of β1, β2, and β3 integrins	Severe leukocyte adhesion dysfunction; abnormal platelet aggregation	Neutrophilia, recurrent bacterial infection without pus, severe bleeding tendency
Neutrophil actin dysfunction	Altered polymerization of neutrophil cytoplasmic actin, perhaps arising from the presence of an inhibitor to F-actin formation	Impaired neutrophil adhesion, chemotaxis, and bacterial killing	Neutrophilia, recurrent bacterial infections without pus
DISORDERS OF CELL CHEMOTAXIS			
Hyperactive Chemotaxis			
Familial Mediterranean fever (FMF)	Autosomal recessive gene responsible for FMF on chromosome 16, which encodes for a protein called pyrin; pyrin may modify neutrophil activation	Excessive accumulation of neutrophils at inflamed sites	Recurrent fever, peritonitis, pleuritis, arthritis, amyloidosis
Depressed Chemotaxis			
Intrinsic defects of the neutrophil, e.g., leukocyte adhesion deficiency, Chédiak-Higashi syndrome, specific granule deficiency, neutrophil actin dysfunction, neonatal neutrophils	In the neonatal neutrophil, there is diminished ability to express β2 integrins and a qualitative impairment in β2 integrin function	Diminished chemotaxis	Propensity for the development of pyogenic infections
Direct inhibition of neutrophil mobility, e.g., drugs	Ethanol, glucocorticoids, cyclic AMP	Impaired locomotion and ingestion, impaired adherence	Possible causes of frequent infections; neutrophilia seen with epinephrine is the result of cyclic AMP release from the endothelium
Immune complexes	Bind to Fc receptors on neutrophils in patients with rheumatoid arthritis, systemic lupus erythematosus, and other inflammatory states	Impaired chemotaxis	Recurrent pyogenic infections
Hyperimmunoglobulin E syndrome	Disorders of cytokine signaling, most commonly due to autosomal dominant mutations in the *STAT3* gene	Impaired chemotaxis, impaired IgG opsonization of *Staphylococcus aureus*	Recurrent skin and sinopulmonary infections
DEFECTS OF MICROBICIDAL ACTIVITY			
Chronic granulomatous disease (CGD)	X-linked and autosomal recessive; failure to express functional gp91^{phox} (in the phagocyte membrane) and p22^{phox} (autosomal recessive). Other autosomal recessive forms of CGD arise from failure to express protein p47^{phox} or p67^{phox}	Failure to activate neutrophil respiratory burst leading to failure to kill catalase-positive microbes	Recurrent pyogenic infections with catalase-positive microorganisms
G6PD deficiency	Less than 5% of normal activity of G6PD	Failure to activate NADPH-dependent oxidase	Infections with catalase-positive microorganisms
Myeloperoxidase deficiency	Autosomal recessive; failure to process modified precursor protein arising from missense mutation	H_2O_2-dependent antimicrobial activity not potentiated by myeloperoxidase	None
Deficiencies of glutathione reductase and glutathione synthetase	Failure to detoxify H_2O_2	Excessive formation of H_2O_2	Minimal problems with recurrent pyogenic infections

TABLE 172-4 DISORDERS OF PHAGOCYTIC FUNCTION—cont'd

DISORDER	ETIOLOGY	IMPAIRED FUNCTION	CLINICAL CONSEQUENCE
IMPAIRED MACROPHAGE FUNCTION			
Defects in the interferon-γ–IL-12 axis	Interferon-γ receptor ligand-binding chain, interferon-γ receptor signaling chain, IL-12 receptor β1 chain, IL-12 p40 deficiency; the interferon-γ receptor abnormalities may be autosomal dominant or recessive; the IL-12 receptor and IL-12 abnormalities are autosomal recessive	Impaired killing of microorganisms. Fatal BCG infection secondary either to an inability to produce IL-12 by dendritic cells and macrophages or to depressed bactericidal activity of macrophages lacking normal function of the interferon receptor	Infection with atypical mycobacteria, *Salmonella*, and *Listeria*

AMP = adenosine monophosphate; BCG = bacille Calmette-Guérin; ELAM = endothelial leukocyte adhesion molecule; G6PD = glucose-6-phosphate dehydrogenase; ICAM = intracellular adhesion molecule; IL-12 = interleukin-12; NADPH = nicotinamide adenine dinucleotide phosphate; NK = natural killer; phox = phagocyte oxidase.

superoxide and are therefore unable to kill catalase-positive organisms. This condition results from mutations in one of the four structural genes of the NADPH oxidase complex. The most common genetic defect occurs in the 91-kD component of cytochrome b_{558}, which is coded on the X chromosome. The other mutations are autosomal recessive and have been detected in the 22-, 47-, and 67-kD structural proteins.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Children are prone to infections or granulomatous lesions in the lungs, skin, and liver. *S. aureus* is the most common organism, but other organisms include *Serratia marcescens, Burkholderia cepacia, Aspergillus* species, and *Nocardia* species. Staphylococcal liver abscesses are pathognomonic of chronic granulomatous disease. Flow cytometry is used to measure the increase in fluorescence generated when dihydrorhodamine is converted to rhodamine by H_2O_2.

TREATMENT Rx

Abscesses can be removed by surgery. Trimethoprim-sulfamethoxazole prophylaxis (5 mg/kg/day divided into two equal doses) and antifungal prophylaxis with itraconazole (100 mg/day for <50 kg, 200 mg/day for >50 kg) have been shown to reduce the frequency of infections in these patients. Interferon-γ (50 μg/m^2 subcutaneously three times per week) prophylaxis is now considered "standard of care" in many centers. Bone marrow transplantation can also be considered for patients with refractory infections. Gene therapy for CGD by gene-modified autologous hematopoietic stem cell transplantation has resulted in transient immune restoration but also genomic instability, monosomy 7, and clonal progression toward myelodysplasia.

Myeloperoxidase Deficiency

Myeloperoxidase deficiency is a relatively common disorder (1 in 4000) in which the enzyme for conversion of neutrophilic hydrogen peroxide to HOCl is absent. This deficiency is not associated with increased susceptibility to infections, probably because of the accumulation of hydrogen peroxide, which is also bactericidal. Myeloperoxidase deficiency is usually asymptomatic, although patients with diabetes mellitus may occasionally experience candidal infections. The diagnosis is made by observation of a negative peroxidase stain of the peripheral blood smear. Symptomatic patients may be treated with prophylactic antibiotics.

Glutathione Synthetase Deficiency

Glutathione, which is a potent antioxidant found in granulocytes, is required for a normal respiratory burst and bacterial killing. Patients with glutathione synthetase deficiency typically have recurrent otitis and hemolytic anemia. The diagnosis is confirmed by verifying low or no glutathione synthetase in red blood cells.

Severe Glucose-6-Phosphate Dehydrogenase Deficiency

Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked disorder. White individuals with a severe reduction in G6PD activity are subject to recurrent infections, whereas Asians or blacks with similarly reduced G6PD levels are not. G6PD is crucial for regulating the availability of NADPH for the respiratory burst. G6PD deficiency results in recurrent bacterial infections, hemolytic anemia (Chapter 164), and jaundice. The diagnosis can be made with flow cytometry to assess the respiratory burst and to demonstrate the absence of G6PD in all blood cells.

MACROPHAGE-RELATED ABNORMALITIES

Accumulation of monocyte-macrophages at sites of infection occurs after the major influx of neutrophils. Macrophages have a critical role in antigen presentation to lymphocytes, thereby activating the adaptive arm of the immune system. A critical defect in macrophage signaling results in susceptibility to mycobacterial infection.

Interferon-γ Receptor 1 Defects

When macrophages phagocytose mycobacteria, they produce IL-12, which in turn stimulates T cells to produce interferon-γ (IFN-γ). IFN-γ is critical to the killing of mycobacteria and other intracellular bacteria. Patients with recurrent and severe mycobacterial infections who are not infected with human immunodeficiency virus should be assessed for abnormalities in pathways that lead to the generation and utilization of IFN-γ.

Patients with autosomal recessive mutations in the IFN-γ receptors typically have a complete loss of function of the IFN-γ receptors. Autosomal dominant mutations in the IFN-γ receptors result in normal ligand binding but defective intracellular signal transduction because of a cytoplasmically truncated form of the receptor.

Recessive mutations typically manifest as severe disseminated infections and poor formation of granulomas. Multifocal mycobacterial osteomyelitis is pathognomonic of an autosomal dominant mutation in the IFN-γ receptor. Flow cytometry confirms the absence of membrane expression of IFN-γ receptor 1 in the autosomal recessive form and up to ten-fold higher membrane expression levels of the cytoplasmically truncated receptor in the autosomal dominant form.

For patients with autosomal dominant mutations, subcutaneous IFN-γ is effective. For autosomal recessive patients completely lacking IFN-γ receptor function, bone marrow transplantation should be considered. Long-term antibiotic prophylaxis against mycobacterial infections with azithromycin or clarithromycin is recommended.

ASSESSING PHAGOCYTE FUNCTION: MAKING THE DIAGNOSIS

If a phagocyte functional disorder may be the underlying cause of recurrent infections in a patient, a complete blood count (CBC) and peripheral smear guide subsequent definitive testing (Fig. 172-4). Cultures from infected areas allow antimicrobial targeting and also provide critical diagnostic information. If the defect is a result of abnormal neutrophil development and maturation, the CBC will show neutropenia; a bone marrow biopsy might be required. Repeated CBC (twice per week for 6 weeks) is indicated if cyclic neutropenia is suspected because of a periodicity of the infections (Chapter 170).

If the CBC reveals neutrophilia, a defect in the recruitment of neutrophils into tissues is suggested. An assessment of the receptors required for transmigration by flow cytometry and specific antibodies to the surface receptors is indicated.

If circulating levels of phagocytes are normal yet the patient is experiencing recurrent infections, a phagocytic defect within the infected tissue is likely. Laboratory testing to evaluate chemotaxis, phagocytosis, and bacterial killing is indicated.

EOSINOPHILIC SYNDROMES

MARC E. ROTHENBERG

DEFINITION

Eosinophilic syndromes are a heterogeneous group of disorders that involve eosinophilia, which is defined as the accumulation of eosinophils in peripheral blood and/or tissues. Circulating eosinophils normally account for only 1 to 3% of peripheral blood leukocytes, and the upper limit of the normal range is 350 cells/mm^3 of blood. Eosinophilia occurs in a variety of disorders (Table 173-1) and is usually arbitrarily classified according to the degree of blood eosinophilia: mild (351 to 1500 cells/mm^3), moderate (>1500 to 5000 cells/mm^3), or severe (>5000 cells/mm^3). Tissue eosinophilic disorders, such as eosinophil-associated gastrointestinal disorders and eosinophilic fasciitis, are not necessarily associated with blood eosinophilia, so their

TABLE 173-1 CAUSES OF EOSINOPHILIA

REACTIVE EOSINOPHILIA
Allergic diseases—asthma, atopic dermatitis, allergic rhinitis
Drug reactions—including cytokine infusions
Infection—viral (human immunodeficiency virus) or fungal (allergic bronchopulmonary aspergillosis, coccidioidomycosis)
Parasitic infection—mostly helminths
EOSINOPHILIA ASSOCIATED WITH OTHER DISEASES
Eosinophil-associated gastrointestinal disorders—eosinophilic esophagitis, gastroenteritis
Skin—bullous pemphigoid, urticaria, eosinophilic cellulitis, episodic angioedema
Pulmonary—eosinophilic pneumonia, allergic bronchopulmonary aspergillosis
Neurologic—eosinophilic meningitis
Autoimmune—Churg-Strauss syndrome, eosinophilic fasciitis
Primary immunodeficiency—hyperimmunoglobulin E syndrome, Omenn's syndrome
Post-transplantation status—liver (in association with immunosuppression)
Transplant rejection—lung, kidney, liver
Malignancy—Hodgkin's disease, solid tumors
Hypoadrenalism—Addison's disease, adrenal hemorrhage
Renal—drug-induced interstitial nephritis, eosinophilic cystitis, dialysis
PRIMARY CLONAL EOSINOPHILIA
Chronic eosinophilic leukemia
Acute eosinophilic leukemia
Acute myelogenous leukemia with eosinophilia
Acute lymphoblastic leukemia with eosinophilia
Myeloblastic disorders with eosinophilia
Myeloproliferative disorders with eosinophilia
Systemic mastocytosis with eosinophilia
FIP1L1-PDGFRA fusion gene–positive disease
IDIOPATHIC HYPEREOSINOPHILIA

diagnosis is based on the microscopic identification of eosinophil-rich inflammatory infiltrates associated with tissue damage.

Historically, hypereosinophilic syndromes were generally classified as idiopathic and were defined by (1) the presence of eosinophilia (>1500 cells/mm^3 for at least 6 months) that remained unexplained despite a comprehensive evaluation for known causes of eosinophilia (such as drug reactions and infections) and (2) evidence of organ dysfunction directly attributable to the eosinophilia. Now, however, it is known that in some patients, a chromosome 4 microdeletion results in the generation of an activated tyrosine kinase (*FIP1L1*-platelet-derived growth factor receptor-α *[PDGFRA]*) that causes a clonal hematologic disorder now better classified as chronic eosinophilic leukemia. Identification of *FIP1L1-PDGFRA*-positive disease has important therapeutic implications because *PDGFRA*-associated disease can be treated with imatinib, a tyrosine kinase inhibitor.

EPIDEMIOLOGY

The most common cause of eosinophilia worldwide is helminth infections, which affect hundreds of millions of people. The most frequent cause in industrialized nations is atopic disease, which affects 10 to 30% of the population. Hypereosinophilic disorders such as *FIP1L1-PDGFRA*-associated disease and Churg-Strauss syndrome (Chapter 278) are very rare. For example, Churg-Strauss syndrome affects 4 to 6 cases per million per year, whereas true idiopathic hypereosinophilic syndromes may affect only 4000 to 5000 people worldwide. Other syndromes such as eosinophil-associated gastrointestinal disorders are more common, with a prevalence of approximately 1 in 10,000 individuals.

PATHOBIOLOGY

Eosinophils are produced in the bone marrow from pluripotential hematopoietic stem cells under regulation of the transcription factor GATA-1 and the cytokines interleukin-3 (IL-3), IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF) (Fig. 173-1). Eosinophils are under the regulation of helper type 2 T cells (T_H2) that secrete IL-4, IL-5, and IL-13. Notably, IL-5 is a cytokine that specifically regulates the selective differentiation of eosinophils, their release from bone marrow into the peripheral circulation, and their survival. A humanized anti-IL-5 drug markedly lowers circulating eosinophilia and reduces tissue eosinophilia more modestly. Recent preliminary studies in patients with severe asthma have shown that anti-IL-5 therapy improves asthma control, including exacerbations, and allows steroid reduction. Similarly, anti-IL-5 has a steroid sparing effect in hypereosinophilic syndromes. Humanized anti-IL-5 therapy is currently in clinical testing for a variety of indications, including eosinophilic esophagitis, asthma, and hypereosinophilic syndromes. IL-4 and IL-13 induce eosinophil recruitment and survival, expression of critical adhesion molecules on the endothelium that bind to the β1 and β2 integrins on eosinophils (such as intercellular adhesion molecule 1 [ICAM-1] and vascular cell adhesion molecule 1 [VCAM-1]), and eosinophil-active chemokines such as the eotaxins. The eotaxins are three structurally related eosinophil chemoattractant and activating proteins that signal exclusively through the eosinophil-selective receptor CCR3. In addition to regulating the baseline homing of eosinophils into various tissues, such as the gastrointestinal tract, wherein most eosinophils reside, the eotaxins are induced by T_H2-associated inflammatory triggers (e.g., IL-13) and thereby promote tissue accumulation of eosinophils. Humanized antibodies against the eotaxins and small-molecule inhibitors against CCR3 are promising new approaches for treating eosinophilic disorders that are in clinical development.

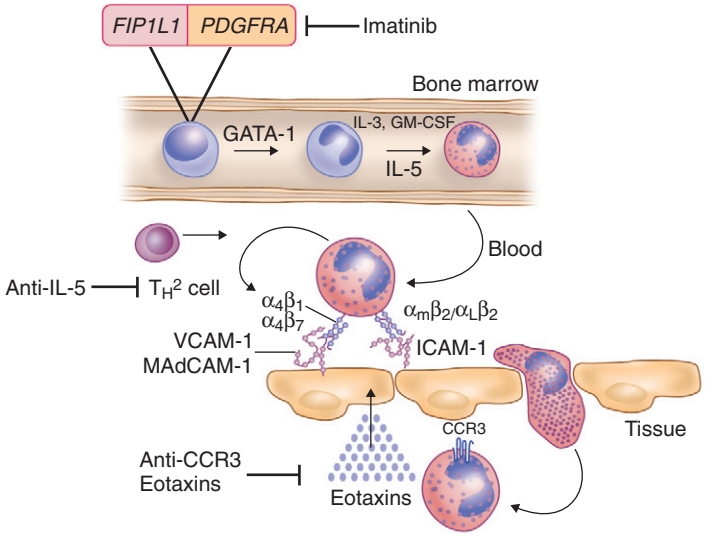

FIGURE 173-1. Schematic representation of eosinophil development, tissue recruitment, and therapeutic intervention. Eosinophil lineage development is specified by the GATA-1 transcription factor and promoted by the cytokines interleukin-3 (IL-3), IL-5, and granulocyte-macrophage colony-stimulating factor (GM-CSF). IL-5 is most selective to the eosinophil lineage and regulates eosinophil movement from the bone marrow into the peripheral blood. Eosinophil adhesion is mediated by β1, β2, and β7 integrins and their interaction with the endothelial adhesion molecules intercellular adhesion molecule 1 (ICAM-1), vascular cell adhesion molecule 1 (VCAM-1), and mucosal address in cell adhesion molecule 1 (MAdCAM-1). Recruitment of eosinophils into tissue is regulated by the eotaxin chemokines that stimulate eosinophilic chemoattraction and activation through their receptor CCR3. Hypereosinophilic syndromes can develop after an 800-kilobase microdeletion on chromosome 4 results in fusion of the *FIP1L1* and *PDGFRA* genes, thereby resulting in activation of an imatinib-sensitive tyrosine kinase. Targeted therapeutic intervention for eosinophilic syndromes includes anti-IL-5 and anti-CCR3/eotaxins, which are currently in clinical development.

Eosinophil granules contain a crystalloid core composed of major basic protein (MBP-1 and MBP-2), as well as a matrix composed of eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and eosinophil peroxidase (EPO). MBP, EPO, and ECP have cytotoxic effects on a variety of tissues in concentrations similar to those found in biologic fluids from patients with eosinophilia. Additionally, ECP and EDN belong to the ribonuclease A superfamily and possess antiviral and ribonuclease activity. ECP can insert voltage-insensitive, ion-nonselective toxic pores into the membranes of target cells, and these pores may facilitate the entry of other toxic molecules. MBP directly increases smooth muscle reactivity by causing dysfunction of vagal muscarinic M_2 receptors, and this process has been postulated to contribute to the airway hyperresponsiveness associated with asthma. MBP also triggers degranulation of mast cells and basophils. Triggering of eosinophils by engagement of receptors for cytokines, immunoglobulins, and complement can lead to the generation of a wide range of inflammatory cytokines, including IL-1, IL-3, IL-4, IL-5, IL-13, GM-CSF, transforming growth factor-α/β, tumor necrosis factor-α, RANTES, macrophage inflammatory protein 1α (MIP-1α), and the eotaxins, thus indicating that eosinophils have the potential to modulate multiple aspects of the immune response. Additionally, eosinophils can directly activate T cells by antigen presentation and help polarize dendritic cells to promote a T_H2 phenotype. Further eosinophil-mediated damage is caused by toxic hydrogen peroxide and halide acids generated by EPO and by superoxide generated by the respiratory burst oxidase enzyme pathway in eosinophils. Eosinophils also generate large amounts of cysteinyl leukotriene C_4 (LTC_4), which is metabolized to LTD_4 and LTE_4. These three lipid mediators increase vascular permeability and mucus secretion and are potent stimulators of smooth muscle contraction. Finally, bipyramidal Charcot-Leyden crystals are derived from a nongranule lysophospholipase in eosinophils and are frequently found in sputum, feces, and tissues infiltrated by eosinophils.

CLINICAL MANIFESTATIONS

Hypereosinophilia is often recognized on a routine blood count in a patient who is asymptomatic or being evaluated for unrelated or nonspecific signs or symptoms. On other occasions, the possibility of eosinophilia may be specifically investigated in a patient with gastrointestinal or respiratory symptoms because helminthic disease or allergic causes are suspected. The clinical signs and symptoms of hypereosinophilic syndromes are heterogeneous because of the diversity of the causes and potential organ involvement. Common signs and symptoms include dermatitis, heart failure, neuropathy, and abdominal pain. One of the most serious complications of hypereosinophilia is cardiac disease secondary to endomyocardial thrombus formation and restrictive fibrosis (Chapter 60). Mitral and tricuspid valve regurgitation may result from progressive fibrotic damage to the chordae tendineae, and resultant heart failure can develop from valvular insufficiency and endomyocardial fibrosis. Cardiac involvement can occur in association with eosinophilia from diverse causes, including parasitic infections. Hypereosinophilic syndromes can result in cerebral emboli from cardiac disease, diffuse encephalopathy, and peripheral neuropathy.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of eosinophilia includes reactive eosinophilia, eosinophilia associated with other primary disorders, and eosinophilia

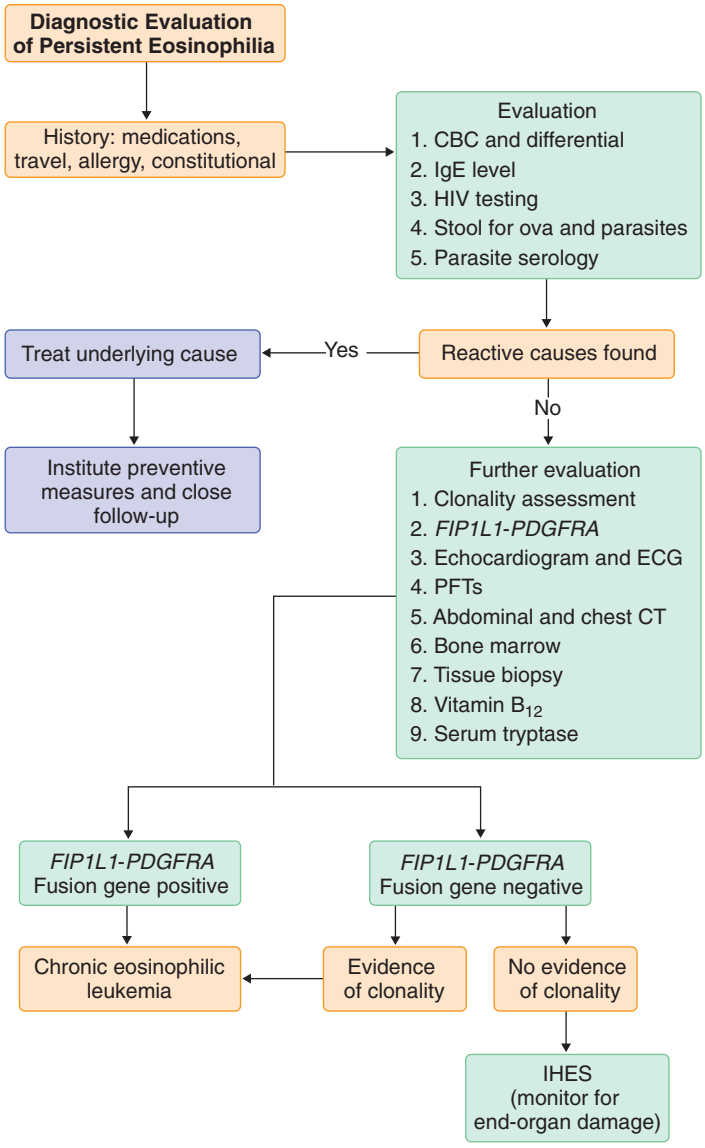

FIGURE 173-2. Diagnostic evaluation of persistent eosinophilia. CBC = complete blood count; CT = computed tomography; ECG = electrocardiogram; IgE = immunoglobulin E; IHES = idiopathic hypereosinophilic syndrome; HIV = human immunodeficiency virus; PDGFRA = platelet-derived growth factor-receptor α; PFTs = pulmonary function tests.

associated with clonal hematopoiesis (see Table 173-1). Evaluation of patients is based on their history and clinical characteristics (Fig. 173-2). The initial goal is to determine whether the eosinophilia is secondary to a reactive cause (i.e., in response to another primary trigger such as allergy, infection, solid tumor, vasculitis). If reactive causes are not identified, further evaluation should determine whether the eosinophilia is secondary to a clonal hematologic disorder. If no evidence of clonality is determined, the patient is considered to have an idiopathic hypereosinophilic syndrome.

The differential diagnosis of eosinophilia requires a review of the patient's history, which may reveal wheezing (Chapter 87), rhinitis (Chapter 259), or eczema (indicating atopic causes); travel to areas where helminth infections (e.g., schistosomiasis [Chapter 363]) are endemic; the presence of a pet dog (indicating possible infection with *Toxocara canis* [Chapter 365]); symptoms of cancer; or drug ingestion (indicating a possible hypersensitivity reaction [Chapter 262]). Eosinophilia caused by drugs (Chapter 262) is usually benign but can sometimes be accompanied by tissue damage, as in hypersensitivity pneumonitis (Chapter 97). In most cases, the eosinophilia resolves when use of the drug ceases, but in some cases, such as eosinophilia-myalgia syndrome secondary to the ingestion of contaminated L-tryptophan, the disease can persist despite withdrawal of the drug.

The presence of abnormal morphologic features of eosinophils, an increase in immature and dysplastic cells in the bone marrow or blood, elevated levels of vitamin B_{12}, and splenomegaly raises suspicion of a clonal hypereosinophilic syndrome. In such cases, evidence of clonality (e.g., by analysis of X chromosome inactivation patterns in female patients), an elevated level of mast cell tryptase (elevated in myelodysplastic variants of hypereosinophilic syndrome), the presence of aberrant lymphocyte phenotypes (elevated in lymphocytic variants of hypereosinophilic syndrome), abnormal cytogenetics, and the possible presence of specific fusion genes such as *FIP1L1-PDGFRA* should be investigated.

Other eosinophilic syndromes such as Churg-Strauss syndrome (Chapter 278) should be considered in patients with a history of worsening asthma, sinus disease, neuropathy, or blood eosinophilia and the presence of abnormal laboratory findings associated with autoimmunity, such as an elevated erythrocyte sedimentation rate, C-reactive protein, and antineutrophil cytoplasmic antibodies.

An accumulation of eosinophils that is limited to specific organs is characteristic of particular diseases, such as eosinophilic cellulitis (Wells' syndrome), eosinophilic esophagitis, eosinophilic pneumonias (e.g., Löffler's syndrome [Chapter 92]), and eosinophilic fasciitis (Shulman's syndrome).

Diagnostic Evaluation

Diagnostic studies that should be performed in patients with moderate to severe eosinophilia and considered in patients with persistent mild eosinophilia include morphologic examination of a blood smear, human immunodeficiency virus (HIV) screen, serial stool examinations for ova and parasites, parasite serology, and plasma immunoglobulin E (IgE) level. Parasitic infections that cause eosinophilia are usually limited to helminthic parasites, with the exception of two enteric protozoans, *Isospora belli* (Chapter 361) and *Dientamoeba fragilis* (Chapter 361). *Strongyloides stercoralis* (Chapter 366) infection is important to diagnose because it can cause disseminated fatal disease in immunosuppressed patients; detection of such infection often requires serologic testing. Other infections to consider include trichinosis (Chapter 366), *T. canis* infection (Chapter 365), and HIV infection (Chapter 400).

Patients with sustained hypereosinophilia should be monitored closely for the subsequent development of cardiac disease. A pathologically similar disease, Löffler's endomyocarditis (Chapter 60), has been noted in tropical regions, where antecedent parasite-elicited eosinophilia may be responsible for the cardiac damage.

TREATMENT Rx

Reactive Hypereosinophilia and Hypereosinophilia Associated with Other Diseases

Treatment of reactive hypereosinophilia and hypereosinophilia associated with other diseases centers around identifying the cause and then treating the underlying disease process. For example, reactive eosinophilia typically responds by removal of the inciting triggers (e.g., allergens, parasites, and medications). Eosinophilia associated with other disease processes typically improves after treatment of the underlying disease, such as dietary manipulation in patients with allergic eosinophilic gastroenteritis.

FIP1L1-PDGFRA-Positive Disease

Imatinib should be considered as first-line therapy in patients in whom the *FIP1L1-PDGFRA* fusion gene has been demonstrated and in selected patients with the characteristic clinical and laboratory features of this myeloproliferative subtype of hypereosinophilic syndrome (e.g., male gender, tissue fibrosis, elevated serum vitamin B_{12} and tryptase levels). Clinical responses to imatinib in *FIP1L1-PDGFRA*-positive patients are rapid, with normalization of eosinophil counts generally occurring within 1 week of initiation of treatment and reversal of the signs and symptoms occurring within 1 month. Doses of imatinib as low as 100 mg daily appear to be effective in controlling symptoms and eosinophilia in most patients, but some recommend beginning imatinib treatment at 400 mg daily to achieve molecular remission and then decreasing the dose slowly while monitoring the patient closely for evidence of molecular relapse. In imatinib-resistant patients, sorafenib may be effective. The utility of imatinib therapy in hypereosinophilic patients without a demonstrable *FIP1L1-PDGFRA* mutation remains controversial, although some patients have responded. Nonmyeloablative allogeneic bone marrow transplantation (Chapter 181) has also been used successfully in several patients with hypereosinophilia.

Other Hypereosinophilic Syndromes

Corticosteroids, which have been used for decades in the treatment of idiopathic hypereosinophilic syndromes, remain the first-line treatment for most patients except those with *PDGFRA*-associated hypereosinophilia. The most appropriate initial corticosteroid dose and the duration of steroid therapy have not been subjected to randomized trials, but a general recommendation is to start with a moderate to high dose (≥40 mg prednisone equivalent) and taper very slowly while monitoring the eosinophil count

closely. With this approach, most patients will respond initially, and some will be able to be maintained on low doses of corticosteroids for prolonged periods.

Monoclonal anti-IL-5 antibody therapy (e.g., mepolizumab or reslizumab) for hypereosinophilia and eosinophil-associated asthma[1,2] has a number of unique advantages related to the specificity of IL-5 for the eosinophil lineage. In patients treated with this agent, eosinophil counts are twice as likely to fall below 600/μL (95% vs. 45%, $P < .001$) with significantly lower prednisone doses.[3] Of the cytotoxic therapies that have been used for steroid-refractory hypereosinophilia, hydroxyurea has been the most extensively studied at doses of 1 to 3 g/day. Vincristine at a dose of 1 to 2 mg intravenously can rapidly lower eosinophilia in patients with extremely high eosinophil counts (>100,000/mm^3) and may be useful for the treatment of children whose aggressive disease is unresponsive to other therapies. In patients who have corticosteroid-refractory hypereosinophilic syndromes or who develop intolerable side effects of steroid treatment, immunomodulatory agents that are sometimes helpful include interferon-α, cyclosporine, and alemtuzumab. Responses can often be achieved with relatively low doses of interferon-α (1 to 2×10^6 U/day) and may persist for prolonged periods. Because the effects of interferon-α on eosinophil numbers in peripheral blood may not become evident for several weeks, escalation to an effective dose may require several months. Rarely, patients have remained in remission for extended periods after cessation of interferon-α therapy, suggesting that interferon-α may be curative in a small subset of individuals. Low-dose (500 mg daily) hydroxyurea appears to act synergistically with interferon-α to lower the eosinophil count without increasing side effects.

FUTURE DIRECTIONS

Treatments on the horizon for hypereosinophilic disorders include targeted therapy against the eotaxin chemokines and their receptor CCR3, as well as anti-IL-5 and anti-IL-5 receptor–based antibody therapy.

PROGNOSIS

The prognosis of hypereosinophilic syndromes depends on the primary cause. Whereas *FIP1L1-PDGFRA*-positive disease and other forms of clonal disorders have a poor prognosis (25 to 50% 5-year mortality rate if responsiveness to therapeutic intervention is not achieved), the prognosis of hypereosinophilia from reactive and other causes is usually better.

APPROACH TO THE PATIENT WITH BLEEDING AND THROMBOSIS

ANDREW I. SCHAFER

MECHANISMS OF HEMOSTASIS AND THROMBOSIS

The coagulation system is normally quiescent, and blood fluidity is maintained by the actions of a continuous monolayer of endothelial cells that line the intimal surface of the vasculature throughout the circulatory tree. At a site of vascular damage, the antithrombotic properties of endothelium are lost, and thrombogenic constituents of the subendothelial vessel wall become exposed to circulating blood. The result is rapid formation of a hemostatic clot that consists of platelets and fibrin and is localized to the area of vascular injury. Activation of platelets and formation of fibrin occur essentially simultaneously and interdependently to effect hemostasis. Subsequently, vascular repair is accomplished by thrombolysis and recanalization of the occluded site.

Platelet activation at a site of vascular injury begins with the adhesion of platelets to the locally de-endothelialized intimal surface (platelet–vessel wall interaction). Platelet adhesion is mediated by von Willebrand factor, which sticks circulating platelets to the area of damaged vessel wall by binding to its receptors located in platelet membrane glycoprotein Ib. The adherent platelets then undergo a "release reaction," during which they discharge constituents of their storage granules, including adenosine diphosphate (ADP), and simultaneously elaborate thromboxane A_2 from arachidonic acid through the aspirin-inhibitable cyclooxygenase reaction. ADP, thromboxane A_2, and other components of the release reaction act in concert to recruit and activate additional platelets from the circulation to the site of vascular injury. These activated platelets expose binding sites for fibrinogen by forming the surface membrane glycoprotein IIb/IIIa complex. In the process of platelet aggregation (platelet-platelet interactions), fibrinogen (or von Willebrand factor under conditions of high shear stress) mediates the final formation of an occlusive platelet plug.

Fibrin, which anchors the hemostatic platelet plug, is formed from soluble plasma fibrinogen by the action of the potent protease enzyme thrombin (Fig. 174-1). The fibrin mesh is stabilized by covalent cross-linking mediated by factor XIII. Thrombin is formed from its inactive (zymogen) plasma precursor, prothrombin, by the action of activated factor X (Xa) and its cofactor, factor Va. This sequence of reactions has classically been referred to as the *common pathway* of coagulation. Factor X can be activated by either the *tissue factor (extrinsic) pathway* or the *contact activation (intrinsic) pathway* of coagulation. The tissue factor pathway is now considered to be the major physiologic initiator of coagulation activation. It is triggered by the formation of the complex of tissue factor, which is exposed on the surfaces of activated vascular and blood cells, with activated factor VII (VIIa). The contact activation pathway involves a series (or cascade) of zymogen-protease reactions that are initiated by factor XII, high-molecular-weight kininogen, and prekallikrein. Activated factor XII (XIIa) converts factor XI to XIa, which in turn activates factor IX to IXa. Factor IXa is the enzyme that converts factor X to Xa, a reaction that requires factor VIIIa as a cofactor.

Intact, normal endothelium promotes blood fluidity by inhibiting platelet activation. It likewise plays a crucial role in preventing fibrin accumulation. Among the physiologic antithrombotic systems that produce this latter effect are (1) antithrombin III, (2) protein C and protein S, (3) tissue factor pathway inhibitor (TFPI), and (4) the fibrinolytic system. Antithrombin is the major protease inhibitor of the coagulation system: it inactivates thrombin and other activated coagulation factors. Heparin functions as an anticoagulant by binding to antithrombin and greatly accelerating these reactions. Heparin and heparin sulfate proteoglycans are naturally present on endothelial cells, so antithrombin inactivation of thrombin and other coagulation proteases most likely occurs physiologically on vascular surfaces rather than in fluid plasma. Activated protein C, with its cofactor protein S, functions as a natural anticoagulant by destroying factors Va and VIIIa, two essential cofactors of the coagulation cascade. Thrombin itself is the activator of

protein C, and this reaction occurs rapidly only on the surfaces of intact vascular endothelial cells, where thrombin binds to the glycosaminoglycan thrombomodulin. TFPI is a plasma protease inhibitor that specifically quenches tissue factor–induced coagulation. Finally, what little fibrin can be produced, despite these potent physiologic antithrombotic mechanisms, is digested rapidly by the endogenous fibrinolytic system. Fibrinolysis is mediated by the protease plasmin, which is generated from plasminogen in plasma by the action of endothelium-derived plasminogen activators.

EVALUATION OF THE PATIENT WITH A POSSIBLE BLEEDING DISORDER

History and Physical Examination

A thorough history is paramount in evaluating a patient for a possible systemic bleeding disorder. In addition to asking the patient about spontaneous bleeding episodes in the past, responses to specific hemostatic challenges should be recorded. A bleeding tendency may be suspected if a patient previously experienced excessive hemorrhage after surgery or trauma, including common events such as circumcision, tonsillectomy, labor and delivery, menses, dental procedures, vaccinations, and injections. Conversely, a history of normal blood clotting after such specific challenges in the recent past is just as important to note. It may be a better test of the integrity of systemic hemostasis than any laboratory measurement can provide.

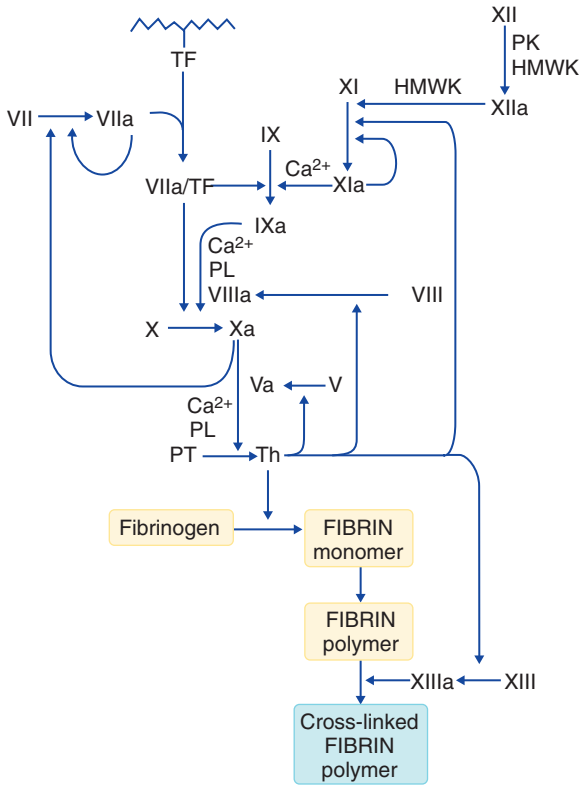

FIGURE 174-1. Coagulation cascade. This scheme emphasizes an understanding of (1) the importance of the tissue factor pathway in initiating clotting in vivo, (2) the interactions among pathways, and (3) the pivotal role of thrombin in sustaining the cascade by feedback activation of coagulation factors. HMWK = high-molecular-weight kininogen; PK = prekallikrein; PL = phospholipid; PT = prothrombin; TF = tissue factor; Th = thrombin. (From Schafer AI. Coagulation cascade: an overview. In: Loscalzo J, Schafer AI, eds. *Thrombosis and Hemorrhage.* Cambridge, MA: Blackwell Scientific Publications; 1994:3-12.)

In a patient with a history of excessive or unexplained bleeding, the initial goal is to determine whether the cause is a systemic coagulopathy or an anatomic or mechanical problem with a blood vessel. This situation is encountered most frequently in patients with excessive postoperative bleeding, which could be due to either local surgical trauma or a coagulation abnormality. A history of prior bleeding suggests a coagulopathy, as does the finding of bleeding from multiple sites. However, this is not always the case. Even diffuse bleeding may arise from anatomic rather than hemostatic abnormalities. An example of this is recurrent mucosal hemorrhage in patients with hereditary hemorrhagic telangiectasia. Conversely, a single episode of bleeding from an isolated site may be the initial manifestation of a coagulopathy.

The history must include a survey of coexisting systemic diseases and drug ingestions that could affect hemostasis. Renal failure and the myeloproliferative disorders are associated with impaired platelet–vessel wall interactions and qualitative platelet abnormalities, connective tissue diseases and lymphomas are associated with thrombocytopenia, and liver disease causes a complex coagulopathy (Chapter 178). Ingestion of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) that cause nonselective inhibition of cyclooxygenase leads to platelet dysfunction; these drugs are often contained in over-the-counter preparations that patients may neglect to report without specific questioning. Other drugs, such as antibiotics, also may be associated with a bleeding tendency by causing abnormal platelet function or thrombocytopenia. Finally, it is important to elicit a family history of bleeding problems. Although a positive history provides an important clue to a possible inherited coagulopathy, a negative history does not exclude a familial cause; for example, 20% of patients with classic hemophilia have a completely negative family history of bleeding.

Patterns of clinical bleeding, as revealed by the history and physical examination, may be characteristic of certain types of coagulopathy (Table 174-1). In general, patients with thrombocytopenia or qualitative platelet or vascular disorders present with bleeding from superficial sites in the skin and mucous membranes. These may involve petechiae, which are pinpoint cutaneous hemorrhages that appear particularly over dependent extremities (characteristic of severe thrombocytopenia), ecchymoses (common bruises), purpura, gastrointestinal and genitourinary tract bleeding, epistaxis, and hemoptysis. In these types of disorders, bleeding tends to occur spontaneously or immediately after trauma. In contrast, patients with inherited or acquired coagulation factor deficiencies, such as hemophilia, or those on anticoagulant therapy tend to bleed from deeper tissue sites (e.g., hemarthroses, deep hematomas, retroperitoneal hemorrhage) and in a delayed manner after trauma.

Laboratory Testing

Four simple screening tests have traditionally been used in the initial evaluation of patients with a suspected coagulopathy: platelet count, bleeding time, prothrombin time (PT), and activated partial thromboplastin time (aPTT). Thrombocytopenia, reported by electronic particle counting, should be verified by examination of the peripheral smear. Pseudothrombocytopenia, a laboratory artifact of ex vivo platelet clumping, may be caused by the ethylenediaminetetraacetic acid (EDTA) anticoagulant used in tubes for blood cell counts, by other anticoagulants, or by nonphysiologic cold agglutinins acting at room temperature. It should be suspected whenever a very low platelet count is unexpectedly reported in a patient who does not exhibit any clinical bleeding. Pseudothrombocytopenia is indicated by the finding of platelet clumps on the peripheral smear, and the diagnosis is supported by the finding of simultaneously normal platelet counts in blood samples obtained by finger stick, in tubes containing other anticoagulants, or in a tube maintained at 37° C before platelet counting. Examination of the blood smear

TABLE 174-1 CHARACTERISTIC PATTERNS OF BLEEDING IN SYSTEMIC DISORDERS OF HEMOSTASIS

TYPE OF DISORDER	*Sites of Bleeding*				ONSET OF BLEEDING	CLINICAL EXAMPLES
	GENERAL	SKIN	MUCOUS MEMBRANES	OTHER		
Platelet-vascular disorders	Superficial surfaces	Petechiae, ecchymoses	Common: oral, nasal, gastrointestinal, genitourinary	Rare	Spontaneous or immediately after trauma	Thrombocytopenia, functional platelet disorder, vascular fragility, disseminated intravascular coagulation, liver disease
Coagulation factor deficiency	Deep tissues	Hematomas	Rare	Common: joint, muscle, retroperitoneal	Delayed after trauma	Inherited coagulation factor deficiency, acquired inhibitor, anticoagulation, disseminated intravascular coagulation, liver disease

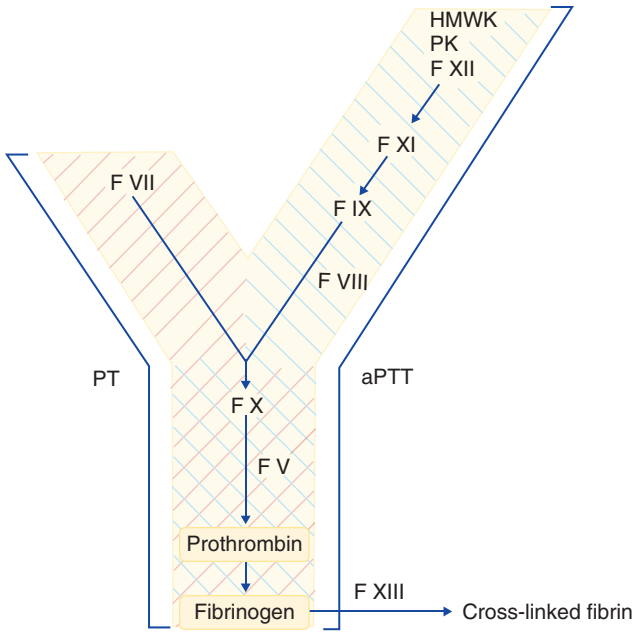

FIGURE 174-2. Classic coagulation cascade. The prothrombin time (PT) measures the integrity of the extrinsic and common pathways, whereas the activated partial thromboplastin time (aPTT) measures the integrity of the intrinsic and common pathways. Factor (F) XIII deficiency is not detected by PT or aPTT. HMWK = high-molecular-weight kininogen; PK = prekallikrein.

can also reveal clues to the cause of real thrombocytopenia, such as fragmented red blood cells in thrombotic thrombocytopenic purpura.

The bleeding time is a widely used clinical screening test for disorders of platelet–vessel wall interactions. It measures the time to cessation of bleeding after a standardized incision over the volar aspect of the forearm, now most commonly performed by disposable automated devices. The bleeding time is prolonged in thrombocytopenia, qualitative platelet abnormalities, defects in platelet–vessel wall interactions (e.g., von Willebrand disease), and primary vascular disorders. The bleeding time usually is not prolonged in patients with coagulation factor deficiencies. The test is prone to problems related to reproducibility, sensitivity, and specificity, however. Therefore, because von Willebrand disease is the most common genetic cause of abnormal platelet–vessel wall interactions, some experts now recommend replacing the bleeding time with specific tests for von Willebrand disease in the initial evaluation of patients with a suspected coagulopathy (Chapter 176).

The PT measures the integrity of the extrinsic and common pathways of coagulation (factors VII, X, and V; prothrombin; and fibrinogen) (Fig. 174-2). The aPTT measures the integrity of the intrinsic and common pathways of coagulation (high-molecular-weight kininogen; prekallikrein; factors XII, XI, IX, VIII, X, and V; prothrombin; and fibrinogen). The sensitivity of the PT and aPTT in detecting coagulation factor deficiencies may vary with the reagents used to perform these tests, and each laboratory must determine its own reference standards.

With a few notable exceptions, normal results for all these screening tests of hemostasis essentially exclude any clinically significant systemic coagulopathy. However, patients with factor XIII deficiency may have a serious bleeding diathesis but normal screening tests; specific tests for factor XIII deficiency should be performed if this disease is suspected. The PT and aPTT detect only the more severe deficiencies of coagulation factors, usually at levels less than 30% of normal; specific factor levels should be determined if a mild coagulation factor deficiency is suspected. Patients with von Willebrand disease sometimes have normal bleeding times and usually do not have sufficiently reduced levels of factor VIII to affect the aPTT, requiring specific testing for the disease. Rare disorders of fibrinolysis also may be associated with normal screening tests, necessitating more specialized tests when indicated. Abnormalities in the screening tests of hemostasis may be pursued by more specialized tests to establish a specific diagnosis.

The initial approach to a prolonged bleeding time in the absence of thrombocytopenia is to determine whether the patient is taking any drugs that might interfere with platelet function (e.g., aspirin, other NSAIDs) or has a coexisting disease that might explain the finding (e.g., renal failure). If these conditions are absent or if the bleeding time fails to correct after discontinuation of any potentially offending drugs, further specialized testing may include platelet aggregation studies to identify specific qualitative abnormalities of platelet function and specific assays to exclude one of the types of von Willebrand disease.

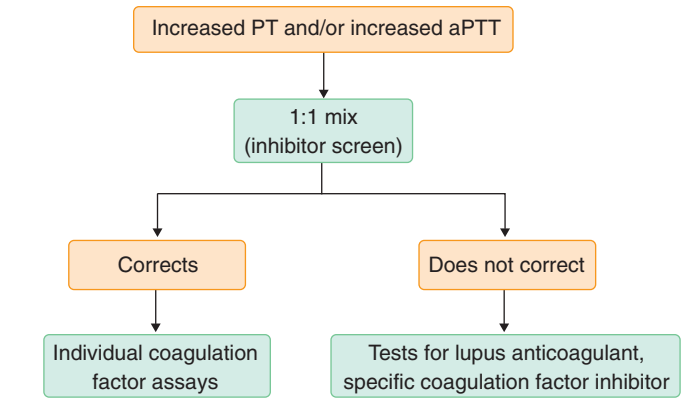

FIGURE 174-3. Approach to evaluating patients with prolonged prothrombin time (PT) or activated partial thromboplastin time (aPTT).

The finding of a prolonged PT and/or aPTT indicates either a deficiency of one or more coagulation factors or the presence of an inhibitor, usually an antibody, directed at one or more components of the coagulation system (Fig. 174-3). These two possibilities can be distinguished by performing a simple inhibitor screen, which involves a 1 : 1 mix of the patient's plasma and normal plasma. The premise of the test is that even if the patient's plasma is completely deficient (0% level) in a certain factor, mixing it 1 : 1 with normal plasma (100% level) should bring the concentration of that factor to 50% in the mixture; this is sufficient to correct the prolonged PT or aPTT. If correction occurs with the inhibitor screen, individual coagulation factor levels should be assayed for a specific deficiency state. If the 1 : 1 mix fails to correct the prolonged PT and/or aPTT, an inhibitor is likely to be present, and it is interfering with coagulation in vitro in both the patient's plasma and the normal plasma. Specific assays should then be performed to determine whether there is a true inhibitor against a coagulation factor (e.g., factor VIII antibody) or whether the inhibitor is a lupus anticoagulant.

EVALUATION OF THE ASYMPTOMATIC PATIENT WITH ABNORMAL COAGULATION TESTS

In asymptomatic individuals who are discovered incidentally to have abnormalities in screening laboratory tests of hemostasis, the first critical question is whether the findings are clinically relevant. Patients with inherited deficiencies of one of the contact activation coagulation factors (factor XII, high-molecular-weight kininogen, prekallikrein) characteristically have a markedly prolonged aPTT, yet they do not have a clinical bleeding tendency. Likewise, patients with lupus anticoagulants typically have prolongation of the aPTT and sometimes also the PT; they more often have thrombotic rather than bleeding complications. In patients with heparin-induced thrombocytopenia, a marked decrease in the platelet count is sometimes associated with arterial and venous thrombosis rather than bleeding. It is crucial to view the clinical setting, history, physical examination, and screening laboratory tests as complementary facets of the approach to patients with suspected coagulopathies.

EVALUATION OF THE PREOPERATIVE PATIENT

Routine screening of all preoperative patients with a platelet count, bleeding time, PT, and aPTT not only is uninformative but also may be counterproductive if follow-up testing causes unnecessary expense and delays in surgery (Chapter 439). Preoperative bleeding time, PT, and aPTT do not predict surgical bleeding risk in patients who are not found to be at increased risk on clinical grounds, so a thorough clinical assessment should guide the need for these preoperative screening tests. Laboratory testing and possibly further specialized tests of coagulation are indicated for patients whose bleeding histories are suspicious for a hemostatic abnormality. Preoperative screening tests of coagulation are probably warranted for patients who cannot cooperate with an adequate clinical assessment and for those who will be undergoing procedures in which even minimal postoperative hemorrhage could be hazardous.

EVALUATION OF THE PATIENT WITH A POSSIBLE HYPERCOAGULABLE STATE

Most patients with venous thromboembolism (VTE) have an inherited basis for hypercoagulability (Chapter 179). Patients with inherited hypercoagulable states (or thrombophilia) typically present with an initial episode of VTE in early adulthood, but thrombotic manifestations may begin at any time from early childhood to old age. Patients usually have deep vein thrombosis of the lower extremities or pulmonary embolism, but other uncommon sites of venous thrombosis may be involved. Arterial thrombosis is not characteristically associated with inherited hypercoagulable states. Arterial thrombosis that occurs prematurely or in the absence of apparent risk factors should trigger a different line of investigation, possibly including evaluation for vasculitis, myeloproliferative disorders, hyperhomocysteinemia, antiphospholipid syndrome, and potential sources of systemic embolization.

The primary or hereditary hypercoagulable states (see Table 179-1 in Chapter 179) result from specific mutations or polymorphisms that lead to decreased levels of physiologic antithrombotic proteins or increased levels of procoagulant proteins. In contrast, the secondary or acquired hypercoagulable states (see Fig. 179-2 in Chapter 179) are a heterogeneous group of disorders that predispose to thrombosis by complex mechanisms. VTE is often precipitated by the combination of an underlying hypercoagulable genotype and an acquired prothrombotic, hypercoagulable state such as pregnancy, immobilization, or the postoperative state. Certain clinical characteristics suggest the presence of an inherited hypercoagulable state (Table 174-2). Patients with recurrent thrombosis should be tested for these disorders and, in most cases, committed to lifelong prophylactic anticoagulation. It is not clear whether it is essential to order these tests after a single episode of VTE. Counterintuitively, it has been found that most of the common inherited hypercoagulable states—which, to varying extents, clearly increase the risk of a *first* episode of VTE—are at best only weak predictors of *recurrent* VTE. It has been argued, therefore, that making a specific thrombophilia diagnosis after an initial episode of VTE will not influence the decision about the duration of prophylactic anticoagulation. However, the increased risk of recurrent VTE with the more prothrombotic mutations (e.g., antithrombin III, protein C or S deficiency), combined inherited thrombophilias, or antiphospholipid syndrome may necessitate long-term anticoagulation, and their diagnosis after a first episode of VTE will in fact alter decisions about the duration of anticoagulation. Even if they are not maintained on long-term anticoagulation, patients with diagnosed primary hypercoagulable states should receive prophylactic anticoagulation during situations that pose a high risk for thrombosis, such as the peripartum period. There is no simple screening test for primary hypercoagulable states, and the timing of obtaining these tests is crucial to avoid erroneous diagnoses. Acute thrombosis itself can cause transient decreases in the levels of antithrombin, protein C, and protein S. Heparin therapy can cause a decrease in plasma antithrombin activity. Warfarin therapy lowers the functional levels of protein C and protein S. Inherited deficiency states can be diagnosed spuriously under these conditions.

Patients who present with VTE probably have an increased risk of harboring an occult malignancy (Chapter 187). This association is increased further in patients with recurrent and unprovoked thrombosis. There are conflicting opinions whether an evaluation for occult malignancy in these patients must be exhaustive. Some contend it can be limited to a thorough history, physical examination, routine complete blood cell count and chemistries, test of fecal occult blood, urinalysis, mammogram (in women), and chest radiograph, with further testing guided by any abnormalities found in this initial evaluation. Others argue for routine CT scanning of the chest, abdomen, and pelvis.

In addition to classic deep vein thrombosis and pulmonary embolism, certain characteristic types of thrombosis may provide important clues to the cause and trigger a more directed evaluation. Migratory, superficial thrombophlebitis (Trousseau's syndrome) or nonbacterial thrombotic endocarditis suggests the presence of an occult malignancy (Chapter 187). Hepatic vein thrombosis (Budd-Chiari syndrome; Chapter 145) or portal vein thrombosis may indicate a myeloproliferative disorder (Chapter 169) or paroxysmal nocturnal hemoglobinuria (Chapter 163). Warfarin-induced skin necrosis strongly suggests an underlying protein C or protein S deficiency. Recurrent, spontaneous miscarriages are characteristic of the antiphospholipid syndrome (Chapter 177), although they are also associated with other thrombophilias.

TABLE 174-2 CLINICAL CHARACTERISTICS OF PATIENTS WITH INHERITED HYPERCOAGULABLE STATES (THROMBOPHILIA)

Venous thromboembolism (>90% of cases)
Deep vein thrombosis and/or pulmonary embolism most common
Mesenteric, cerebral vein thrombosis rare but characteristic
Frequent family history of thrombosis
Typically autosomal dominant
First episode of thrombosis typically in young adulthood (<40 yr)
Often idiopathic (but an acquired thrombosis trigger is not infrequently identified with a careful history)
More common thrombophilias (factor V Leiden, prothrombin 20210G→A) are associated with a lower thrombosis risk; rarer thrombophilias (antithrombin III, protein C, protein S deficiency) are associated with a higher thrombosis risk
Warfarin-induced skin necrosis or neonatal purpura fulminans with protein C or protein S deficiency (very rare)

THROMBOCYTOPENIA

CHARLES S. ABRAMS

Thrombocytopenia is defined as a platelet count less than the normal range, typically below 150,000/μL. In the absence of qualitative platelet defects (Chapter 176), excessive bleeding does not occur in thrombocytopenic patients following trauma or surgery unless the platelet count is lower than 75,000/μL. In otherwise hemostatically normal patients, spontaneous hemorrhage typically does not occur with platelet counts above 30,000/μL. Patients with platelet counts less than 5000 to 10,000/μL are at high risk for spontaneous, life-threatening hemorrhage. However, there is no absolute threshold for spontaneous bleeding due to thrombocytopenia. It may occur at higher counts when fever, sepsis, severe anemia, and other hemostatic defects are present or when platelet function is impaired by medication. Notably, a prolonged cutaneous bleeding time test does not accurately predict the risk of clinical bleeding. Therefore, it is critical that the physician consider the gamut of possibilities when diagnosing and managing a patient with a low platelet count.

Typically, the first step in diagnosing a patient with a low platelet count is to determine whether the thrombocytopenia is attributable to one of the three broad mechanisms for developing thrombocytopenia: (1) increased destruction, such as that seen in immune-mediated causes; (2) decreased production, usually due to an underlying bone marrow disorder; or (3) sequestration of platelets within the spleen, as occurs in conditions that cause splenomegaly (hypersplenism).

Determining the cause of the patient's thrombocytopenia is essential to select the most appropriate therapy and to avoid unnecessary procedures. Because there is no easy test to differentiate among the three possibilities, clinical evaluation is critical. Therefore, a thorough history and physical examination, with attention to possible alternative explanations for thrombocytopenia, are mandatory. Particular attention should be paid to the duration of symptoms, which helps determine whether the patient has acute or chronic thrombocytopenia. Attention should also focus on the patient's recent exposure to new medications that might induce thrombocytopenia as a side effect.

Preliminary laboratory tests include a complete blood count (CBC) with a differential, along with an examination of the peripheral blood smear.

Abnormalities in the number or morphology of the leukocytes or erythrocytes may indicate a systemic inflammatory disorder or pathology within the bone marrow. Clumping of the platelets on the peripheral blood smear may indicate that the patient has pseudothrombocytopenia (Chapter 174). This anomaly is usually due to an antibody that binds to and thereby agglutinates platelets only in the presence of ethylenediaminetetraacetic acid (EDTA) or when the blood sample is allowed to cool to room temperature. Repeating the platelet count in a blood sample that has been anticoagulated with heparin and kept warm until it is analyzed can help exclude this spurious diagnosis. Any additional testing is based solely on the available clinical information; for example, human immunodeficiency virus (HIV) testing would be prudent in a patient with risk factors. A bone marrow aspirate and biopsy are typically not required for a patient with thrombocytopenia who has an otherwise normal CBC and peripheral blood smear count. However, a bone marrow aspirate and biopsy should be considered in older patients or in patients in whom standard therapy has not been effective.

GENERAL MECHANISMS OF THROMBOCYTOPENIAS

Increased Platelet Destruction

An acute drop in a patient's platelet count implies that a peripheral destructive process is the likely cause. For example, a patient who develops abrupt thrombocytopenia during hospitalization most likely has a low platelet count caused by an infection or a new medication. Both nonimmune and immune processes can lead to a shortened platelet lifespan. Nonimmune reasons for the accelerated destruction of platelets include sepsis, disseminated intravascular coagulation (DIC), thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), preeclampsia or eclampsia, cardiopulmonary bypass, and giant cavernous hemangioma. Thrombocytopenia that occurs in these circumstances usually resolves with treatment of the underlying disorder, and platelet transfusions are rarely necessary. Thrombocytopenia due to TTP, HUS, or heparin-induced thrombocytopenia (HIT) is associated with thrombosis rather than bleeding (Table 175-1), so platelet transfusions are rarely necessary. In addition, controversial reports have noted the clinical deterioration of patients with TTP or HIT following platelet transfusion, suggesting that platelets should not be given to most patients with these disorders.

Immune-mediated platelet destruction can occur owing to drugs, alloimmune sensitization, or autoimmunity. Medications should always be considered as a possible cause of acute thrombocytopenia. The list of potential offending agents is long, but drugs with strong evidence of antibody-mediated platelet destruction include quinine, quinidine, sulfonamides, and gold salts. In addition to stopping the offending medication, platelet transfusions might be required for severe thrombocytopenia.

Platelet Sequestration

Approximately 30% of the circulating platelet mass is normally sequestered within the spleen. Even more platelets may be sequestered when the spleen enlarges owing to portal hypertension or infiltrative diseases. This in turn can result in moderate thrombocytopenia. Because hypersplenism never causes a platelet count less than 40,000 to 50,000/μL, bleeding due to thrombocytopenia from hypersplenism alone is unusual.

Decreased Platelet Production

Decreased platelet production occurs in primary diseases of the bone marrow, such as acute leukemia and aplastic anemia; myelophthisic processes in which marrow is affected by metastatic carcinoma, fibrosis, or other clonal hematopoietic disorders; following chemotherapy and/or radiation therapy; with ethanol toxicity; and during infections with viruses such as HIV, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and varicella. Thrombocytopenia also occurs when normal megakaryocyte proliferation is impaired by myelodysplasia.

TABLE 175-1 DISORDERS THAT CAUSE BOTH THROMBOCYTOPENIA AND THROMBOSIS

Thrombotic thrombocytopenic purpura (TTP)
Hemolytic-uremic syndrome (HUS)
Heparin-induced thrombocytopenia (HIT)
Disseminated intravascular coagulation (DIC)
Paroxysmal nocturnal hemoglobinuria (PNH)
Vasculitis (such as systemic lupus erythematosus)
Antiphospholipid antibody syndrome (APS)

PLATELET TRANSFUSIONS

Clinicians usually consider "wet" bleeding to be much more ominous than "dry" bleeding. Signs of wet bleeding include epistaxis, gingival bleeding, gastrointestinal or genitourinary bleeding, or bleeding around intravenous sites. Dry bleeding is defined as ecchymosis or petechiae. Overt wet bleeding that is clearly due to thrombocytopenia is usually treated with platelet transfusion. Prophylactic platelet transfusion for patients who are not bleeding is controversial. When making the decision whether to treat a nonbleeding patient with thrombocytopenia, the practitioner must consider the short lifespan of platelets (10 days), the 5-day shelf life of stored platelets, and the potential for the patient to develop transfusion-induced platelet alloantibodies. In patients undergoing treatment for acute leukemia, the outcome is unchanged when a platelet count as low as 5000 to 10,000/μL is used as the threshold for prophylactic platelet transfusion. In contrast, a higher platelet count is required when patients are bleeding or undergoing an invasive procedure or surgery. For patients experiencing the most extreme hemostatic challenges (e.g., neurosurgery, cardiopulmonary bypass, thyroid surgery, prostatectomy), a platelet count greater than 75,000 to 100,000/μL for the procedure and for the next several days is advisable. For minor invasive procedures, such as colonoscopy with biopsy, a platelet count of 30,000 to 50,000/μL is usually adequate.

A donated unit of blood contains approximately 50 billion platelets. Infusing this number of platelets into a patient should increase his or her platelet count by 20,000/μL divided by the patient's surface area in square meters. Therefore, transfusion into a typical patient should increase the recipient's platelet count by 10,000 to 12,000/μL. Bags of platelets used for transfusions are typically obtained by pooling platelets derived from four to eight blood donors. Therefore, a "unit" at one hospital may be derived from more donors than a "unit" obtained at another hospital.

Large quantities of platelets can be derived from a single donor by using apheresis technology (plateletpheresis). Because there is minimal loss of red blood cells with this technique, plateletpheresis allows one individual to donate very large numbers of platelets (equivalent to the number of platelets obtained from 6 to 10 units of donated blood). As discussed in the following section, the risk of platelet alloimmunization is partially dependent on the number of individuals donating platelets to a patient. Therefore, single-donor plateletpheresis platelets can prevent or at least minimize alloimmunization.

Several trials have addressed how many platelets should be transfused into thrombocytopenic patients to maintain hemostasis and minimize exposure to blood products. The largest of these trials was the multicenter Platelet Dose (PLADO) trial.[1] In this study, patients were randomized to receive transfusions of low-dose (110 billion), medium-dose (220 billion), or high-dose (440 billion) platelets per square meter for thrombocytopenia while recovering from hematopoietic stem cell transplantation. Patients who received the low-dose therapy required more frequent platelet transfusions, but overall, they received fewer transfused platelets over the course of the study. Importantly, bleeding complications were identical with all platelet transfusion strategies. This study demonstrates that low doses of platelets (110 billion/square meter of body surface area) are as safe as larger doses in patients with hypoproliferative thrombocytopenia receiving prophylactic platelet transfusion therapy.

Several complications of platelet transfusion therapy merit mention. First, some patients can become alloimmunized against platelet antigens and can become refractory to future platelet transfusion therapy (discussed in detail later). Second, bacterial contamination of stored platelets is a much more common complication than the infectious risk associated with red blood cell transfusions. Unlike red blood cells, which are stored frozen after being harvested from donated blood, platelets are sensitive to cool temperatures and therefore need to be stored at room temperature. This method of storage results in more bacterial overgrowth in the transfusion bags. Transfusion-associated bacterial sepsis is one of the most frequently reported causes of transfusion-induced mortality in the United States, and platelet transfusions are the most common blood products associated with sepsis. It should also be noted that room temperature storage of platelets contributes to their short shelf life of approximately 5 to 7 days. Consequently, unlike the blood-derived products that can be frozen (such as red blood cells and plasma), there is a constant need for platelet donations year-round. In contrast to the risk of bacterial infection, the risk of viral infection from platelet transfusions is no

higher than it is for red blood cell transfusions. From a single unit of platelets, the risk of being exposed to HIV is less than 1 in 2.5 million, the risk of exposure to hepatitis B virus is less than 1 in 750,000, and the risk of exposure to hepatitis C virus is less than 1 in 1 million.

Platelet transfusions have been considered contraindicated for thrombocytopenia owing to TTP or HIT. This recommendation is driven entirely by case reports of thrombotic events occurring soon after platelet transfusions in such patients, not by randomized trials addressing this issue. Because thrombotic events are a known complication of both TTP and HIT, it is difficult to determine whether the thrombi were due to the platelet transfusions or merely the intrinsic prothrombotic risk of TTP and HIT. In any case, there is usually no indication for platelet transfusions in patients with TTP and HIT because thrombosis is a much greater risk than hemorrhage in these disorders.

The Transfusion-Refractory Patient

Many patients do not have an optimal increase in the platelet count following transfusion. Although there are various definitions of platelet refractoriness, it is simplest to base this definition on the timing of platelet loss following transfusion. A patient who does not have the predicted rise in platelet count (between 10,000 and 12,000/μL for every unit of donated platelets) should have the platelet count analyzed before the next platelet transfusion, 1 hour after that transfusion, and again 24 hours later. If the platelet count rises appropriately 1 hour after the transfusion but falls substantially 24 hours later, the patient has ongoing platelet consumption. This is often seen in patients with sepsis, DIC, or severe active hemorrhage or as a result of the drug-mediated immune destruction of platelets. In these situations, the best therapy is to treat the underlying cause and to continue to support the patient with platelet transfusions as clinically indicated. Alternatively, some patients fail to have a significant increase in platelets even 1 hour after a transfusion. These patients have (1) hypersplenism, (2) an autoantibody that eliminates not only endogenous platelets but also allogeneic platelets (as in patients with idiopathic thrombocytopenic purpura [ITP]), or (3) alloantibodies that react with antigens on the transfused platelets.

Alloantibodies develop in approximately 20% of patients who are repeatedly exposed to platelet transfusions, and these patients present some of the most challenging management issues in transfusion medicine (Chapter 180). The alloantibodies may be directed against human leukocyte antigen (HLA) class I antigens (HLA-A and HLA-B) or against platelet-specific antigens present on the surface of the platelets. Because it appears that HLA class II antigens present on the surface of leukocytes are essential for the development of antibodies directed against HLA class I antigens, efforts to remove the contamination of leukocytes in platelet transfusion preparations can minimize alloantibody formation. Therefore, the use of filters that trap leukocytes during transfusions are useful to prevent patients from becoming refractory to future platelet transfusions. Once a patient develops alloantibodies against transfused platelets, the clinician and the blood bank should attempt to identify whether the alloantibody is directed against an HLA or against a platelet-specific antigen. If the alloantibody can be identified, platelets derived from donors matched for HLA or the platelet-specific antigen can be used. Corticosteroids, intravenous immunoglobulin, splenectomy, and recombinant factor VIIa are probably of no value in maintaining hemostasis in platelet-refractory patients. Antifibrinolytic agents (e.g., ε-aminocaproic acid) might be helpful for patients with bleeding predominantly in the oral cavity or the genitourinary tract. However, antifibrinolytic agents are contraindicated in patients with DIC (Chapter 178) because these agents can precipitate thrombotic events.

SPECIFIC CAUSES OF THROMBOCYTOPENIA

Drug-Induced Thrombocytopenia

The abrupt onset of thrombocytopenia implies a high probability of the immune-mediated destruction of platelets. This is particularly likely if the thrombocytopenia is present in the absence of other abnormalities on the CBC. The clinician should first suspect either an infection (viral or bacterial) or a drug. A careful history and physical examination, along with a normal leukocyte count and differential, should help exclude an infectious cause of thrombocytopenia. Drug-induced thrombocytopenia is one of the most frequent causes of cytopenias evaluated by physicians.

The typical drug-induced thrombocytopenia is the result of an immune reaction elicited by either the drug or one of its metabolites. Sometimes the drug is simply deposited on the platelet surface, and antidrug antibodies lead to accelerated platelet clearance, primarily in the spleen. More frequently, the drug binds to a protein on the platelet surface and induces a neoantigen that is ultimately recognized by the immune system. In the absence of the drug or drug metabolites, this platelet neoantigen disappears, and the thrombocytopenia slowly resolves as new platelets are released from the bone marrow. This mechanism explains the vast majority of drug-induced thrombocytopenias, but there are some exceptions. For example, chemotherapy and other bone marrow toxins can decrease platelet production and thereby induce thrombocytopenia by a mechanism independent of the immune system.

Patients with drug-induced thrombocytopenia can have mild, moderate, or even severe forms. Almost all types of drug-induced thrombocytopenia predispose the patient to hemorrhagic but not thrombotic complications. The notable exception to this rule is HIT (discussed separately in the next section). The most difficult diagnostic dilemma is to discern drug-induced thrombocytopenia from ITP. For this distinction, the patient's medical history may be helpful. A gradually progressive thrombocytopenia is more consistent with ITP than with one induced by a medication. Conversely, the rapid onset of thrombocytopenia following the initiation of a new medication indicates that the drug is the most likely culprit. The time between initiation of the offending drug and development of thrombocytopenia has not been well documented for most medications. However, thrombocytopenia typically begins days to a few weeks after the administration of most medications with this type of toxicity. Presumably, this lag represents the period required for the patient to develop an immune response against the drug-platelet complex. Medications that have been taken safely for years before the onset of thrombocytopenia are unlikely to be the offending agents. In addition to an assessment of prescribed medications, a careful evaluation of over-the-counter medications is necessary. Agents that contain quinine lead the list of nonprescribed drugs that can induce life-threatening thrombocytopenia. Quinine is frequently contained in over-the-counter pills for leg cramps. Even the quinine in tonic water can induce severe thrombocytopenia ("gin and tonic purpura") when ingested by certain patients.

Some medications are much more likely to induce thrombocytopenia than others. Table 175-2 contains a partial list of drugs that frequently induce this type of toxicity. One particularly useful online database (*www.ouhsc.edu/platelets/ditp.html*) lists and periodically updates the level of evidence for specific drugs that may induce thrombocytopenia. With the exception of tests for HIT, laboratory tests for drug-induced thrombocytopenia do not have widespread applicability. Usually, drug-induced thrombocytopenia is proved only in retrospect, when the platelet count improves after discontinuation of the suspected medication. Even then, the diagnosis is not conclusive unless thrombocytopenia recurs after rechallenging the patient with the offending drug (a practice that is almost never recommended).

TABLE 175-2 DRUGS THAT ARE STRONGLY ASSOCIATED WITH THROMBOCYTOPENIA

ANTIBIOTICS AND ANTIVIRALS
Quinine/quinidine
Penicillins
Cephalosporins
Vancomycin
Trimethoprim/sulfamethoxazole
Sulfonamides/sulfonylureas
Linezolid
Valacyclovir
Ganciclovir
Indinavir
CARDIOVASCULAR MEDICATIONS
Abciximab
Tirofiban
Eptifibatide
Salicylates
Digoxin
Furosemide
MISCELLANEOUS
Cimetidine
Ranitidine
Famotidine
Valproate
Interferon

The most efficacious method of treating drug-induced thrombocytopenia is to stop all suspected offending medications. Usually, no additional therapy is indicated. The thrombocytopenia typically begins to resolve without further intervention within days to a week of stopping the drug. The notable exceptions involve drugs with particularly long half-lives. Sulfonamides, quinine, and quinidine are particularly notorious for inducing severe or even life-threatening thrombocytopenia. In patients with profound thrombocytopenia (<10,000 to 15,000/μL) or at high risk for bleeding, platelet transfusions are indicated. If ITP cannot be confidently excluded and the thrombocytopenia is life threatening, glucocorticoids can also be initiated (see the discussion of ITP treatment later).

Heparin-Induced Thrombocytopenia

A special case of drug-induced immune-mediated thrombocytopenia associated with arterial and venous thrombosis, rather than bleeding, is HIT. It is seen in 2 to 5% of patients exposed to unfractionated heparin and in 0.7% of patients given low-molecular-weight heparin; it almost never occurs in patients exposed only to fondaparinux. To understand this disease, one must know that platelets can secrete a protein, platelet factor 4 (PF4), that can bind to heparin. HIT is caused by an antibody that binds to this PF4-heparin complex (Fig. 175-1). Large complexes of antibodies directed against heparin-bound PF4 accumulate on the surface of platelets. At times, these anti-PF4 immunoglobulins bind to the Fc receptor that is also present on the platelet surface. The interaction of platelet Fc receptors and anti-PF4 antibodies causes activation of the platelet, release of more PF4, and a cycle of events that leads to the stimulation of even more platelets. Ultimately, it also leads to activation of the coagulation cascade. The activation of platelets and the clotting cascade leads to the formation of thrombi and thrombocytopenia.

When thrombocytopenia is detected in a hospitalized patient, HIT must always be considered. Patients with this syndrome often have multiple potential causes for thrombocytopenia (such as other medications or infections). Therefore, it is important to exclude these other causes. Large retrospective studies of HIT have suggested that the onset of thrombocytopenia relative to the initiation of heparin therapy is useful in establishing or excluding this diagnosis. HIT typically occurs 4 to 14 days after patients are given heparin by any route (even subcutaneously or in extremely low doses by heparin flush). This lag between heparin exposure and the appearance of HIT is due to the time it takes for the immune response to generate the requisite antibodies against the heparin-PF4 complex. Some patients who have been exposed to heparin within the past several months already have preexisting antibodies against the heparin-PF4 complex in their circulation. When these patients are re-exposed to heparin, they may develop an acute onset of HIT within the first day of reinitiating the drug.

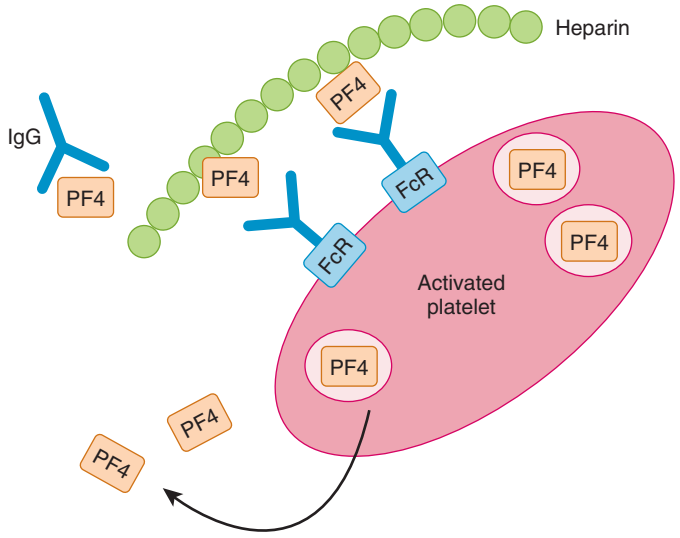

FIGURE 175-1. Pathophysiology of heparin-induced thrombocytopenia. Platelet factor 4 (PF4) is a protein stored in platelet granules and secreted from platelets upon their activation. Heparin can bind to PF4 and induce a conformational change within PF4 that in some patients produces an antibody-mediated immune response. Large complexes of immunoglobulin (Ig), heparin, and PF4 can accumulate on the platelet surface and stimulate the platelet when the Fc portion of the antibody interacts with the platelet's FcγRII receptor (FcR). Once activated, the platelets contribute to thrombosis. In addition, the activated platelets secrete more PF4, continuing the process.

The unique timing of acute-onset HIT within hours of heparin re-exposure and the more typical development of HIT within 4 to 14 days of initial heparin exposure emphasize the importance of a careful and critical history in establishing the diagnosis. HIT should be suspected in any patient who develops thrombocytopenia while on heparin therapy. It is important to note that the normal platelet count varies widely (150,000 to 450,000/μL), so some patients may have a substantial decrease in the platelet count but still remain within the normal range. Therefore, a greater than 50% decrease in the platelet count in a patient on heparin should raise suspicion for this syndrome. HIT should also be suspected in any patient who develops a thrombotic event while on heparin therapy.

Several antibody-based laboratory tests are available to confirm this diagnosis (Table 175-3). Although antibodies against the heparin-PF4 complex are almost always present in patients with HIT, these antibodies are also frequently present in heparin-treated patients who do not have this disorder (i.e., those with neither thrombocytopenia nor thrombosis). In addition, several days may elapse before the test results are available. Therefore, in practice, these laboratory assays provide only confirmatory information. Urgent clinical decisions should *not* be deferred until such test results are available. The timing of the thrombocytopenia with respect to the heparin exposure and the degree of platelet drop are the most important pieces of information needed by the physician evaluating a patient suspected of having HIT.

There are two general categories of laboratory assays for the diagnosis of HIT: functional assays and immunologic assays. Functional assays analyze whether the combination of heparin and the patient's plasma can induce normal platelets to aggregate or to secrete serotonin; these assays have very high specificity but relatively low sensitivity. Immunologic assays test the patient's plasma for antibodies that bind to the heparin-PF4 complex; they have very high sensitivity but lack specificity. Consequently, a *negative immunologic assay* is useful in excluding this diagnosis, and a *positive functional assay* is very useful in confirming the diagnosis of HIT.

Because platelets are consumed as they become activated, the clinical presentation of HIT is thrombocytopenia. However, it is unusual for the thrombocytopenia to actually cause bleeding. Instead, HIT is a highly prothrombotic disorder. Both venous and arterial thromboses are common in HIT. Patients with HIT who do not have thrombosis on initial presentation still have a 20 to 30% chance of developing a thrombus within the next month. Nevertheless, the incidence of HIT-related clinical events is greatest immediately after diagnosis. More importantly, clinical studies report that cessation of heparin frequently fails to prevent thromboses or the development of new thrombotic events.

If a patient has HIT, all heparin should be stopped immediately. This includes subcutaneous injections of "minidose" heparin, heparin flushes of intravenous lines, and low-molecular-weight heparin; even heparin-coated intravenous catheters should be withdrawn. Alternative anticoagulation, such as a direct thrombin inhibitor like recombinant hirudin or argatroban (Chapter 37), should be administered, at least until the platelet count normalizes. Warfarin should not be used in cases of acute HIT because of its delayed therapeutic effect and its association with venous limb gangrene. Because patients rarely become profoundly thrombocytopenic as a result of HIT alone, platelet transfusions are typically not required. In fact, some reports suggest that platelet transfusions can actually precipitate thrombotic complications, although this remains controversial.

TABLE 175-3 LABORATORY ASSAYS FOR HEPARIN-INDUCED THROMBOCYTOPENIA

ASSAY	SENSITIVITY (%)	SPECIFICITY (%)	POSITIVE PREDICTIVE VALUE (%)	NEGATIVE PREDICTIVE VALUE (%)
Functional assay (e.g., serotonin release assay)	88	≈100	≈100	81
PF4/heparin enzyme immunoassay (ELISA)	95-98	86	93	95

ELISA = enzyme-linked immunosorbent assay; PF4 = platelet factor 4.

Sepsis

Along with exposure to certain drugs, bacterial and viral infections are the most common cause of acute thrombocytopenia in hospitalized patients. Acute thrombocytopenia can be caused by the deposition of antibody-antigen complexes on the platelet surface via an "innocent bystander" phenomenon. These antibody-coated platelets are then cleared from the circulatory system by Fc receptor–expressing macrophages in the spleen. Thrombocytopenia associated with infections can also be due to DIC. The treatment of sepsis-induced thrombocytopenia is directed at the underlying cause, along with platelet transfusions as clinically indicated.

Idiopathic (Immune) Thrombocytopenic Purpura

DEFINITION

ITP is an autoimmune disorder caused by circulating antiplatelet autoantibodies. An ITP-like picture can also be found in patients with autoimmune diseases such as systemic lupus erythematosus (see later and Chapter 274), low-grade lymphoproliferative disorders such as chronic lymphocytic leukemia (Chapter 190), and HIV infection (Chapter 400).

CLINICAL MANIFESTATIONS

ITP was originally thought to be a disease of young women. Although this description is appropriate for many individuals with this disorder, more recent data indicate that ITP can occur in patients of either sex and at any age. ITP is a chronic, recurring disorder in the vast majority of adults with this disease. This is in stark contrast to pediatric patients, who usually suffer from acute ITP and rarely have the chronic variant of this disorder.

In contrast to patients with coagulation factor deficiencies who present with bleeding deep within tissues, individuals with ITP (or other disorders of platelets) typically have excessive mucocutaneous bleeding. Consequently, the clinician should inquire whether the patient has noticed epistaxis, gingival bleeding, easy bruising, hematuria, melena, or hematochezia. Female patients should also be asked about inappropriate or excessive vaginal bleeding. The physical examination should pay particular attention to signs of mucocutaneous bleeding. Consequently, the patient should be thoroughly examined for petechiae and ecchymosis, as well as for evidence of hemorrhage within the conjunctiva, retina, and central nervous system.

DIAGNOSIS

Except for the thrombocytopenia, the CBC is usually normal, and the peripheral blood smear is remarkable only for a decreased number of platelets, some of which may be larger than normal. Splenomegaly is absent unless the ITP is due to an underlying disorder, such as lymphoma, that is itself associated with splenomegaly. Bone marrow examination is usually not necessary in the absence of findings that suggest a different disease such as myelodysplasia. If performed, the bone marrow aspirate and biopsy typically show normal or increased numbers of megakaryocytes but are otherwise normal, characteristic of other forms of destructive thrombocytopenia.

TREATMENT

Rx

Because platelet production is assumed to be increased in patients with ITP, traditional therapy has focused on moderating this immune response that ultimately leads to accelerated platelet destruction. For most of the latter half of the 20th century, splenectomy and corticosteroids were the sole therapies for ITP. Although they remain first-line therapeutic modalities, immunomodulating agents such as intravenous immunoglobulin (IVIG) and anti-D, as well as alternative immunosuppressives, have been introduced for the therapy of ITP. Corticosteroids in the form of high-dose dexamethasone (4-day pulses every 14 to 28 days for four to six cycles) are effective. For selected refractory patients, other immunosuppressives, such as cyclophosphamide, azathioprine, cyclosporine A, mycophenolate mofetil, dapsone, interferon, and etanercept, can be used.

For years, the basic mechanism of and rationale for ITP treatment revolved around altering the immune system through immunosuppressives, splenectomy, or immune modulators such as IVIG or anti-D. A more recent addition to the ITP treatment regimen is rituximab, a "humanized" murine monoclonal antibody against CD20, which is a B-cell antigen. Although rituximab has not been approved by the Food and Drug Administration (FDA) for the treatment of ITP, it is currently widely used in patients who are unresponsive to splenectomy and corticosteroids. Response rates vary significantly between studies, ranging from 28 to 44% in larger trials. The combination of high-dose dexamethasone and rituximab was recently shown to be more effective than dexamethasone alone.[2]

Although the vast majority of ITP patients have a compensatory increase in megakaryopoiesis in response to the rapid platelet destruction, plasma derived from some ITP patients was unexpectedly found to inhibit platelet production. This has prompted a re-evaluation of whether impaired megakaryopoiesis contributes to the development of thrombocytopenia in this disease. Thrombopoietin (TPO) is a potent megakaryocyte colony-stimulating factor and, along with other cytokines, increases the size and number of megakaryocytes (Chapter 159). TPO levels are not markedly elevated in ITP, suggesting that supplemental TPO could help increase platelet production and correct the thrombocytopenia.

Early experiments demonstrated that recombinant as well as truncated forms of TPO significantly increased the platelet count in some refractory ITP patients. However, this also induced autoimmune autoantibodies against endogenous TPO, which resulted in profound and persistent thrombocytopenia. Both recombinant TPO and its truncated form were therefore withdrawn from clinical trials. Subsequently, peptides were developed that bear no structural resemblance to TPO but still bind to and activate the TPO receptor; these agents are called *TPO receptor agonists*. Because these recombinant drugs bear little structural similarity to native TPO, they should not trigger autoimmune anti-TPO antibodies. The FDA has approved two of these drugs, and several more are being used in clinical trials. The first of these, called romiplostim, is composed of several copies of the TPO receptor–binding peptide spliced into a recombinant antibody. This peptide agonist competes with TPO for binding to the TPO receptor and activates the receptor in an identical fashion as endogenous TPO. The second FDA-approved TPO receptor agonist is eltrombopag (Promacta). It is an oral drug that activates the TPO receptor by binding to the receptor's transmembrane region.

Both subcutaneously administered romiplostim and orally administered eltrombopag are capable of increasing platelet counts in approximately 70% of patients with ITP. Remarkably, these drugs can also increase the platelet count in patients with ITP that is refractory to other treatment modalities, including splenectomy.[3,4] However, adverse events, including bone marrow fibrosis and thromboembolism, have been reported. It should be noted that the drugs' effects disappear soon after their discontinuation. Therefore, the TPO receptor agonists are not disease modifying and are probably most appropriate for short-term use when a temporary rise in platelet count is required.

General Principles of ITP Therapy

Management of ITP is guided by both symptoms and platelet count.[1] Asymptomatic patients with platelet counts greater than 30,000/μL can be followed without treatment. If the patient is bleeding and/or has a platelet count less than 30,000/μL, treatment with prednisone is recommended (Table 175-4). Refractory patients may require splenectomy, other immunosuppressive medications, or one of the new thrombopoiesis-stimulating agents (Table 175-5). Splenectomy has a long history of success in this disorder; durable complete response rates are approximately 66 to 70%. Approximately half the remaining patients who do not have normal platelet counts following splenectomy achieve a partial response that is clinically meaningful. Unfortunately, 10 to 15% of patients derive no benefit from splenectomy, and there is no test to predict whether a particular patient will respond to this treatment.

ITP patients with severe thrombocytopenia (<5000/μL) and/or internal bleeding should be promptly treated with high doses of pulse corticosteroids and IVIG. Platelet transfusion may be given concurrently with IVIG for critical bleeding. In Rh-positive patients who have not undergone splenectomy, anti-D immune globulin may be substituted for IVIG. However, some patients develop autoimmune hemolysis from this treatment.

TABLE 175-4 THERAPY FOR THE INITIAL MANAGEMENT OF IDIOPATHIC THROMBOCYTOPENIC PURPURA

ORAL PREDNISONE
Effect is dose dependent—approximately 80% of patients respond to 1 mg/kg/day. Toxicity also increases with dose and duration of treatment and includes glucose intolerance, immunosuppression, osteoporosis, and cataracts. Relapse is typical once therapy is discontinued.
INTRAVENOUS IMMUNOGLOBULIN (IVIG)
More rapid than daily prednisone. Administered at a dose of 1 g/kg/day for 2 consecutive days or 0.4 g/kg/day for 5 consecutive days. Response rates are approximately 80%, and effects typically last 2-4 wk. Toxicity includes headache, allergic reactions, and, rarely, thrombosis.
ANTI-D IMMUNOGLOBULIN
Administered at a dose of 50-75 μg/kg IV. Response rates are dose dependent but can approach 75-80%. Hemolysis is a common toxicity. Rarely, hemolysis can be life threatening and can be associated with disseminated intravascular coagulation, renal failure, and end-organ infarction.

Thrombotic Thrombocytopenic Purpura

DEFINITION

TTP is a consumptive thrombocytopenia associated with a mechanical hemolytic anemia. The classic pentad of symptoms—thrombocytopenia, anemia, fever, neurologic problems, and renal abnormalities—is fully present in only a minority of patients. Many patients today have only hemolytic anemia and thrombocytopenia. The poor specificity of the clinical features and laboratory abnormalities makes this disease difficult to diagnose. Historically, untreated TTP had a mortality of 90% within 3 months. With modern therapy, patients with TTP have a mortality of approximately 10 to 20%.

PATHOBIOLOGY

Some patients with recurrent TTP have very large multimers of von Willebrand factor (Chapter 176). Because larger multimers of von Willebrand factor are more efficient at binding and activating platelets than smaller ones, it was speculated that TTP could be due to a deficiency of a protease that cleaves large multimers of von Willebrand factor into smaller, less sticky ones. A genome-wide linkage analysis of patients with inherited recurrent TTP (Upshaw-Schulman syndrome) demonstrated a deficiency of a metalloproteinase that is now called ADAMTS13 (a disintegrin-like and metalloprotease with thrombospondin type 1 repeats). Many patients with adult-onset TTP have an antibody against ADAMTS13 that causes an acquired deficiency of the enzyme. Inherited or acquired ADAMTS13 deficiency causes the accumulation of ultra-large multimers of von Willebrand factor in plasma, which leads to platelet activation and the microvascular thrombosis characteristic of this disease (Fig. 175-2). Because many patients can have a partial deficiency of ADAMTS13 without having TTP, clinical assays of ADAMTS13 enzymatic activity have not been useful in diagnosing TTP. Levels of ADAMTS13 below 5% of normal are considered highly suggestive of TTP, but levels greater than this are not very helpful. This hypothesis still needs to be validated in large clinical trials. Consequently, analysis of ADAMTS13 enzymatic activity should not be used to diagnose TTP outside of a research setting.

Some patients reportedly developed TTP soon after taking an antiplatelet drug of the thienopyridine class. Approximately 1 of every 2000 patients taking ticlopidine will develop TTP. In several individuals with ticlopidine-induced TTP, an antibody against ADAMTS13 was identified. A few studies have also suggested that clopidogrel can induce TTP at an incidence of 1 in 15,000 to 1 in 250,000. Because the incidence of TTP in the general population is approximately 1 in 100,000, it is difficult to determine whether there is a significant risk of TTP in patients who are prescribed clopidogrel. It should be noted that some patients can also develop TTP after exposure to medications that directly injure the vascular endothelium. The majority of these patients do not have TTP but have the related disorder HUS (discussed later in this chapter).

TABLE 175-5 THERAPY FOR THE MANAGEMENT OF REFRACTORY IDIOPATHIC THROMBOCYTOPENIC PURPURA

ORAL PREDNISONE
Effect is dose dependent and rapidly dissipates after discontinuation of the medication. Some patients can be maintained on a very low and tolerable daily dose (e.g., 5 mg). Long-term use is associated with infections, diabetes, osteoporosis, avascular necrosis, weight gain, and cataracts.
ORAL DEXAMETHASONE
Administered at a dose of 40 mg/day for 4 consecutive days. Repeated every 2-4 wk for several months. Sustained response rates of 29-42% are possible. Toxicity is similar to that of oral prednisone.
SPLENECTOMY
Durable (often lifelong), significant responses are seen in 65-70% of patients who undergo this procedure. More modest benefits are seen in another 10-15% of patients. There is no useful way to predict who will respond. Splenectomy is associated with surgical morbidity and some mortality (≈1-2%). Produces lifelong immunosuppression to encapsulated and gram-positive organisms.
RITUXIMAB
Given at a dose of 375 mg/m^2/wk IV for a total of 4 wk. Significant responses are seen in 28-44% of patients and typically last for months. Toxicity includes reactivation of hepatitis B, immunosuppression, and, rarely, progressive multifocal leukoencephalopathy.
THROMBOPOIETIN RECEPTOR AGONISTS
Administered daily (eltrombopag) or weekly (romiplostim). An effect is typically seen in 2-3 wk and disappears a few weeks after discontinuation of the medication. Toxicity from long-term use is not well known but may include excessive thrombosis and bone marrow fibrosis.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients often present with symptoms of excessive mucocutaneous bleeding, but they might present with signs of a thrombotic event (including phlebitis, myocardial infarction, or stroke). Many patients complain of abdominal pain that is presumably due to intestinal ischemia. Signs of central nervous system disease, including somnolence and even frank coma, can also be seen on presentation.

The two major hallmarks of this disorder are microangiopathic hemolytic anemia and thrombocytopenia. Microangiopathic hemolytic anemia is a non-immune-mediated hemolytic anemia caused by red cell fragmentation. Patients with this disorder have typical laboratory findings of hemolytic anemia, including a decreasing hemoglobin concentration, high lactate dehydrogenase level, elevated indirect bilirubin, and increased reticulocyte count. Examination of the peripheral blood smear (Chapter 160) shows torn red blood cells (schistocytes) and, frequently, early red blood cell precursor cells (nucleated red blood cells). The thrombocytopenia may be mild if the disease is diagnosed at an early stage, but advanced cases of TTP can have platelet counts less than 10,000/μL. TTP should be considered in any patient who has evidence of hemolysis accompanied by thrombocytopenia.

Unlike most patients with typical thrombocytopenia, who tend to bleed excessively, patients with TTP have few hemorrhagic complications. Instead, they are markedly predisposed to thrombosis. In fact, a thrombotic complication in a thrombocytopenic patient is another clue that TTP might be the cause of the thrombocytopenia (see Table 175-1). Characteristically, the thrombotic occlusions are in the terminal arterioles and capillaries and are composed mainly of platelets within the damaged vascular lumen. In contrast to most blood clots, these occlusions contain very little fibrin and are referred to as hyaline thrombi. Before plasmapheresis was used, TTP typically progressed and caused renal disease, neurologic symptoms, and fever. These symptoms are believed to be due to ischemia and infarction of the affected

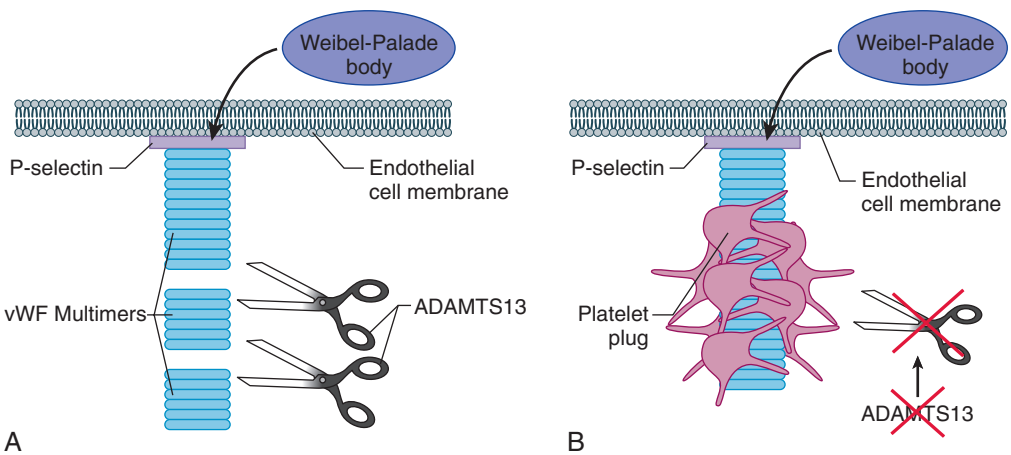

FIGURE 175-2. Pathophysiology of thrombotic thrombocytopenia purpura (TTP). A, Von Willebrand factor (vWF) is synthesized in endothelial cells and stored in Weibel-Palade bodies. The vWF is assembled into ultra-large multimers that are cleaved once they are released into the blood stream by the protease ADAMTS13. The resultant smaller multimers of vWF can bind to platelets to participate in normal hemostasis. **B,** Some patients with TTP have a deficiency of ADAMTS13. This results in the accumulation of ultra-large multimers of vWF within the circulation, promoting the excessive adhesion of platelets. This produces large hyaline plugs of vWF and platelets that cause vascular occlusions.

organs. Today, this disease is often diagnosed in its early stages, so patients may have only microangiopathic hemolytic anemia and thrombocytopenia.

TREATMENT

Rx

The prompt initiation of plasma exchange (plasmapheresis with plasma replacement) reduces the mortality of TTP from 90% to approximately 15%. The mechanism of this benefit is not entirely known. A randomized trial demonstrated that plasmapheresis is more beneficial than plasma infusion for the treatment of TTP, implying that some of the benefit of plasmapheresis is attributable to the removal of a pathologic substance from the patient's plasma. Assuming that the pathogenesis of most acquired forms of TTP is the antibody-mediated inhibition of ADAMTS13, plasmapheresis might have two benefits. First, it helps remove the pathogenic antibody from the plasma. Second, the normal plasma infused into the patient during plasmapheresis repletes the deficiency of ADAMTS13. Both these benefits probably play a role in the efficacy of plasma exchange in the treatment of this disease.

Because patients with TTP can develop sudden thrombotic events (including stroke and myocardial infarction) without warning and deteriorate quickly, it is prudent to initiate plasma exchange as rapidly as possible. Given the morbidity and mortality of untreated TTP and the relatively low risk of plasmapheresis, this therapy should be initiated even when the diagnosis is not certain. As discussed in the section on HUS, plasmapheresis is not beneficial in children with Shiga toxin–induced microangiopathic hemolytic anemia or in patients who develop HUS following exposure to endothelium-toxic drugs, such as chemotherapy.

Plasma exchange is administered to replace one entire plasma volume and is usually repeated once daily. An average-sized individual requires 20 to 30 units of fresh-frozen plasma for each plasmapheresis session. Therapy is usually administered daily, and the patient is monitored for signs of improvement in thrombocytopenia, hemolysis, neurologic symptoms, fever, and renal disease. Appropriate daily laboratory tests to monitor the patient are CBC, lactate dehydrogenase, reticulocyte count, and creatinine. Once the thrombocytopenia and hemolysis have been corrected for a few days, the daily plasmapheresis can be either discontinued or continued every other day for several more days. A typical duration of therapy is 1 to 2 weeks, although some patients require treatment far beyond this usual time course.

Approximately one third of patients relapse quickly after plasmapheresis is stopped. These patients require a reinitiation of plasma exchange and perhaps the addition of an immunosuppressive drug, such as a glucocorticoid. Some reports indicate that rituximab shows promise in reducing the incidence of relapse. However, given that this drug does not decrease antibody production for weeks to months after its administration, it is likely that if rituximab has any benefit in the treatment of TTP, it is probably only to minimize the incidence of late relapses.

Major complications of plasmapheresis do occur and are often attributable to the use of a central venous catheter. Hypotension, bacteremia, hemorrhage, and thrombosis are among the most common life-threatening complications of plasmapheresis therapy. Two specific complications deserve emphasis. First, patients on angiotensin-converting enzyme (ACE) inhibitor antihypertensives are susceptible to plasmapheresis-induced hypotension owing to these drugs' interference with bradykinin catabolism. Second, a patient who develops recurrent thrombocytopenia and fever several days to a week into treatment may not be having an exacerbation of TTP but may be developing central line–induced sepsis. Consequently, a vigorous investigation for infection should be initiated in patients who appear to be relapsing early.

Hemolytic-Uremic Syndrome

DEFINITION

HUS is another cause of microangiopathic hemolytic anemia, and it may be difficult to distinguish from TTP. When acute renal failure is predominant and there are no neurologic symptoms, many clinicians consider the syndrome to be HUS, not TTP. In contrast to TTP, HUS is not caused by a deficiency of ADAMTS13. However, at this point, it is not clear whether ADAMTS13 levels will be clinically useful to distinguish between HUS and TTP. Because there is such overlap between the signs and symptoms of TTP and those of HUS, the distinction and diagnosis may be impossible in some cases.

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

A toxin that directly damages endothelial cells can cause HUS. These direct endothelial toxins are either infectious or the result of a drug. Perhaps the best-characterized infectious agent that damages endothelial cells is Shiga toxin–producing enterohemorrhagic *Escherichia coli* (Chapter 312). In Shiga toxin–induced HUS, the renal disease and microangiopathic hemolytic anemia occur after an episode of diarrhea that is often bloody. *E. coli* O157:H7 is the cause of many cases in the United States. The toxin damages endothelial cells within the glomeruli and promotes the adhesion of platelets and the trapping of red blood cells.

Several drugs can induce HUS by directly damaging endothelial cells. These include calcineurin inhibitors such as tacrolimus and cyclosporine; sometimes, lowering the dose of these drugs can reverse the microangiopathic hemolytic anemia. Cytotoxic drugs such as mitomycin C, cisplatin, and bleomycin can also induce HUS by damaging endothelial cells.

Inherited forms of HUS have been described, and they usually involve dysregulation of the complement cascade (Chapter 49). The best-described genetic mutations cause the deficiency of factor H, a complement regulatory protease. HUS-inducing mutations in other components of complement regulation include those found in C3, CD46, and factor I.

TREATMENT AND PREVENTION

Rx

Reducing the spread of Shiga toxin–producing *E. coli* is vital, because antibiotics and antimotility drugs do not lower the risk of developing HUS symptoms. In contrast to TTP, there is little evidence that plasma exchange is beneficial. The infusion of plasma or plasmapheresis is reportedly beneficial in the treatment of atypical forms of HUS caused by the dysregulation of complement.

Disseminated Intravascular Coagulation

DIC is a pathologic condition that depletes components of the coagulation system, including platelets. Therefore, in contrast to TTP and HUS, the thrombocytopenia of DIC is associated with the consumption of coagulation factors and increased fibrinolysis, often leading to prolongations of the prothrombin time and activated partial thromboplastin time, as well as increased levels of D-dimers. In its fully manifested state, DIC can be associated with arterial and venous thrombi, hemorrhage, microangiopathic hemolysis, thrombocytopenia, excessive fibrinolysis, and deficiency of coagulation factors such as fibrinogen. For a more complete review of DIC and related disorders, see Chapter 178.

Thrombocytopenia during Pregnancy

Thrombocytopenia occurs in approximately 5% of pregnant women. It may be due to a normal variant of pregnancy (gestational thrombocytopenia), a pregnancy-specific condition (preeclampsia and HELLP syndrome [hemolysis, elevated liver enzymes, and low platelets]), or a condition exacerbated by pregnancy (ITP, vasculitis, TTP). The prognosis and treatment vary tremendously based on the underlying cause.

Gestational thrombocytopenia (incidental thrombocytopenia of pregnancy) is a mild, asymptomatic thrombocytopenia that typically occurs late in pregnancy. There is no association with fetal thrombocytopenia, and this maternal thrombocytopenia resolves spontaneously after delivery. Other than thrombocytopenia during previous pregnancies, women with gestational thrombocytopenia have no prior history of a low platelet count. This lack of previous thrombocytopenia helps distinguish gestational thrombocytopenia from ITP. Additionally, in contrast to other causes of maternal thrombocytopenia, gestational thrombocytopenia does not produce a platelet count lower than 70,000/μL. Consequently, deviation from standard obstetric care is usually not required for a patient with gestational thrombocytopenia.

Preeclampsia is a syndrome that causes the gradual development of proteinuria and hypertension during the later stages of pregnancy (Chapter 247). A minority of women with preeclampsia progress to have seizures; when this occurs, the syndrome is called *eclampsia*. Approximately 15% of women with preeclampsia have thrombocytopenia, and 5% of patients with preeclampsia have platelet counts less than 50,000/μL. Some patients have a more severe form of preeclampsia associated with HELLP syndrome. Preeclampsia and HELLP syndrome are believed to be caused by a factor produced within the placenta, because these syndromes usually resolve rapidly and spontaneously after delivery. They can present post partum, but they still resolve within a few days of delivery. Consequently, immediate delivery of the child is recommended, if possible, because the microangiopathic process stops soon thereafter. If these syndromes do not resolve spontaneously within 3 days, alternative diagnoses such as ITP and TTP should be considered.

Most patients with ITP or vasculitis during pregnancy have a history of thrombocytopenia before pregnancy. The antiplatelet immunoglobulin G antibodies that cause this disease in the mother can cross the placenta and lead to thrombocytopenia in the fetus. However, the platelet count in the unborn child does not correlate well with the platelet count of the mother,

and attempts to sample fetal blood to monitor platelet counts are associated with significant risk. Because the vast majority of children born to women with ITP have a platelet count high enough for a successful delivery, the management of ITP focuses on keeping the maternal platelet count acceptable for the mother's safety. In the early stages of pregnancy, a platelet count of 30,000 to 50,000/μL is considered safe. In preparation for delivery, a platelet count of 50,000 to 80,000/μL is more desirable. This can be managed by the use of oral glucocorticoids and, if necessary, by the administration of IVIG. The safety of rituximab and thrombopoiesis-stimulating agents during pregnancy is not known. Splenectomy performed during the first trimester has a risk of inducing miscarriage, and this operation is technically difficult during the later stages of pregnancy because of uterine enlargement. There is no evidence that a cesarean section is safer than vaginal delivery.

The diagnosis of TTP during pregnancy can be difficult because many of the symptoms are identical to those of preeclampsia. If the symptoms develop during the early stages of pregnancy, when preeclampsia is unlikely, the diagnosis of TTP is more certain. The presence of hyperuricemia, hypoproteinemia, elevated liver transaminases, and direct bilirubin is more consistent with preeclampsia. The development of microangiopathic hemolytic anemia and thrombocytopenia in the peripartum period is presumed to be attributable to preeclampsia, and immediate delivery of the fetus is desirable if it is safe to do so. Typically, the thrombocytopenia starts to resolve rapidly after delivery. If no improvement is seen by the third postpartum day, standard management for TTP, including plasma exchange, is recommended.

Post-Transfusion Purpura and Neonatal Alloimmune Thrombocytopenia

Alloimmune thrombocytopenia is due to sensitization to alloantigens such as Pl^{A1} (HPA-1a). These alloimmune antibodies can cause thrombocytopenia approximately a week after a blood transfusion (post-transfusion purpura, or PTP). A similar alloimmune antibody can cause thrombocytopenia in a fetus when it is produced by the mother (neonatal alloimmune thrombocytopenia, or NAIT). PTP causes profound thrombocytopenia 7 to 10 days after exposure to platelets that contaminate red blood cell transfusions. However, it can be treated with IVIG or plasma exchange. NAIT can cause severe thrombocytopenia and bleeding in neonates and is treated with the transfusion of platelets derived from a Pl^{A1}-negative donor (most conveniently the newborn's mother herself), corticosteroids, and IVIG.

Vasculitis

Autoimmune diseases such as systemic lupus erythematosus, rheumatoid arthritis, and other forms of vasculitis can also involve thrombocytopenia. This can be due to an ITP-like process that occurs in patients with a propensity for the development of autoantibodies. The treatment for these patients is immunosuppression, similar to the treatment for other patients with ITP. Some patients with active vasculitis and endothelial inflammation consume circulating platelets due to this damaged vessel wall, creating a clinical picture that is difficult to distinguish from that of TTP without a tissue diagnosis that documents vasculitis. Owing to the difficulty of discerning TTP from a flare-up of vasculitis, these patients are often treated with both plasma exchange and immunosuppression.

Dilutional Thrombocytopenia

Thrombocytopenia does not typically occur after blood loss, possibly due in part to the release of platelets from the splenic pool. Thrombocytopenia occasionally occurs after massive hemorrhage, but only when the hemorrhage is severe enough to necessitate replacement of 1.5 to 2 times the total blood volume, which usually requires transfusion of at least 15 to 20 units of packed red blood cells over a short period. Even in this circumstance, the thrombocytopenia is only mild to moderate. Therefore, the clinician should remain vigilant for another cause of the thrombocytopenia (such as DIC resulting from hemorrhage-induced hypotension and shock). There is no reason to routinely transfuse platelets in a fixed ratio to packed red blood cells unless thrombocytopenia is present and doing so is otherwise indicated. When indicated, dilutional thrombocytopenia can be corrected with platelet transfusions.

Congenital Thrombocytopenias

Lifelong thrombocytopenia can be due to an inherited defect that affects platelet production or survival. These disorders can be autosomal dominant (May-Hegglin anomaly, Alport's syndrome), autosomal recessive (Bernard-Soulier disease, Fanconi's anemia, gray platelet syndrome, thrombocytopenia with absent radius syndrome), or X-linked (Wiscott-Aldrich syndrome). Many of these disorders are associated with other abnormalities in addition to thrombocytopenia. A congenital cause of thrombocytopenia should be suspected in a patient who has long-standing moderate thrombocytopenia presumed to be treatment-refractory ITP.

VON WILLEBRAND DISEASE AND HEMORRHAGIC ABNORMALITIES OF PLATELET AND VASCULAR FUNCTION

WILLIAM L. NICHOLS

VON WILLEBRAND DISEASE

DEFINITION AND EPIDEMIOLOGY

Von Willebrand disease (VWD), a usually autosomal dominantly inherited condition affecting both males and females of all ethnicities, is the most common hereditary bleeding disorder worldwide, with prevalence estimates dependent on case definition. It may also occur less frequently as an acquired disorder (acquired von Willebrand syndrome [AVWS]). Von Willebrand factor (VWF) plasma levels are variably decreased (minimally to substantially) in at least 2.5% of humans, whereas approximately 0.1% (1 in 1000) have definite VWD with medically significant bleeding symptoms related to low VWF, and approximately 0.01% (1 in 10,000) have more severe forms of VWD that often result in referral to tertiary care centers including hemophilia centers.

PATHOBIOLOGY

VWD reflects deficiency or dysfunction of VWF, a multimeric plasma glycoprotein that mediates platelet adhesion and aggregation at sites of vascular

injury (Chapter 174), and that also carries and stabilizes blood coagulation factor VIII (FVIII) in the circulation. The *VWF* gene is located on chromosome 12, with a partial pseudogene on chromosome 22 that potentially complicates DNA-based mutation detection (which remains primarily a research application, with evolving clinical diagnostic potential). The protein is synthesized by vascular endothelium as ~270-kD subunits (protomers) that are dimerized, then processed and polymerized into very large (up to about 20,000 kD) hemostatically active VWF multimers, and finally secreted into the blood. Vascular endothelial cells additionally provide a storage reservoir of multimerized VWF (in intracellular Weibel-Palade bodies) from which it can be released by stress or drugs such as DDAVP (desmopressin). VWF is also synthesized and multimerized by bone marrow megakaryocytes and stored in circulating blood platelet α granules, from which it is secreted with platelet activation. Platelet-stored VWF represents about 10% of total blood VWF.

Multimerization of VWF is essential for its hemostatic activity that is mainly mediated by the higher-molecular-weight (larger) multimers. Circulating plasma VWF does not interact with platelets, but when VWF binds to injured (de-endothelialized) blood vessel walls, reflecting its collagen-binding activity, multimers can be stretched and unfolded by high intravascular shear forces, such as in the microvasculature, exposing and activating previously cryptic platelet-binding domains to promote platelet adhesion and aggregation to vessel-bound VWF. Simultaneously, activated (stretched) VWF multimers expose protomer cleavage sites for proteolysis by the circulating enzyme, ADAMTS13 (A Disintegrin And Metalloprotease domain with ThromboSpondin type 1 motifs, member 13), ultimately decreasing the size of VWF multimers and thereby downregulating VWF hemostatic function. Severe deficiency of ADAMTS13 is associated with the pathologic microangiopathy of thrombotic thrombocytopenic purpura (TTP) (Chapter 175), in which the microvascular thrombosis is mediated by ultralarge VWF multimers in the circulation.

VWD is classified into three major types that vary in severity and differ in clinical management, such that defining the VWD subtype is important. Type 1 VWD reflects partial quantitative deficiency of normally functioning VWF, of variable severity, and comprises 75 to 80% of individuals with symptomatic VWD. Type 2 VWD reflects qualitative VWF deficiency, with four subtypes (A, B, M, N), and comprises 20 to 25% of persons with VWD. Type 3 VWD reflects the virtual absence of VWF, with secondary near-absence of FVIII, and is rare (<1% of VWD). Inheritance of VWD is usually autosomal dominant, except that type 3 VWD is typically autosomal recessive in inheritance. Table 176-1 summarizes the classification of VWD subtypes and their basic pathophysiology.

The FVIII deficiency that often accompanies different types of VWD (see Table 176-1) is not genetically related to the disease; the gene that encodes FVIII is on the X chromosome, and its primary deficiency causes classic hemophilia (Chapter 177). FVIII deficiency in VWD is due to a primary deficiency or defect in the VWF molecule, which normally carries and stabilizes FVIII in the circulation. Therefore, FVIII is more rapidly cleared from the circulation, leading to its secondary deficiency in VWD.

TABLE 176-1 CLASSIFICATION OF VON WILLEBRAND DISEASE

TYPE	DESCRIPTION
1	Partial quantitative deficiency of VWF (~75-80% of VWD)
2	Qualitative VWF defect (~20-25% of VWD)
2A	Caused by VWF mutations that decrease the proportion of large functional VWF multimers, leading to decreased VWF-dependent platelet adhesion and aggregation
2B	Caused by VWF mutations that increase platelet-VWF binding, resulting in depletion of large, functional VWF multimers. Circulating platelets are coated with mutant VWF, which may impair platelet adhesion and aggregation at sites of injury. Thrombocytopenia, persistent or intermittent, is observed in most cases. Distinguishing type 2B VWD may require RIPA to detect increased (abnormal) platelet aggregation response to low-dose ristocetin; the latter may also reflect platelet-type (pseudo) VWD caused by rare mutations in the platelet VWF receptor.
2M	Caused by VWF mutations that decrease VWF-dependent platelet adhesion and aggregation, but do not deplete the large VWF multimers. Distinguishing between types 2A and 2M VWD requires VWF multimer gel electrophoretic analysis.
2N	Caused by VWF mutations that impair binding to FVIII, thereby shortening FVIII survival and lowering FVIII levels so that type 2N VWD can masquerade as an autosomal recessive form of hemophilia A. Discrimination from hemophilia A may require assays of VWF-FVIII binding.
3	Virtually complete VWF deficiency, associated with markedly decreased FVIII (<1% of VWD)

FVIII = factor VIII coagulant activity; RIPA = ristocetin-induced platelet aggregation/aggregometry; VWD = von Willebrand disease; VWF = von Willebrand factor.

CLINICAL MANIFESTATIONS

Individuals with VWD usually experience mucocutaneous bleeding symptoms such as easy bruising, prolonged or excessive bleeding from minor cuts or other injuries, nosebleeds or other mucosal bleeding such as gastrointestinal hemorrhage, or heavy menstrual bleeding (in women), and they may be at increased risk for bleeding following surgery or invasive procedures, dental extractions, traumatic injury, or childbirth. Symptoms can range from relatively mild or infrequent bleeding in type 1 VWD to severe, life-threatening bleeding in type 3 VWD. As a group, women with VWD may be more affected by bleeding symptoms than men because of hemostatic challenges of menstruation and childbirth.

DIAGNOSIS

Clinical Assessment

Diagnosis of VWD (or other bleeding disorders) begins with clinical assessment to evaluate for a personal and possible family history of abnormal bleeding, accompanied by focused physical examination to detect signs or symptoms of bleeding (e.g., petechiae, ecchymoses, hematomas, anemia), as well as findings that may suggest other causes of increased bleeding such as liver disease (e.g., hepatosplenomegaly, jaundice), joint or skin laxity (e.g., Ehlers-Danlos syndrome), telangiectasia (e.g., hereditary hemorrhagic telangiectasia), or anatomic lesions on gynecologic examination. Because bleeding symptoms are common in apparently normal individuals, with prevalence of certain symptoms as high as 25 to 50%, clinical assessment for VWD or other possible bleeding disorders can be challenging (Chapter 174).

The most important parts of the medical history include (1) family history of a known or suspected bleeding disorder; (2) review of personal surgical or other hemostatic challenges lifelong and recently, including dental extractions and traumatic injuries, and whether abnormal bleeding occurred and its severity; (3) mucocutaneous bleeding symptoms (e.g., bruising, nosebleeds, ecchymoses, gastrointestinal bleeding, menorrhagia), including frequency, severity and spontaneity of events; and (4) assessment for medical conditions that can increase risk for bleeding, such as use of certain drugs that can impede normal hemostasis, including aspirin or other nonsteroidal anti-inflammatory drugs (NSAIDs), clopidogrel, or warfarin or heparin anticoagulants; presence of liver or kidney disease (e.g., cirrhosis, uremia); and history of low or high platelet count and blood or bone marrow disorders.

Bleeding history scoring tools are being developed and applied for studying populations with VWD or other bleeding disorders but are not yet validated for routine clinical use. However, in general, an increasing number of positive or abnormal clinical bleeding history items increases the likelihood that an individual has a bleeding disorder, including VWD, and may merit undergoing appropriate laboratory evaluation (Chapter 174).

Laboratory Evaluation

Because no simple, single laboratory test is available to screen for VWD, the initial laboratory evaluation requires measurements of plasma: (1) VWF antigen (VWF:Ag); (2) ristocetin cofactor activity (VWF:RCo); and (3) factor VIII coagulant activity (FVIII). All three tests are recommended for initial evaluation, and the results may not only establish the diagnosis but also suggest the type and severity of VWD if it is present. These three tests are also used for monitoring therapy. Tests such as the bleeding time (BT) or platelet function analyzer (PFA-100, Siemens) assay lack sufficient sensitivity and specificity and are not recommended for routine screening.

If one or more of the three test results are abnormally low, or if the ratio of VWF:RCo to VWF:Ag is below 0.5 to 0.7, additional laboratory evaluation may include selecting one or more of the following tests, based on the pattern

of initial results together with clinical assessment and experience: (1) repeating the three initial VWD tests with timing and procedures optimized for conditions of the patient, the blood sample, and laboratory testing (see later for additional information about these conditions); (2) VWF multimer analysis to help differentiate or exclude types 2A, 2B, or 2M VWD; (3) ristocetin-induced platelet aggregometry (RIPA), including low-dose ristocetin testing to evaluate for type 2B VWD or platelet-type (pseudo) VWD; (4) VWF-FVIII binding assay (or molecular DNA-based VWF testing) to evaluate for type 2N VWD; and (5) other tests such as VWF:CB (collagen-binding activity) to supplement VWF:RCo testing and the overall evaluation. Some of these tests have limited availability and are mainly performed in reference laboratories. Consultation with a hemostasis specialist can help guide test selection.

Multimer analysis visualizes the distribution of plasma VWF multimers, is technically complex, is qualitatively interpreted in conjunction with results of the initial three tests and available clinical information, and is used to help determine the VWD subtype. Therefore, VWF multimer analysis is not recommended for initial VWD screening and should only be performed if initial VWD testing identifies an abnormal result (e.g., abnormally low VWF:RCo or ratio of VWF:RCo to VWF:Ag) or clinical information suggests a high likelihood of abnormal VWF multimer analysis.

Table 176-2 provides prototypical laboratory values for VWD subtypes. Diagnosis, especially for individuals with mildly decreased VWF (30 to 50% or IU/dL), requires correlation of clinical assessment (personal and family history of bleeding) and results of laboratory testing, the latter preferably performed or repeated in the absence of conditions associated with elevation of baseline VWF and with careful attention to blood specimen collection, processing, transportation, and storage.

The laboratory evaluation of a person for possible VWD or AVWS is relatively complex, particularly because results of the laboratory tests can be influenced by certain conditions of the patient and by variables in the blood sample and laboratory testing methodology (Table 176-3). In interpreting test results, therefore, it is important to be aware of these variabilities and the status of the patient at the time of evaluation.

TABLE 176-2 PATTERNS OF LABORATORY TEST RESULTS FOR VON WILLEBRAND DISEASE DIAGNOSIS AND CLASSIFICATION*

CONDITION	VWF:RCo (IU/dL)	VWF:Ag (IU/dL)	FVIII (IU/dL)	VWF:RCo/VWF:Ag RATIO[¶]	RIPA	VWF MULTIMERS
Type 1 VWD	<30[†]	<30[†‡]	↓ or Normal	>0.5-0.7	Often normal	Normal
Type 2A VWD	<30[†]	<30-200[†‡]	↓ or Normal	<0.5-0.7	↓ or Normal	↓ HMW
Type 2B VWD	<30[†]	<30-200[†‡]	↓ or Normal	Usually <0.5-0.7	↑ (Low dose)	↓ HMW
Type 2M VWD	<30[†]	<30-200[†‡]	↓ or Normal	<0.5-0.7	↓ or Normal	No ↓ HMW
Type 2N VWD	30-200	30-200	↓↓	>0.5-0.7	Normal	Normal
Type 3 VWD	<3	<3	↓↓↓ (1-9)	NA	Absent	NA
"Low VWF"[§]	30-50[§]	30-50[§]	Normal	>0.5-0.7	Normal	Normal
Normal	50-200	50-200	Normal	>0.5-0.7	Normal	Normal

*Values in the table represent prototypical cases without additional VWF (or other disease) abnormalities. Exceptions occur, and repeat testing and clinical experience may be necessary for clarification and interpretation of laboratory test results.

[†]VWF values <30 IU/dL (or %) are designated as the level for definite diagnosis of VWD (especially type 1 VWD) because (1) there is a high frequency of blood type O that is associated with "low VWF" levels but not necessarily VWD; (2) bleeding symptoms are reported by a significant proportion of individuals with no disease; and (3) no abnormality in the VWF gene has been identified in many individuals who have only mildly to moderately decreased VWF levels. VWF values of 30-50 IU/dL include both apparently normal persons and those with mild VWD.

[‡]VWF:Ag is <50 IU/dL in most persons with types 2A, 2B, or 2M VWD.

[§]Diagnosis of VWD is not precluded for persons with VWF:RCo of 30-50 IU/dL if there is supporting clinical or family evidence for VWD, nor is the use of agents to increase VWF levels precluded in those who have VWF:RCo of 30-50 IU/dL and who may be at risk for bleeding.

[¶]Until more laboratories clearly define a reference range, the VWF:RCo/VWF:Ag ratio of <0.5-0.7 is recommended to distinguish type 1 vs. type 2 VWD variants (A, B, or M).

FVIII = factor VIII coagulant activity; HMW = high molecular weight VWF multimers; IU/dL = international units per deciliter (e.g., 100 IU/dL = 100% of mean normal level); NA = not applicable; RIPA = ristocetin-induced platelet aggregation/aggregometry; VWD, von Willebrand disease; VWF = von Willebrand factor; VWF:Ag = von Willebrand factor antigen; VWF:RCo = von Willebrand factor ristocetin cofactor activity; ↓, ↓↓, ↓↓↓, ↑, refer to varying degrees of decrease, or an increase, of the test result compared to the laboratory reference range.

Diagnosis and management of von Willebrand disease: guidelines for primary care. *Am Fam Physician.* 2009;80:1261-1268, 1269-1270.

TABLE 176-3 VARIABLE CONDITIONS OF THE PATIENT, BLOOD SAMPLING, AND LABORATORY TESTING AFFECTING LABORATORY EVALUATION FOR VON WILLEBRAND DISEASE

Phlebotomy conditions—An atraumatic blood draw limits the exposure of tissue factor from the site and the activation of clotting factors, minimizing falsely high or low values. Lipemia should be avoided because it may interfere with photo-optical testing methods, especially some used for VWF:RCo assay.

Patient stress level—Undue stress, such as struggling or crying in children or anxiety in adults, may falsely elevate VWF and FVIII levels. Very recent exercise can also elevate VWF levels.

Additional conditions in the individual—The presence of an acute or chronic inflammatory illness may elevate VWF and FVIII levels, as may pregnancy or administration of estrogen or oral contraceptives. Individuals with blood group O have VWF levels approximately 25% lower than those of other ABO blood groups. African Americans have higher VWF levels than whites.

Sample processing—To prevent cryoprecipitation of VWF and other proteins, blood samples for VWF assays should be transported to the laboratory at room temperature. Plasma should be separated from blood cells promptly at room temperature, and the plasma should be centrifuged thoroughly to remove platelets. If plasma samples will be assayed within 2 hours, they should be kept at room temperature. Frozen plasma samples should be carefully thawed at 37° C and kept at room temperature for <2 hours before assay.

Sample storage—Plasma samples that will be stored or transported to a reference laboratory must be frozen promptly at or below −40° C and remain frozen until assayed. A control sample that is drawn, processed, stored, and transported under the same conditions as the tested person's sample may be helpful in indicating problems in the handling of important test samples. Activity of FVIII typically is 10-20% lower in frozen-thawed plasma than in fresh (nonfrozen) plasma, and can be even lower if blood processing or storage conditions are suboptimal.

Laboratory testing—Calibrators for assays of VWF:Ag, VWF:RCo, and FVIII should be referenced to the World Health Organization (WHO) plasma standard. These three tests have relatively high coefficients of variation (CVs of 10-30%), especially the VWF:RCo assay. The quality of laboratory testing also varies considerably among laboratories (high interlaboratory CV). Test results can be reported as international units per deciliter (IU/dL), rather than as a percentage (%) of mean normal, if WHO-linked calibrators are used. Referencing VWF testing results to the population reference range, rather than to ABO-stratified reference ranges, may be clinically useful.

FVIII = coagulation factor VIII; VWF = von Willebrand factor; VWF:Ag = VWF antigen; VWF:RCo = VWF ristocetin cofactor activity.

TABLE 176-5 INITIAL DOSING RECOMMENDATIONS FOR VON WILLEBRAND FACTOR CONCENTRATE REPLACEMENT FOR PREVENTION OR MANAGEMENT OF BLEEDING

MAJOR SURGERY/BLEEDING
Loading dose*: 40-60 U/kg
Maintenance dose†: 20-40 U/kg every 8 to 24 hours
Monitoring: VWF:RCo and FVIII trough and peak, at least daily
Therapeutic goal: trough VWF:RCo and FVIII >50 IU/dL for 7-14 days
Safety parameter: do not exceed VWF:RCo >200 IU/dL or FVIII >250-300 IU/dL
May alternate with desmopressin (DDAVP) for latter part of treatment
MINOR SURGERY/BLEEDING
Loading dose*: 30-60 U/kg
Maintenance dose†: 20-40 U/kg every 12 to 48 hours
Monitoring: VWF:RCo and FVIII trough and peak, at least once
Therapeutic goal: trough VWF:RCo and FVIII >50 IU/dL for 3-5 days
Safety parameter: do not exceed VWF:RCo >200 IU/dL or FVIII >250-300 IU/dL
May alternate with desmopressin (DDAVP) for latter part of treatment

*Loading dose is in VWF:RCo IU/dL.
†Dosing intervals reflect approximately 12-hour average half-lives of plasma VWF and FVIII, without conditions resulting in shortened survival or enhanced clearance such as bleeding or surgery.
FVIII = factor VIII; VWF = von Willebrand factor; VWF:RCo = VWF ristocetin cofactor activity.
Adapted and modified from National Heart, Lung, and Blood Institute. *The Diagnosis, Evaluation, and Management of von Willebrand Disease.* Bethesda, MD: National Institutes of Health Publication 08-5832. December 2007 (released Feb. 29, 2008). http://www.nhlbi.nih.gov/guidelines/vwd.

TREATMENT

Rx

Management of patients with VWD is focused on treatment or prevention of bleeding episodes. There are three main approaches to treatment of VWD that are used individually or in combination: (1) increasing plasma concentration of VWF and FVIII by releasing endogenous VWF stores through stimulation of endothelial cells with DDAVP; (2) replacing or supplementing VWF and FVIII by using human plasma-derived, viral-inactivated concentrates; and (3) promoting hemostasis using hemostatic agents that work by mechanisms other than increasing VWF and FVIII. Regular prophylaxis is seldom required, and treatment is given primarily before and after planned invasive procedures or in response to episodes of bleeding. Table 176-4 outlines usual durations of treatment for a variety of surgical and other invasive procedures.

Desmopressin (DDAVP)

DDAVP (desmopressin: 1-desamino-8-D-arginine vasopressin) is a synthetic derivative of the antidiuretic hormone and causes release of preformed VWF from endothelial cells. It is mainly used in type 1 VWD, is contraindicated for type 2B VWD (because it can cause thrombocytopenia), has limited efficacy for types 2A, 2M, or 2N VWD, and has no efficacy for type 3 VWD. DDAVP is generally administered for short time periods (48 to 72 hours) and usually not more frequently than at 24- to 48-hour intervals, owing to tachyphylaxis and side effects. If it is required for longer periods or more frequently, the patient should be monitored for fluid and electrolyte problems because DDAVP may cause symptomatic hyponatremia. DDAVP therapy is potentially mildly thrombogenic, especially for persons who are at increased risk for atherosclerotic cardiovascular disorders such as stroke or myocardial infarction.

The hemostatic dose of DDAVP is 0.3 µg/kg body weight, infused intravenously over about 30 minutes, or administered subcutaneously; however, a concentrated formulation for the latter is not available in the United States. For outpatients, DDAVP can also be administered nasally, using a concentrated spray (Stimate, CSL Behring) that delivers 150 µg per nostril (300 µg total dose for persons ≥50 kg body weight). Peak increments of plasma VWF and FVIII occur about 1 to 2 hours after DDAVP, typically reaching two- to four-fold higher levels than at baseline, and decline toward baseline during the next 24 hours, reflecting VWF and FVIII plasma half-lives that are about 12 hours on average. However, plasma half-lives depend on the specific VWF subtype and phenotype and also vary considerably among individuals. Because of variability in response, before therapy with DDAVP, it is important to perform a treatment trial with pharmacokinetic monitoring of VWF and FVIII, measuring baseline (pre-DDAVP) and peak (~1 hour post-DDAVP) levels, supplemented with testing about 4 to 6 hours after DDAVP if shortened survival of endogenous VWF is a consideration. A DDAVP treatment trial with extended monitoring can also help diagnose VWD variants with intrinsically heightened VWF clearance. Because of the problem of rapid tachyphylaxis, the trial of DDAVP should be performed at least 1 to 2 weeks before an elective procedure.

Factor Replacement Therapy

Alphanate SD/HT (Grifols), Humate-P (CSL Behring), and Wilate (Octapharma) are U.S. Food and Drug Administration–approved plasma-derived VWF concentrates for treatment of VWD by intravenous infusions. They also contain FVIII but differ in VWF/FVIII ratios and in content of large (high-molecular-weight) VWF multimers. Other VWF-containing concentrates include Koate-DVI (Talecris) and Wilfactin (LFB, France), which lacks FVIII (endogenous levels of which rise secondarily within a few hours after infusion) and is not available in the United States. Cryoprecipitate is no longer recommended for VWF (or for FVIII) replacement, and its use should be limited to urgent situations when VWF concentrates are not available.

Table 176-5 outlines dosing and laboratory monitoring recommendations for treatment or prevention of bleeding in patients with VWD. Whenever possible, and particularly for individuals with more severe forms of VWD, major surgeries or bleeding events should be managed in hospitals with appropriate laboratory capability and clinical staff, including a hematologist and a surgeon skilled in the management of bleeding disorders.

Other Hemostatic Agents

Epsilon-aminocaproic acid and tranexamic acid are oral (or intravenous) antifibrinolytic agents that are useful for mucous membrane bleeding such as dental procedures. Antifibrinolytic therapy is potentially thrombogenic, particularly in patients who have coexisting disseminated intravascular coagulation (DIC) or advanced liver disease (Chapter 178), and caution should be applied for use. Topical agents such as bovine or human thrombin, or fibrin sealants, may be indicated for accessible bleeding sites.

Treatment with combined oral contraceptive pills can ameliorate menorrhagia in women with VWD, mediated partly by hormonal effects on uterine tissues as well as by elevating blood VWF and FVIII. Contraceptive hormonal skin patches have similar effects, and either type of therapy can also increase the risk for thromboembolic events. The levonorgestrel-releasing intrauterine device is an alternative to oral or skin-patch hormonal agents. For pregnancy and delivery in women with VWD, it is important to ensure that VWF and FVIII levels are normalized at the time of delivery, either spontaneously (which often occurs) or by therapy, including before administration of epidural anesthesia and postpartum.

ACQUIRED VON WILLEBRAND SYNDROME

AVWS refers to deficiencies or defects in VWF concentration, structure, or function that are not inherited but are consequences of other medical disorders. AVWS is less common than congenital (hereditary) VWD and is typically etiologically associated with several different mechanisms and medical conditions (Table 176-6).

Laboratory findings in AVWS are similar to those in congenital VWD (types 1, 2A, or 3). Although VWF:RCo values are typically decreased in AVWS (with variably decreased VWF:Ag or FVIII), sometimes only VWF multimer analysis is abnormal, with mild to moderate reduction or loss of the highest-molecular-weight (largest) multimers. This latter situation is more

TABLE 176-6 CAUSES OF ACQUIRED VON WILLEBRAND SYNDROME

PATHOPHYSIOLOGIC CATEGORY*	DISEASE OR ASSOCIATION
Antibodies to VWF	Monoclonal gammopathies, lymphoproliferative disorders, or autoimmune diseases such as systemic lupus erythematosus
Shear-induced VWF conformational changes leading to increased proteolysis of VWF	Aortic valvular stenosis, ventricular septal defect, hypertrophic obstructive cardiomyopathy, left ventricular assist device, or primary pulmonary hypertension
Markedly elevated blood platelet count	Essential thrombocythemia, polycythemia vera, myeloid metaplasia with myelofibrosis, or other myeloproliferative disorders
Removal of VWF from circulation by aberrant binding to tumor cells	Wilms' tumor and certain lymphoproliferative or plasma cell proliferative disorders
Decreased VWF synthesis	Hypothyroidism
Drugs associated with AVWS	Ciprofloxacin, valproic acid, hydroxyethyl starch or griseofulvin

*Pathophysiologic categories are listed in descending order of approximate prevalence.
AVWS = acquired von Willebrand syndrome; VWF, von Willebrand factor.
Adapted and modified from Nichols WL, Rick ME, Ortel TL, et al. Clinical and laboratory diagnosis of von Willebrand disease: a synopsis of the 2008 NHLBI/NIH guidelines. *Am J Hematol.* 2009;84:366-370.

likely for AVWS associated with enhanced VWF proteolysis reflecting shear-induced conformational changes in VWF leading to increased proteolysis of VWF by ADAMTS13, such as with severe aortic valvular stenosis and other conditions causing abnormally high shear forces somewhere in the circulation (see Table 176-6). Heyde's syndrome refers to AVWS caused by severe aortic stenosis and accompanied by gastrointestinal bleeding from arteriovenous malformations.

AVWS, and disorders causing it, should be considered in individuals found to have abnormal VWF test results and bleeding symptoms, without a personal or family history consistent with hereditary VWD. Conversely, when bleeding occurs in association with one of the known causative conditions, AVWS should be considered and initial VWD testing performed if indicated.

TREATMENT Rx

Treatment of AVWS should be focused first on elimination or amelioration of the associated causative disorder, if amenable to treatment (e.g., aortic valve replacement or repair for Heyde's syndrome). Survival of both endogenous and infused VWF is often shortened in AVWS, and replacement therapy should be monitored with measurement of plasma VWF (VWF:RCo and VWF:Ag) and FVIII. For AVWS due to immunoglobulin G MGUS (monoclonal gammopathy of undetermined significance), intravenous immunoglobulin infusion may temporarily normalize plasma VWF and FVIII and stop abnormal bleeding by abrogating heightened VWF clearance. However, such treatment reflects an off-label product use.

BLEEDING DUE TO QUALITATIVE PLATELET DISORDERS

Hereditary Platelet Bleeding Disorders

Hereditary defects in platelet function can occur at all stages of the linked sequence of events involved in hemostatic platelet activation at sites of vascular injury, as described in Chapter 174: (1) platelet adhesion (Bernard-Soulier syndrome [BSS]), (2) platelet release reaction (storage pool disorders), and (3) platelet aggregation (Glanzmann's thrombasthenia [GT]). They lead to varying levels of severity of bleeding.

BERNARD-SOULIER SYNDROME AND GLANZMANN THROMBASTHENIA

These rare, autosomally recessive platelet hypofunctional disorders typically manifest moderately severe (minimally provoked or spontaneous) mucocutaneous bleeding symptoms during childhood and beyond as well as abnormal bleeding with hemostatic challenges such as surgery. BSS results from deficiency or dysfunction of the platelet membrane glycoprotein (GP) Ib-IX-V complex that is the principal receptor for binding VWF, mediating platelet adhesion to injured blood vessels. (In some ways, therefore, BSS is the platelet counterpart of VWD as an adhesion defect, the latter being caused by an abnormality in the VWF rather than the platelets.) GT reflects deficiency or dysfunction of the platelet GPIIb-IIIa complex that is the principal receptor for binding plasma fibrinogen, mediating platelet aggregation. The platelet count and morphology are normal in GT, but BSS demonstrates moderate thrombocytopenia and enlarged (giant) platelets. BT or PFA-100 test results are typically markedly abnormal in both disorders, but nonspecific. Platelet aggregometry findings are usually diagnostic. BSS demonstrates absence of aggregation response to ristocetin, whereas responses to other agonists are relatively normal. GT demonstrates relatively normal response to ristocetin, contrasting with complete absence of aggregation response to other agonists, such as adenosine diphosphate, collagen, arachidonic acid, and epinephrine. Quantitative analysis of platelet membrane GPs by flow cytometry is evolving as a supplemental diagnostic tool for BSS and GT. Mutational DNA-based testing is primarily a research endeavor.

PLATELET STORAGE POOL DISORDERS

Platelet dense (δ) granule storage pool deficiency (DG-SPD) is more common than BSS and GT. Inheritance is typically autosomal recessive, or occasionally dominant, with evolving understanding of different mutational causes. Bleeding symptoms are usually mild but may be clinically significant. Hermansky-Pudlak syndrome (HPS) describes oculocutaneous albinism associated with platelet DG-SPD, with a propensity to develop pulmonary fibrosis or granulomatous colitis. DG-SPD can accompany some other hereditary disorders such as the X-linked Wiskott-Aldrich syndrome, in which it is associated with microthrombocytopenia, or Chédiak-Higashi syndrome with partial albinism and leukocyte inclusions. Isolated DG-SPD, including HPS, demonstrates normal blood platelet count and morphology by peripheral blood smear review. Results of BT, PFA-100, or platelet aggregometry testing may or may not be abnormal. Platelet content and secretion of adenosine triphosphate are decreased in DG-SPD, and platelet electron microscopy can diagnostically confirm absence or marked decrease of dense granules; however, these tests have limited availability.

Platelet α-granule deficiency manifests as the gray platelet syndrome, which is typically autosomal recessive in inheritance and may result in mild bleeding symptoms. Moderate thrombocytopenia is present, and peripheral blood smear review is usually diagnostic, demonstrating enlarged platelets that are "gray" (absence of granulomere staining, reflecting absence of α granules and their contents that include VWF). X-chromosome-linked mutations of *GATA1*, the gene encoding a transcription factor essential for erythropoiesis and megakaryocytopoiesis, can cause a gray platelet syndrome–like disorder affecting males.

OTHER HEREDITARY PLATELET HYPOFUNCTIONAL DISORDERS

Hereditary platelet secretion disorders (defective release of α- and δ-granule contents without granule deficiency) comprise a variety of abnormalities affecting various platelet receptors or mechanisms of signal transduction and platelet activation, including defective platelet procoagulant activity, with or without thrombocytopenia or other syndromic features, and with variable bleeding propensity and symptoms. Some of these disorders are reviewed in Chapter 175.

TREATMENT Rx

For treating or preventing major bleeding events (e.g., certain surgical challenges), judicious use of platelet transfusion may be indicated for patients with more severe hereditary platelet bleeding disorders such as BSS and GT. To reduce the risk for platelet alloimmunization, single-donor apheresis platelet concentrates are preferred when available, and HLA-matched transfusions may sometimes be indicated. DDAVP administration has been reported to improve hemostasis in DG-SPD, BSS, and some other hereditary platelet disorders. Treatment with recombinant activated coagulation factor VII (NovoSeven, NovoNordisk) has been reported as an alternative or salvage therapy for bleeding in GT and certain other platelet hypofunctional disorders. Antifibrinolytic therapy with epsilon-aminocaproic acid or tranexamic acid can be useful for dental extractions or for surgical procedures involving other tissues with high intrinsic fibrinolytic activity (e.g., nose, mouth and throat, extraocular tissues).

Acquired Platelet Bleeding Disorders

DRUGS

Drugs are a relatively common cause of platelet hypofunction that can result in mild bleeding symptoms, particularly if other bleeding propensities are present, such as thrombocytopenia. Aspirin, thienopyridines (e.g., clopidogrel, prasugrel, ticagrelor), dipyridamole, and inhibitors of platelet GPIIb/IIIa function are used therapeutically or prophylactically for atherosclerotic cardiovascular disorders such as coronary artery or cerebrovascular disease. In addition to aspirin, other NSAIDs can inhibit platelet arachidonic acid metabolism (Chapter 36) and contribute to bleeding. Other agents that may sometimes impair platelet function include certain selective serotonin reuptake inhibitors or antibiotics and some herbal or nutritional supplements. Laboratory testing for platelet hypofunction is not often indicated and may not yield diagnostic findings.

OTHER ACQUIRED PLATELET BLEEDING DISORDERS

Myelodysplastic or myeloproliferative disorders can sometimes manifest intrinsic platelet hypofunction, disproportionate to thrombocytopenia or thrombocytosis when they are present. Cirrhosis or liver failure can cause platelet hypofunction as well as thrombocytopenia. Uremia may induce platelet hypofunction that can be ameliorated by dialysis and erythropoietin therapy. Antibodies causing autoimmune thrombocytopenia (Chapter 175) can sometimes cause acquired platelet hypofunction (e.g., acquired GT or BSS) in addition to the low platelet count.

TREATMENT Rx

Review of patient medicaments and medical conditions, and modifications of them when feasible and indicated, can often suffice for recognition and management of acquired platelet hypofunctional disorders.

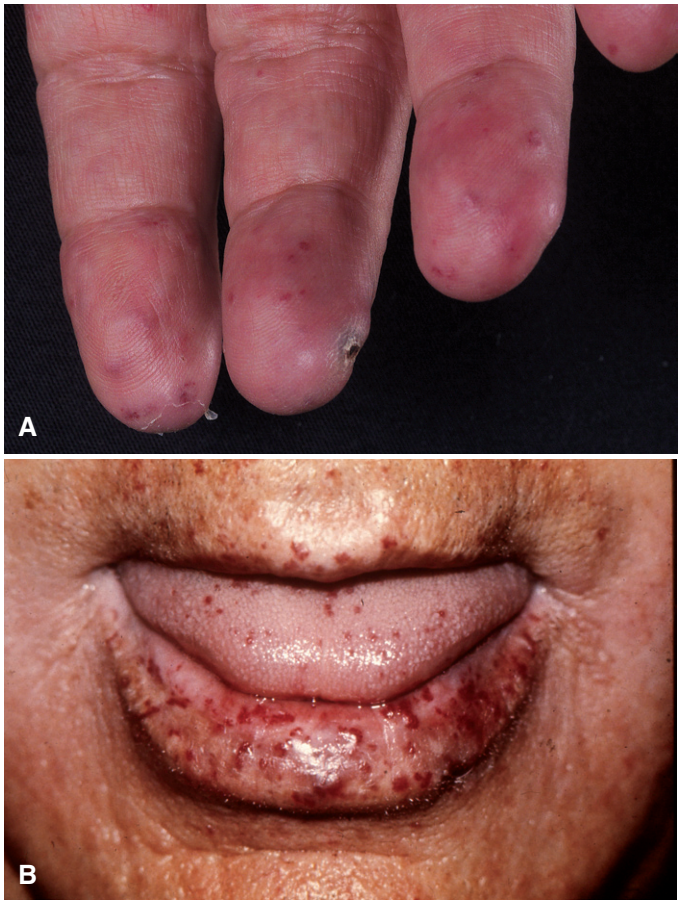

FIGURE 176-1. Hereditary hemorrhagic telangiectasia (HHT). Telangiectasias commonly occur on the face, lips, tongue, and fingers as well as in other areas, including nasal and gastrointestinal mucosa, and may develop in certain other internal organs. Skin or mucous membrane lesions typically blanch with pressure, in contrast to petechiae that do not. (**A,** Copyrighted and used with permission of the Mayo Foundation for Medical Education and Research, all rights reserved. **B,** Courtesy of Dr. Andrew Schafer.)

VASCULAR HEMORRHAGIC DISORDERS

Hereditary Vascular Hemorrhagic Disorders

Hereditary hemorrhagic telangiectasia (HHT), also called Osler-Weber-Rendu syndrome, is an autosomal dominant vascular disorder characterized by development of telangiectases and arteriovenous malformations in the skin, mucous membranes, and certain viscera (especially the central nervous system, lung, and liver), with a propensity for severe recurring nosebleeds and gastrointestinal bleeds resulting in chronic anemia and iron deficiency. Diagnosis primarily relies on physical examination (Fig. 176-1). Several mutations in two genes have been described: endoglin in HHT type 1 and activin receptor-like kinase-1 (ALK1) in HHT type 2. These genes encode proteins that modulate transforming growth factor-β signaling in vascular endothelial cells, and mutations in them in HHT lead to the development of fragile telangiectatic vessels and arteriovenous malformations. Molecular DNA-based testing has limited availability. Supportive treatment includes supplemental iron therapy for iron deficiency anemia. In a small randomized trial, tamoxifen (20 mg per day for 6 months) significantly reduced bleeding in patients with recurrent epistaxis caused by HHT.■

Ehlers-Danlos syndrome is caused by mutations in genes encoding fibrillar collagen or related genes and includes at least six subtypes that vary in clinical manifestations, severity, and prognosis. Inheritance is primarily autosomal dominant. Principal manifestations of Ehlers-Danlos syndrome include skin or joint hyperextensibility, with an associated bleeding tendency including easy bruisability (purpura), surgical bleeding, poor wound healing, and menorrhagia in women. Diagnosis depends mainly on physical examination, supplemented with molecular DNA-based testing that currently has limited availability.

Acquired Vascular Hemorrhagic Disorders

Systemic amyloidosis, Waldenström's macroglobulinemia, and cryoglobulinemia are dysproteinemic disorders reflecting monoclonal gammopathies or hyperglobulinemias (Chapters 193 and 194) that can manifest purpuric or other bleeding symptoms caused by either vascular deposition of immunoglobulin fragments (amyloidosis) or inhibition of platelet-vessel hemostatic functions by immunoglobulins. Henoch-Schönlein purpura is primarily a transient disease of children that typically presents with a palpable purpuric rash of the lower extremities, arthralgias, abdominal pain and renal symptoms (hematuria, proteinuria) in some cases, manifestations of a systemic vasculitis characterized by deposition of immunoglobulin A–containing immune complexes in the skin, gastrointestinal tract, and kidneys. Palpable purpura can also result from systemic sepsis or DIC. Scurvy is caused by the effects of vitamin C deficiency on collagen structure and often presents with bruising or petechiae, including tiny perifollicular hemorrhages. Senile purpura or purpura simplex is thought to reflect partly the age-related changes of skin vascular structure and is typified by easy bruisability of the dorsa of the hands, forearms, and lower legs. Psychogenic purpuras are controversial entities that include Gardner-Diamond syndrome, which is characterized by recurring focal pain preceding development of ecchymoses, believed to reflect poorly understood psychosomatic mechanisms. It can be difficult to differentiate this rare syndrome from factitious or self-induced purpura and bleeding.

HEMORRHAGIC DISORDERS: COAGULATION FACTOR DEFICIENCIES

MARGARET V. RAGNI

COAGULATION DEFICIENCIES

Severe coagulation deficiencies, or coagulopathies, are typically characterized by spontaneous or traumatic bleeding, such as during surgery or trauma, and may result in life- or limb-threatening complications. By contrast, moderate and mild coagulopathies may remain clinically silent until they are detected coincidentally on routine laboratory screening tests (e.g., prothrombin time [PT], activated partial thromboplastin time [aPTT]) or when these tests are ordered to evaluate the cause of abnormal bleeding or bruising. Much of the morbidity of coagulopathies can be minimized or avoided altogether by prophylactic replacement of the deficient clotting factor proteins. In contrast to the lifelong clinical manifestations of hereditary or congenital coagulopathies, acquired deficiencies usually appear acutely in previously asymptomatic individuals; they may not be suspected and often remit spontaneously or after eradication of an inciting disease state or withdrawal of an offending medication. Acquired coagulation disorders may be associated with more severe bleeding than congenital disorders, in part because of the delay in diagnosis. In general, coagulopathies may result from inadequate synthesis of coagulation factor proteins or from inhibition of activated clotting factor proteins by acquired antibodies or anticoagulant medications. Finally, qualitative defects, either congenital or acquired, may also result in bleeding.

Hereditary Hemophilias

DEFINITION

The hemophilias include hemophilia A and hemophilia B, caused by deficiencies or defects in clotting factor VIII (antihemophilic factor) and factor IX (antihemophilic factor B, or Christmas factor), respectively. A deficiency of either of these intrinsic coagulation pathway proteins results in inadequate formation of thrombin at sites of vascular injury.

EPIDEMIOLOGY

Hemophilia A and B are sex-linked recessive disorders estimated to occur in 1 in 5000 and 1 in 30,000 male births, respectively. The higher incidence of hemophilia A may be due to the greater amount of DNA "at risk" for mutation in the factor VIII gene (186,000 base pairs) compared with the factor IX gene (34,000 base pairs). Hemophilia A and B are observed in all racial and ethnic groups, and, in the United States, more than 20,000 individuals are affected. Although carrier testing, genetic counseling, and prenatal diagnosis are widely available in the United States through the network of federally funded hemophilia treatment centers (HTCs), fecundity rates remain high, and few confirmed carriers elect to terminate their pregnancies, even if an affected fetus is detected in utero. These decisions are likely influenced by the wide availability of safe and effective coagulation factor replacement concentrates and by the prospect of an eventual cure for the hemophilias through gene transfer. A substantial proportion (30%) of hemophilia cases arise as new, spontaneous mutations. Overall, the hemophilias are much more common than the autosomal recessive coagulation disorders (see later), which often affect progeny from consanguineous relationships and require the inheritance of two defective alleles for the bleeding manifestations to become evident.

PATHOBIOLOGY

Genetics

As with other sex-linked recessive diseases, the genes for factor VIII and factor IX are located on the long arm of the X chromosome. Males with a defective allele on their single X chromosome transmit this gene to all their daughters, who are obligate carriers, but to none of their sons. Because the offspring of female carriers inherit one affected X chromosome, half of their sons develop the coagulation disorder, and half of their daughters are obligate carriers. Female carriers may manifest hemophilia-like symptoms if the alleles on the X chromosome are unequally inactivated (lyonization); the defective hemophilic allele is expressed in preference to the normal allele, plasma factor VIII levels are below 50%, and phenotypic hemophilia results. Female hemophilia may arise as a result of mating between a hemophilic male and a female carrier (homozygous for the defective factor VIII or IX gene) or in carrier females who have the 45 XO karyotype (Turner's syndrome) and are hemizygous for the defective hemophilia gene.

No single mutation is responsible for the hemophilias. Many missense and nonsense point mutations, deletions, and inversions have been described. Severe molecular defects predominate, with 40 to 50% of all cases of severe hemophilia A evolving from a unique inversion of intron 22 (the largest of the factor VIII introns). This inversion results from the recombination and translocation of DNA within intron 22 of the factor VIII gene, with areas of extragenic but homologous "nonfunctional" DNA located at a distance from intron 22. Other less common severe molecular defects include large gene deletions (5 to 10% of cases) and nonsense mutations (10 to 15% of cases). The encoded proteins resulting from these mutations are defective and do not express any factor VIII activity. Mild or moderate hemophilia A is commonly associated with point mutations and deletions. In contrast, factor IX mutations are more diverse, and severe hemophilia B is more likely caused by large deletions. Hemophilia B also may result from mutations that alter the γ-glutamyl residues of the factor IX protein, which normally become carboxylated through a vitamin K–dependent process and are then assembled on a phospholipid surface for eventual activation. Mutated clotting factor genes responsible for the hemophilias may also encode for the production of defective nonfunctional proteins that circulate in the plasma and are detected at normal quantitative levels by immunoassays but not by functional assays. A listing of the mutations that cause the hemophilias can be accessed via the Human Gene Mutation Database (*www.hgmd.org*). Designated cross-reacting material, these proteins have no clinical relevance except that individuals without cross-reacting material may be more susceptible to alloantibody inhibitor formation.

CLINICAL MANIFESTATIONS

Hemophilia A and hemophilia B are said to be clinically indistinguishable, with clinical severity corresponding inversely to the circulating levels of plasma coagulant factor VIII or IX activity. Several studies have found a higher bleeding frequency, greater factor use, and more frequent hospitalizations in hemophilia A, suggesting a greater clinical severity than hemophilia B. Individuals with less than 1% of normal factor VIII or IX activity are classified as having "severe" disease, characterized by frequent spontaneous bleeding events in joints (hemarthrosis) and soft tissues and by profuse hemorrhage with trauma or surgery. Although spontaneous bleeding is uncommon in mild deficiencies (>5% normal activity), excess bleeding typically occurs with trauma or surgery. A moderate clinical course is associated with factor VIII or IX levels between 1 and 5%. Approximately 60% of all cases of hemophilia A are clinically severe, whereas only 20 to 45% of cases of hemophilia B are severe.

Severe hemophilia is typically suspected and diagnosed during infancy in the absence of a family history. Among newborns, intracranial hemorrhage is the leading cause of morbidity and mortality, with a cumulative incidence of 3.8%, according to data collected by the Centers for Disease Control and Prevention. Intracranial hemorrhage does not appear to be related to the mode of delivery, although half of such hemorrhages occur in the newborn period; whether prospective computed tomography screening should be instituted at birth remains unknown. Vacuum extraction may increase cephalohematoma formation and is discouraged. Circumcision within days after birth is accompanied by excessive bleeding in less than half of severely affected boys. The first spontaneous hemarthrosis in severely affected hemophiliacs usually occurs between 9 and 18 months of age, when ambulation begins; in moderately affected individuals, it generally does not occur until 2 to 5 years of age. The knees are the most prominent sites of spontaneous bleeds, followed by the elbows, ankles, shoulders, and hips; wrists are less commonly involved.

Acute hemarthroses (Fig. 177-1) originate from the subsynovial venous plexus underlying the joint capsule and produce a tingling or burning sensation, followed by the onset of intense pain and swelling. On physical examination, the joint is swollen, hot, and tender to palpation, with erythema of the overlying skin. Joint mobility is compromised by pain and stiffness, and the joint is usually maintained in a flexed position. Immediate or early replacement of the deficient clotting factor to normal hemostatic levels rapidly

FIGURE 177-1. Acute hemarthrosis of the knee is a common complication of hemophilia. It may be confused with acute infection unless the patient's coagulation disorder is known, because the knee is hot, red, swollen, and painful. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

FIGURE 177-2. Severe chronic arthritis in hemophilia. The knee is the most commonly affected joint. Both knees are severely deranged in this patient. Note that he is unable to stand with both feet flat on the floor. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

reverses the pain. Delayed treatment results in excess pain, morbidity, and joint damage. Optimal management includes rest, ice, (factor) concentrate, and elevation (RICE). Swelling and joint immobility improve as the intra-articular hematoma resolves. Intra-articular needle aspiration of fresh blood is not recommended because of the risk of introducing infection. Short courses of oral corticosteroids may be helpful to reduce the acute joint symptoms in children but are rarely used in adults.

Recurrent or untreated bleeds result in chronic synovial hypertrophy and, eventually, damage to the underlying cartilage, with subsequent subchondral bone cyst formation, bony erosion, and flexion contractures. The intra-articular iron deposited in hemarthroses may activate oncogenes, which subsequently stimulate synovial proliferation. Abnormal mechanical forces from weight bearing can produce subluxation, misalignment, loss of mobility, and permanent deformities of the lower extremities (Fig. 177-2). These changes are accompanied by chronic pain, swelling, arthritis, and disability. Plain radiographs and clinical examination of chronic hemarthroses often underestimate the extent of bone and joint damage; serial magnetic resonance imaging is superior to radiography or computed tomography and is the most sensitive and specific means of detecting and monitoring early and progressive disease.

Intramuscular hematomas account for about 30% of hemophilia-related bleeding events and are rarely life threatening. They are usually precipitated by physical or iatrogenic trauma (e.g., after intramuscular injections) and may compromise sensory and motor function or arterial circulation if they entrap and compress vital structures in closed fascial compartments. The latter occurrence, termed *compartment syndrome*, presents with the rapid onset of swelling and severe pain in an extremity, unrelieved by factor infusion and standard analgesics. This is considered a medical emergency and may require fasciotomy to preserve tissue and provide pain relief. Retroperitoneal hematomas may be confused clinically with appendicitis or hip bleeds but should be suspected in a patient who is hunched over and unable to stand erect owing to the pain of muscle extension in the presence of hematoma. Unless these bleeding episodes are treated immediately and aggressively, permanent anatomic deformity, such as flexion contracture, nerve damage, or pseudotumor formation (expanding hematomas that erode and destroy adjacent skeletal structures), may occur. Bleeding from mucous membranes is very common and may be exaggerated by the degradation of fibrin clots by fibrinolytic enzymes contained in secretions. Bleeding involving the tongue or the retropharyngeal space may rapidly produce life-threatening compromise of the airway. Gastrointestinal hemorrhage typically originates from anatomic lesions proximal to the ligament of Treitz and may be exacerbated by esophageal varices secondary to cirrhosis and portal hypertension or by the use of nonsteroidal anti-inflammatory drugs (NSAIDs) for the treatment of hemarthroses. Spontaneous bleeding in the genitourinary tract secondary to hemophilia is a diagnosis of exclusion after ruling out renal stones and infection. Ureteral blood clots produce renal colic, which may be confused with nephrolithiasis and may be worsened by the use of antifibrinolytic agents. A short course of steroids may be helpful, especially in children, to hasten their resolution. Ninety percent of hemophiliacs experience at least one episode of gross hematuria or hemospermia.

Intracranial bleeds occur in 10% of patients, are usually induced by trauma, and may be fatal in 30% of cases. The risk of developing an intracranial hemorrhage is approximately 2% per year. Neuromuscular defects, seizure disorders, and intellectual deficits may ensue.

Individuals with hemophilia cared for at HTCs have lower mortality and reduced costs of care compared with those receiving treatment elsewhere. The chronic care model practiced at HTCs emphasizes prevention to reduce joint disease and complications, optimization of factor dosing, and counseling regarding safe sports and the avoidance of aspirin and other drugs that inhibit platelet function.

DIAGNOSIS

The diagnosis of hemophilia is suspected on the basis of a family and personal bleeding history and laboratory detection of prolongation of the aPTT (with normal PT). It is confirmed by significantly reduced plasma factor VIII or IX activity. As noted in Chapter 174, the aPTT is not a sufficiently sensitive screening test to be prolonged in mild hemophiliacs, in whom the factor VIII level is sometimes greater than 30% of normal. Therefore, if mild hemophilia is clinically suspected in an individual with a normal aPTT, a specific factor VIII level should be measured. Severe hemophilia is usually recognized in infancy, with circumcision bleeding; by contrast, moderate or mild disease is recognized later in life after trauma or surgery. Hemophilia can be distinguished from von Willebrand disease (VWD; Chapter 176) by normal ristocetin cofactor and von Willebrand factor antigen levels. In type 2N VWD, factor VIII is significantly lower than ristocetin cofactor and von Willebrand factor antigen levels due to reduced factor VIII binding; this variant of VWD may require genotyping to distinguish it from hemophilia A. Other congenital intrinsic factor deficiencies (e.g., factor XI and XII) can be determined by coagulation factor–specific assays. Vitamin K deficiency (see later and Chapter 178) can be detected by the associated PT prolongation; combined deficiencies of factors II, VII, IX, and X; and resolution of the coagulation defect with vitamin K. The presence of heparin can be confirmed by correction of the aPTT after running the sample over a heparin absorption column. Failure of the aPTT to correct in a 1 : 1 mix with normal plasma suggests the presence of an inhibitor; specific inhibitors are associated with a single decreased factor level (usually factor VIII; see Alloantibody Inhibitors to Factors VIII and IX under Treatment), whereas blocking inhibitors cause nonspecific factor level changes associated with a positive hexagonal lipid assay (see Antiphospholipid Syndrome and Lupus Anticoagulant later).

TREATMENT

Rx

Treatment and prevention of acute bleeding events in hemophilia A and B are based on replacement of the missing or deficient clotting factor protein to restore adequate hemostasis (E-Table 177-1). The morbidity, mortality, and overall cost of care for individuals with hemophilia are reduced significantly if care is provided by comprehensive HTCs that have the multispecialty expertise and laboratory capabilities to coordinate and monitor specific patient needs.

The goal of replacement therapy (Table 177-1) is to achieve plasma factor VIII and IX activity levels of 25 to 30% for minor spontaneous or traumatic

E-TABLE 177-1 FDA-APPROVED CLOTTING FACTOR CONCENTRATES FOR HEMOPHILIA A AND B AVAILABLE IN THE UNITED STATES

VIRUCIDAL TECHNIQUE	TYPE/NAME OF PRODUCT (MANUFACTURER)	SPECIFIC ACTIVITY (IU/MG PROTEIN AFTER ADDITION OF STABILIZER)
RECOMBINANT FACTOR VIII CONCENTRATES		
First generation: immunoaffinity chromatography	Recombinate (Baxter); synthesized in CHO cell lines; human albumin added as stabilizer	1.65-19
Second generation: albumin-free final formulation; solvent detergent viral attenuation (TNBP/Triton X100); ion exchange chromatography; nanofiltration	Refacto (Wyeth); B-domain-deleted molecule; synthesized in CHO cell lines; sucrose added as stabilizer	9.110-13,700
Second generation: albumin-free final formulation; immunoaffinity chromatography; solvent detergent viral attenuation (TNBP/polysorbate 80); ultrafiltration	Kogenate FS (Bayer Inc.), Helixate FS (Bayer Inc. for ZLB Behring Inc.); both synthesized in baby hamster kidney cell lines; sucrose added as stabilizer	4000
Third generation: no human or animal protein used in the culture medium or manufacturing process; immunoaffinity and ion exchange chromatography; solvent detergent viral attenuation (TNBP/polysorbate 80)	Advate (Baxter); synthesized in CHO cell lines; trehalose added as stabilizer	4000-10,000
Third generation: no human or animal protein used in the culture medium or manufacturing process	Xyntha (Baxter); synthesized in CHO cell lines; sucrose added as stabilizer	5500-9900
PLASMA-DERIVED FACTOR VIII CONCENTRATES		
Immunoaffinity chromatography and pasteurization (60° C, 10 hr)	Monoclate P (CSL Behring Inc.)	5-10
Immunoaffinity chromatography, solvent detergent (TNBP/Octoxynol 9)	Hemofil M (Baxter), Monarc M (Baxter, from American Red Cross–collected plasma)	2-20
PLASMA-DERIVED FACTOR VIII AND VON WILLEBRAND'S FACTOR–CONTAINING CONCENTRATES		
Affinity chromatography, solvent detergent (TNBP/ polysorbate 80), and terminal dry heating (80° C, 72 hr)	Alphanate SD (Grifols Inc.); contains functional VWF protein	>5
Solvent detergent; terminal dry heating (80° C, 72 hr)	Koate-DVI (Talecris); contains functional VWF protein	9-22
Pasteurization (heating in solution, 60° C, 10 hr)	Humate-P (CSL Behring, GmbH, Marberg, Germany); contains functional VWF protein	1-2
RECOMBINANT FACTOR IX CONCENTRATE		
Affinity chromatography and ultrafiltration	BeneFIX (Wyeth); CHO cell lines maintained in fetal calf serum-free medium; sucrose added as stabilizer	200-360
PLASMA-DERIVED FACTOR IX CONCENTRATES		
Dual-affinity chromatography, solvent detergent (TNBP/polysorbate 80), and nanofiltration (viral filter)	AlphaNine SD (Grifols Inc.)	>150
Monoclonal antibody immunoaffinity chromatography, solvent detergent (sodium thiocyanate), and ultrafiltration	Mononine (CSL Behring Inc.)	>190
PLASMA-DERIVED FACTOR IX COMPLEX CONCENTRATES		
Solvent detergent (TNBP/polysorbate 80)	Profilnine SD (Grifols Inc.)	4.5
Vapor heat (10 hr, 60° C, 190 mbar pressure plus 1 hr, 80° C, 375 mbar)	Bebulin VH (Baxter, Vienna)	2.0
ACTIVATED PLASMA-DERIVED PROTHROMBIN COMPLEX CONCENTRATES (ANTI-INHIBITOR COAGULATION COMPLEX FOR USE IN PATIENTS WITH INHIBITORS TO FACTOR VIII OR IX)		
Vapor heat (10 hr, 60° C, 190 mbar plus 1 hr, 80° C, 375 mbar)	FEIBA VH (Baxter, Vienna)	0.8
RECOMBINANT FACTOR VIIA (FOR USE IN PATIENTS WITH INHIBITORS TO FACTOR VIII OR IX)		
Second generation: affinity chromatography; solvent detergent (TNBP/polysorbate 80)	NovoSeven (Novo Nordisk Inc., Bagsvaerd, Denmark); synthesized in baby hamster kidney cells; solvent (bovine calf serum used in culture medium); albumin-free formulation, mannitol added as stabilizer	50,000

Baxter = Baxter/Immuno Inc.; CHO = Chinese hamster ovary; FDA = U.S. Food and Drug Administration; TNBP = tri(*n*-butyl)phosphate; VWF = von Willebrand's factor; Wyeth = Wyeth/Pfizer Inc.

bleeds (e.g., hemarthroses, persistent hematuria), at least 50% clotting factor activity for the treatment or prevention of severe bleeds (e.g., major dental surgery, maintenance replacement therapy after major surgery or trauma), and 80 to 100% activity for any life-threatening or limb-threatening hemorrhagic event (e.g., major surgery, trauma). After major trauma or if visceral or intracranial bleeding is suspected, replacement therapy adequate to achieve 100% clotting factor activity should be administered *before* diagnostic procedures are initiated. To calculate the initial dose, plasma factor VIII activity generally increases about 2% (0.02 IU/mL) for each unit of factor VIII administered per kilogram of body weight, and factor IX activity increases about 1% (0.01 IU/mL) for each unit of factor IX administered per kilogram of body weight. The initial dose of factor IX diffuses into the extravascular space and binds to endothelial cell surfaces to a much greater degree than is observed with factor VIII. Therefore, a 70-kg individual with severe hemophilia A or B (factor VIII or IX activity <1% of normal) who requires replacement to 100% activity for major surgery should initially receive 3500 IU of factor VIII or 7000 IU of factor IX concentrate. The circulating half-lives of factors VIII and IX require subsequent dosing at half the initial dose every 8 to 12 hours and every 18 to 24 hours, respectively. However, this empirical dosing (based on calculations) should be individualized according to the peak recovery increment within 10 to 15 minutes after bolus infusion, as well as trough activity levels. The frequency of repeat dosing is also determined by the rapidity of pain relief, recovery of joint function, and resolution of active bleeding. Replacement is usually maintained for 10 to 14 days after major surgery to allow proper wound healing. Bolus dosing typically results in wide fluctuations in clotting factor activity levels and requires frequent laboratory monitoring to avoid suboptimal troughs. A continuous infusion regimen, consisting of 1 to 2 IU of factor VIII or IX concentrate per kilogram per hour after a bolus dose, maintains a plateau level without the need for frequent laboratory testing. Continuous infusion also reduces total concentrate consumption by 30 to 75% in surgical settings. Long-acting recombinant factors VIII and IX, linked to the Fc domain of immunoglobulin G (IgG) or to liposomes, are currently in clinical trials. If these preparations

TABLE 177-1 FDA-APPROVED COAGULATION PROTEINS AND REPLACEMENT THERAPIES AVAILABLE IN THE UNITED STATES

COAGULATION PROTEIN DEFICIENCY	INHERITANCE PATTERN	PREVALENCE	MINIMUM HEMOSTATIC LEVEL	REPLACEMENT SOURCES
Factor I (fibrinogen) Afibrinogenemia Dysfibrogenemia	 Autosomal recessive Autosomal dominant or recessive	 Rare (<300 families) Rare (>300 variants)	50-100 mg/dL	Cryoprecipitate, FFP, fibrinogen concentrate
Factor II (prothrombin)	Autosomal dominant or recessive	Rare (25 kindreds)	30% of normal	FFP, factor IX complex concentrates
Factor V (labile factor)	Autosomal recessive	1 in 1 million births	25% of normal	FFP
Factor VII	Autosomal recessive	1 in 500,000 births	25% of normal	Recombinant factor VIIa (15-20 μg/kg), FFP, factor IX complex concentrates
Factor VIII (antihemophilic factor)	X-linked recessive	1 in 5000 male births	80-100% for surgery/life-threatening bleeds, 50% for serious bleeds, 25-30% for minor bleeds	Factor VIII concentrates (see E-Table 177-1)
Von Willebrand disease Type 1 and 2 variants Type 3	 Usually autosomal dominant Autosomal recessive	 1% prevalence 1 in 1 million births	>50% VWF antigen and ristocetin cofactor activity	DDAVP for mild to moderate disease (except type 2B; variable response to 2A); cryoprecipitate and FFP (not preferred, except in emergencies); factor VIII/VWF concentrates, viral attenuated, intermediate purity (preferred for disease unresponsive to DDAVP and for type 3 (see E-Table 177-1)
Factor IX (Christmas factor)	X-linked recessive	1 in 30,000 male births	25-50% of normal, depending on extent of bleeding, surgery	Factor IX concentrates; FFP not preferred except in dire emergencies (see E-Table 177-1)
Factor X (Stuart-Prower factor)	Autosomal recessive	1 in 500,000 births	10-25% of normal	FFP or factor IX complex concentrates
Factor XI (hemophilia C)	Autosomal dominant; severe type is recessive	4% of Ashkenazi Jews; 1 in 1 million general population	20-40% of normal	FFP or factor XI concentrate
Factor XII (Hageman factor), prekallikrein, high-molecular-weight kininogen	Autosomal recessive	Not available	No treatment necessary	—
Factor XIII (fibrin stabilizing factor)	Autosomal recessive	1 in 3 million births	5% of normal	FFP, cryoprecipitate, or viral-attenuated factor XIII concentrate

DDAVP = desmopressin; FDA = U.S. Food and Drug Administration; FFP = fresh-frozen plasma; VWF = von Willebrand factor.

prolong the circulation times of factors VIII and IX with similar efficacy and safety as standard recombinant products, they may allow simpler dosing schedules and fewer intravenous factor infusions.

Because of the potential thrombogenicity associated with the repeated administration of prothrombin complex concentrates to replace factor IX deficiency, high-purity, plasma-derived, or genetically engineered factor IX concentrates, which lack activated vitamin K–dependent clotting factors, are preferred in hemophilia B.

Cryoprecipitate (a cold precipitate of fresh-frozen plasma [FFP] after thawing at 4° C) and FFP contain factor VIII, but only FFP contains factor IX. However, neither cryoprecipitate nor FFP is an optimal replacement product for either hemophilia A or hemophilia B because these agents may transmit blood-borne pathogens. Plasma-derived clotting factor concentrates are manufactured from the plasma donations pooled from thousands of individual donors and are subjected to various types of viral inactivation techniques. Only lipid-enveloped viruses are susceptible to these procedures. By contrast, non-lipid-enveloped parvovirus B19 and hepatitis A virus, as well as prions (implicated in variant Creutzfeldt-Jakob disease), remain inactivated and may potentially be transmitted by products subjected to these procedures. The safety of these products has been enhanced by deferring the inclusion of first-time donor plasma collections from the plasma pool and by implementing more rigorous and specific viral surveillance of "minipools" (16 individual plasma donors) before manufacture. Nucleic acid amplification testing is used to detect hepatitis C, West Nile virus, hepatitis B, human immunodeficiency virus (HIV-1, HIV-2), and human T-lymphotropic cirus (HTLV-1, HTLV-2); polymerase chain reaction (PCR) testing is used to detect parvovirus B19. Hepatitis B surface antigen is also measured. No assay is available to detect variant Creutzfeldt-Jakob disease in plasma.

All clotting factor concentrates available in the United States (E-Table 177-1), whether plasma derived or genetically engineered, are equally efficacious and are considered extremely safe; none has ever been implicated in the transmission of blood-borne viral pathogens or prions. Newer second- and third-generation recombinant factor VIII and IX concentrates are manufactured free of added human or animal proteins in the culture medium or in the final formulation, eliminating the theoretical risks of transmission of prions or murine viruses.

HEMARTHROSES

The moderate or severe pain that accompanies acute hemarthroses responds to immediate analgesic relief, temporary immobilization, restraint from weight bearing, and clotting factor replacement. Narcotic analgesics, such as codeine or synthetic derivatives of codeine, should be prescribed alone or combined with doses of acetaminophen that are low enough to avoid hepatic toxicity in patients with chronic hepatitis. Although these medications do not possess significant anti-inflammatory activity, they are preferable to NSAIDs or aspirin, which can exacerbate bleeding complications through their inhibition of platelet aggregation. Although cyclooxygenase 2 inhibitors (e.g., celecoxib) may provide effective pain relief for chronic arthritis when used in a dose of 100 to 200 mg once or twice daily in patients without sulfonamide allergy, caution must be exercised not only because of potential arterial thrombosis but also because of severe gastrointestinal bleeding, which may be more common in patients with hemophilia. Alternative approaches that may reduce narcotic consumption include acupuncture, transdermal nerve stimulation, and hypnosis.

Strategies intended to prevent end-stage joint destruction should be initiated at an early age. Although prophylaxis beginning soon after the first bleed is the optimal approach (see later), the majority of adults have not had the benefit of early prophylaxis and thus have advanced arthropathy with reduced motion, disability, and pain, for which surgery may be recommended. Synovectomy through open surgery or arthroscopy removes the inflamed tissue and should result in substantially decreased pain and less recurrent bleeding. Nonsurgical synovectomy (synoviorthosis), which involves the intra-articular administration of a radioisotope, is particularly useful for high-risk patients and for those with alloantibody inhibitors to factor VIII or IX (see later). The occurrence of leukemia in three hemophilic children receiving radioisotopic synoviorthosis has raised concerns about leukemogenesis, especially given the low background rate of cancers in individuals with hemophilia. Neither synovectomy nor synoviorthosis reverses joint damage, but both procedures may delay its progression. Non-weight-bearing exercises, such as swimming and isometrics, are important to periarticular muscle development and

maintenance of joint stability for ambulation. Intractable pain and severe joint destruction secondary to repeated hemorrhage require prosthetic replacement. Chronic ankle pain responds best to open surgical or arthroscopic fixation and fusion (arthrodesis).

The ultimate strategy to minimize or eliminate progressive joint destruction by recurrent hemarthroses is predicated on the concept of prophylaxis—the scheduled administration of clotting factor concentrates several times weekly (twice a week for factor IX, three times a week for factor VIII) at doses to maintain trough factor activity levels greater than 1 to 2% of normal. In a prospective, randomized clinical trial, prophylaxis with factor VIII (25 IU/kg every other day) was superior to episodic therapy (on demand) in young children with severe hemophilia in reducing joint bleeding and joint damage as shown by magnetic resonance imaging and radiography.[1,2] Although prophylaxis uses more factor product at greater expense, the benefits of long-term prophylaxis to promote joint health and avert disability have led to the recommendation that it be initiated in young children with severe disease at the time of the first bleed. Compliance with this recommendation is not easy, given the invasiveness of intravenous factor administration, the requirement for central venous access devices, and the complication of access device infection. With the development of long-acting factor VIII and IX preparations, currently in clinical trials, bleeding management may become less invasive and simpler. Some unanswered questions include whether prophylaxis is necessary in adulthood and what the minimal effective dose is for prophylaxis or for acute bleeds. The risk of bleeding is thought to be related to the time spent at nadir factor levels less than 1% (0.01 IU/mL) between dosing. It is generally agreed that spontaneous bleeding may be averted by maintaining factor levels at 1% (0.01 U/mL) or greater, which is supported by animal studies of factor IX gene therapy.

FACTOR CONCENTRATE–TRANSMITTED VIRAL INFECTIONS

In contrast to other at-risk groups, individuals with hemophilia were exposed at a young age to transmissible agents through clotting factor concentrates. This included hepatitis C virus (HCV), leading to infection in 90% of those transfused from the late 1970s through the mid-1980s, and HIV infection in 80% of those transfused with factor VIII products and 50% of those transfused with factor IX products from 1978 through the mid-1980s. Overall, of those with HCV infection (Chapter 151), 40% have coinfection, and hepatitis C remains the leading cause of death in hemophilia. With the implementation of viral inactivation and recombinant technologies, new HCV and HIV infections have been virtually eliminated in hemophiliacs born since the 1990s. Nevertheless, among those exposed to HCV, a large multicenter biopsy study found that 25% have liver fibrosis, and those with HIV coinfection have a 1.4-fold greater fibrosis rate. Among the latter, those receiving highly active antiretroviral therapy (HAART) experience a significant slowing in the rate of HCV progression, to the rates observed in hemophilic men infected only with HCV.

Hepatitis G, observed in 15 to 25% of hemophiliacs, is susceptible to current viral attenuation procedures. Hepatitis B is now a rare problem for those with hemophilia because vaccination at an early age is the standard of care. Hepatitis A virus was transmitted to a small but significant number of patients through solvent detergent-treated factor VIII and factor IX concentrates in the past; hepatitis A vaccination now eliminates this risk. Parvovirus B19 seroprevalence approaches 80% in older adult hemophiliacs exposed to plasma-derived products. The long-term clinical consequences of hepatitis A and parvovirus B19 are unclear. Nevertheless, their transmission via plasma-derived concentrates highlights the vulnerability of hemophiliacs to blood-borne pathogens that escape viral attenuation processes. Cadaver and living-donor liver transplantation (Chapter 157) has improved the survival of hemophilic men with chronic hepatitis-induced liver failure and has also resulted in the phenotypic cure of hemophilia, confirming that the liver is the predominant source of normal synthesis of factors VIII and IX. Liver transplantation can also be performed successfully in men coinfected with HIV and HCV with a good response to HAART therapy.

ANCILLARY AND OTHER THERAPIES

Ancillary treatment strategies for the hemophilias include antifibrinolytic agents, such as ε-aminocaproic acid (50 mg/kg 3 to 4 times daily) or tranexamic acid (3 or 4 g PO daily in divided doses), to minimize mucous membrane bleeding and the application of fibrin glue to bleeding sites. Desmopressin (DDAVP) can be administered by nasal insufflation 2 hours before a scheduled surgical procedure (one spray per nostril, to provide a total dose of 300 μg; or, in patients weighing <50 kg, 150 μg administered as a single spray); alternatively, DDAVP can be administered intravenously (dissolved in 50 mL normal saline) over 30 minutes at a dose of 0.3 μg/kg. DDAVP is useful in patients with mild hemophilia A because an adequate incremental rise in factor VIII activity can circumvent the use of clotting factor concentrates. Repeated administration of DDAVP (intravenously or by intranasal spray) may be complicated by facial flushing, tachyphylaxis, hyponatremic seizures (primarily in children), and, rarely, angina.

ALLOANTIBODY INHIBITORS TO FACTORS VIII AND IX

Alloantibodies—that is, antibodies to "foreign" infused factor VIII or, less frequently, factor IX—are usually detected in childhood after a median of 9 to 12 days of exposure to clotting factor. These inhibitors occur preferentially in those with a family history of inhibitors and those with large, multidomain factor VIII and factor IX gene deletions. The incidence of factor VIII alloantibodies among hemophilia A patients is 15 to 25%, with a higher frequency in blacks and Hispanics. Factor IX alloantibodies are observed in 1.5 to 3% of hemophilia B patients and predominate among Scandinavians. Patients with factor IX inhibitors seem to be susceptible to anaphylaxis and the development of nephrotic syndrome with subsequent exposure to sources of factor IX. Increasing evidence suggests that exposure to high-dose bolus treatment early in life increases the risk of inhibitor development, especially in those with a predisposition, such as a family history and an at-risk mutation (e.g., a large deletion mutation).

The development of an alloantibody inhibitor is suspected when replacement therapy is ineffective in controlling bleeding symptoms. These IgG antibodies, usually of the IgG4 subclass, completely neutralize clotting factor activity and prevent or reduce any increment in factor VIII or IX levels following bolus infusions of concentrate. Characterized as time and temperature dependent, inhibitors are quantitated in Bethesda units (BU): by definition, 1 BU is the amount of inhibitor that neutralizes 50% of the specific clotting factor activity in normal plasma. "High responders," or patients with high-titer inhibitors (>5 BU), mount an anamnestic antibody response to factor VIII clotting factor protein, usually within 5 to 7 days after subsequent exposure. "Low responders," or patients with low-titer inhibitors (≤5 BU), do not manifest anamnesis. Low-titer inhibitors can easily be overwhelmed by large amounts of human factor VIII or factor IX concentrate, usually three to four times the usual dose.

Treatment of patients with high-titer inhibitors against factor VIII or IX is difficult, and no single approach is uniformly successful. There are two components: first, assurance of hemostasis using "bypass therapy," and second, eradication of inhibitor formation. Hemostasis can be provided by "bypass" agents that are used to treat bleeding episodes (see E-Table 177-1); specifically, the activated prothrombin complex concentrate FEIBA VH (75 to 100 IU/kg initially, then 50 to 100 IU/kg every 6 to 8 hours) and recombinant factor VIIa (90 μ/kg every 2 to 3 hours) can be administered until bleeding is controlled. In studies of congenital hemophilia A patients with alloantibody inhibitors, one dose of FEIBA VH or two doses of recombinant factor VIIa controlled hemarthrosis episodes 81 and 79% of the time, respectively. The activated and unactivated prothrombin complex concentrates contain activated vitamin K–dependent clotting factors that "bypass" the intrinsic pathway (factor VIII or IX) inhibitor. As a result, repeated administration over a short time may be complicated by potential thrombogenicity: the aPTT and clotting factor assays are not helpful in monitoring hemostasis. In patients with high-titer inhibitors to factor VIII or IX, recombinant factor VIIa may achieve effective hemostasis, but its use is limited by the need for frequent intravenous dosing, usually every 2 hours to start. Although continuous dosing has been used in some patients, general experience dictates that for surgery or procedures in which significant bleeding is likely, bolus dosing is required to achieve optimal hemostasis—a "thrombin burst." The product has also been effective in patients who experience anaphylactic reactions or nephrotic syndrome after exposure to factor IX–containing replacement products or FFP. Eradication of inhibitor formation is usually attempted with "immune tolerance induction" regimens, which are generally effective if initiated within 12 months of the inhibitor's detection. Tolerance regimens consist of daily doses of factor concentrates to accomplish desensitization to infused factor, a process associated with a 68% success rate. Although factor dose is not critical in achieving tolerance, the higher the inhibitor titer, the greater the time required to achieve tolerance induction. Those in whom

tolerance is successful are typically young, have a low-titer inhibitor, and initiate tolerance within 1 year of inhibitor detection. After tolerance is achieved, maintenance prophylaxis with factor VIII or IX concentrate administered two or three times weekly (at 20 to 30 IU/kg) is necessary. Individuals with inhibitors since childhood who have not undergone immune tolerance induction before adulthood are unlikely to respond. An alternative approach involves treatment with single or combination immunosuppressive agents, including rituximab (currently in clinical trials), mycophenolate, or cyclosporine. Because only a minority respond, adults are typically managed with bypass agents alone.

PREVENTION

Carrier Detection and Prenatal Diagnosis

Carrier detection and prenatal diagnosis have become technically feasible, very sensitive, and widely available. The application of these diagnostic tools, however, is influenced by ethical, cultural, religious, economic, educational, and personal considerations. For instance, carrier detection is particularly useful in identifying women who may be at risk for hemorrhagic complications during the delivery process and male offspring who are particularly vulnerable to intracerebral bleeds at birth. Alternatively, these techniques can provide important information used to make difficult reproductive decisions. Patients may decide to accept the 50% likelihood that any male child of a confirmed carrier of hemophilia A or B will be affected; to abstain from pregnancy or to adopt; to determine the sex of the fetus and terminate the pregnancy if an affected male child is identified; or to use in vitro fertilization, with subsequent uterine transfer of only harvested female embryos, as confirmed by fluorescence in situ hybridization, or genetically unaffected male and female embryos, as determined by PCR-based techniques for specific hemophilia gene mutations. Despite the availability of these techniques, genetic counseling and testing have not resulted in increased rates of pregnancy termination for hemophilia in developed countries, where safe and effective replacement products are ubiquitous and the potential of a normal lifespan with greatly reduced disability is now becoming the norm. In contrast, in economically developing nations, limited health resources result in a lack of timely or adequate treatment, significant morbidity, and death in childhood.

The phenotypic identification of obligate female carriers of hemophilia, who are related to affected males, can be accomplished with 90% accuracy by measuring low levels of factor IX activity or relatively low factor VIII coagulant activity compared with levels of von Willebrand's factor antigen. Coagulation activity assays used for the phenotypic identification of carriers or affected males may be less sensitive when large populations are screened for random mutations, and the assays are not readily applied to fetal blood specimens or amniotic fluid, which is typically contaminated by thromboplastic materials that may spuriously increase factor activity levels. In addition, in the case of hemophilia B, the presence of cross-reactive factor IX antigen may confound the ability to predict carrier status or fetal involvement. Genotypic analysis for specific mutations is the most accurate and reliable means of prenatal detection and carrier testing for the hemophilias. Molecular genetic testing used in hemophilia includes targeted mutation analysis, mutation scanning or sequence analysis, and deletion analysis. Several hundred heterogeneous point mutations of the factor VIII gene (186 kb, 26 exons) have been associated with the development of hemophilia A, necessitating linkage analysis employing DNA polymorphic markers in assays based on restriction fragment length polymorphism. Increased accuracy is achieved if the specific gene defect is known and genetic material is available from the propositus and the carrier. PCR amplification of DNA and denaturing gradient gel electrophoresis analysis are useful for detection of the intron 22 inversion, which accounts for nearly half the cases of severe hemophilia A. Of those without this mutation, the majority have gross gene alterations, including deletions, insertions, and frameshift, nonsense, and missense mutations. The molecular basis of hemophilia B is more heterogeneous than that of hemophilia A; several hundred causative mutations—predominantly single-nucleotide polymorphisms with ethnic variation but no frequent mutation type—have been reported in this considerably smaller gene (34 kb, 8 exons, 7 introns). Sequence analysis can identify a mutation in 97% of those with hemophilia B, and deletion analysis identifies large deletions or exonic deletions in the remaining 3%.

PROGNOSIS

The life expectancy of individuals with severe hemophilia is approaching that of the normal population. The age-matched death rate in hemophilia is 2.7-fold greater than that in the general population, although ischemic heart disease mortality is 60% lower than in the general population. Life expectancy is related to the severity of hemophilia: the mortality rate of severely affected patients is 4- to 6-fold greater than that of patients with mild deficiency. Among those with alloantibody inhibitors, mortality rates are significantly higher than in noninhibitor patients. The three leading causes of death are hepatitis C, HIV/AIDS, and central nervous system bleeding. Hepatitis C has become the leading cause of death, accounting for over half; deaths from HIV have declined with the availability of HAART (Chapter 396). Unfortunately, despite the availability of pegylated interferon-α and ribavirin therapy, fewer than 70% of monoinfected and 40% of coinfected patients sustain durable antiviral responses, and hepatitis C remains a major cause of morbidity and mortality (Chapter 151). Among those with HIV/HCV coinfection, HAART also slows the progression of HCV-related liver disease. Predictors of hepatitis C disease progression in hemophilia include alcohol use, the use of acetaminophen for pain relief of hemophilic arthropathy, hepatitis B surface antigenemia, and HIV coinfection.

The lifetime risk of intracranial hemorrhage is 2 to 8%. It is the leading cause of morbidity and mortality in the newborn period, and prospective monitoring of central nervous system function is a priority as the population ages. Finally, with the essential elimination of disease transmission through blood products in this population, it is anticipated that the normal problems of aging will be increasingly recognized in those with hemophilia, including atherosclerosis, hypertension, hyperlipidemia, obesity, and diabetes. The impact of these conditions on the natural history of hemophilia, given the recognized lower mortality from ischemic heart disease, remains to be seen.

FUTURE DIRECTIONS

Gene Therapy for Hemophilia A and B

The hereditary hemophilias are model diseases for gene therapy because they are caused by specific, well-defined gene mutations; a small, incremental rise in clotting factor synthesis can lead to substantially improved treatment and quality of life; and inadvertent overexpression by successful gene transfer would not be detrimental. Although successful gene transfer techniques have been developed to provide long-term therapeutic benefits in hemophilic mice and dog models, sustained responses have not yet been achieved in patients with hemophilia—a problem at least in part related to immune responses directed against the vector that suppress long-term expression of clotting factor activity. Approaches under study to avert the immune response to vectors include short-term immunosuppression during the first weeks after vector-gene administration; use of modified, less immunogenic vectors; and use of innovative delivery systems, such as platelets.

Novel therapeutic approaches to enhance clotting factor replacement therapy include long-acting factor products pegylated with liposomes or linked to IgG molecules to prolong factor activity half-life, now in clinical trials; oral delivery systems using bioencapsulated proteins; and molecular modifications to enhance the desirable properties of clotting factor, so-called designer molecules.

Acquired Hemophilias

EPIDEMIOLOGY AND PATHOBIOLOGY

Autoantibody inhibitors occur spontaneously in individuals with previously normal hemostasis (nonhemophiliacs). In contrast to alloantibody inhibitors in hemophilic men, which are directed against foreign infused clotting factor, autoantibody inhibitors are directed against a "self" clotting factor, most commonly factor VIII. These autoantibodies typically arise in individuals with no past bleeding history; thus the diagnosis may be missed until a prolonged aPTT and aPTT mix tests are obtained (Chapter 174). Although half of those with autoantibody inhibitors have no obvious underlying cause, autoimmune diseases, lymphoproliferative disorders, idiosyncratic drug reactions, pregnancy, and advanced age are associated in the other half.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Massive hemorrhagic events, even more severe than in hemophilia patients with alloantibodies, may occur in those with autoantibodies because of a delay in diagnosis and treatment. The laboratory expression of autoantibodies is similar to that of alloantibodies, except that clotting factor activity is not completely neutralized. Residual clotting factor activities between 3 and 20% of normal are frequently observed in patients with autoantibodies.

TREATMENT

Rx

The same principles of replacement therapy for alloantibodies apply to these acquired autoantibody inhibitors. There are two goals of treatment: stop the bleeding and assure hemostasis, and eradicate the inhibitor. For hemostasis, recombinant factor VIIa or factor VIII bypass activity is commonly used, in similar doses used to achieve hemostasis with alloantibody. Porcine factor VIII concentrate is also useful in acquired hemophilia A because little cross-reactivity usually occurs, even with extremely high titers of anti–human factor VIII antibodies; however, its availability is limited. Clinical studies are under way to assess the utility of long-acting VIIa as well as genetically engineered forms of the porcine factor VIII protein. For eradication of the inhibitor, immunosuppressive therapy is generally more effective than in alloantibody patients; this includes corticosteroids (prednisone 1 mg/kg/day PO), cytotoxic agents (e.g., cyclophosphamide 150 mg/day PO or 500 to 750 mg/m^2 IV bolus every 3 to 4 weeks), or a combination, with dose titration based on inhibitor levels and complicating cytopenias. Anti-CD20 antibody (rituximab) 375 mg/m^2 intravenously weekly for 4 weeks is also effective. These agents are continued until the autoantibody inhibitor has disappeared; then they are tapered and discontinued. Whether these agents are also effective for the long-term eradication of autoantibody inhibitors is not known; the question has not been studied in randomized controlled trials. High-dose intravenous gamma globulin may be a useful adjunctive therapy. Immune tolerance induction regimens that combine alkylating agents, the daily administration of clotting factor concentrate, and high-dose corticosteroids have been successful in eradicating autoantibody inhibitors. Rarely, if inhibitor-related hemorrhage is refractory to bypassing agents, extracorporeal plasmapheresis over a staphylococcal protein A column may remove enough neutralizing IgG alloantibody or autoantibody to facilitate successful hemostasis after replacement therapy.

PROGNOSIS

Several large series of patients with acquired hemophilia reveal a substantial mortality rate of 15 to 25%, which is considerably higher than that observed with alloantibody factor VIII inhibitors. A large meta-analysis found that overall survival in acquired hemophilia was influenced primarily by the achievement of a complete remission, age younger than 65 years at diagnosis, and related diseases (malignancy vs. postpartum vs. others). As many as 17% of the deaths were associated with sepsis, and 71% of those arose as a complication of cyclophosphamide-induced neutropenia. Hemorrhagic complications were the primary cause of death, but these could be reduced if the inhibitor could be eradicated. Of note, complete remission was observed in 89% of cyclophosphamide-treated individuals, compared with 70% of those treated with corticosteroids alone and 41% of those who received no treatment.

Von Willebrand Disease

The most common congenital bleeding disorder is VWD. This disorder is inherited in an autosomal dominant fashion and affects both sexes, with a prevalence of 1 to 3% and no ethnic predominance. Homozygous patients are rare and carry a recessive mutant gene. Von Willebrand factor, the protein that is decreased or defective in VWD, is a large, multimeric glycoprotein encoded by the *VWF* gene, located on chromosome 12. Detailed discussion of VWD is provided in Chapter 176.

Factor XI Deficiency

EPIDEMIOLOGY

Factor XI deficiency has a prevalence of 1 in 1 million in the general population and 1 in 500 births in Ashkenazi Jewish families. Factor XI is the only component of the contact phase system (factor XII, prekallikrein, and high-molecular-weight kininogen) of the intrinsic pathway of coagulation that is associated with excessive bleeding complications when a deficiency exists.

PATHOBIOLOGY

Factor XI deficiency is predominantly an autosomal recessive trait, although some mutations may have a dominant transmission pattern. The factor XI gene *(FXI)* is located on chromosome 4, and the protein circulates as a homodimer, with each FXI monomer composed of 4 apple domains encoded by exons 3 through 10 and a protease domain encoded by exons 11 through 15. The Glu117 stop mutation in *FXI* is the most common cause of factor XI deficiency, secondary to poor secretion or stability of the truncated protein or decreased levels of messenger RNA. To date, more than 170 mutations of *FXI* have been identified in factor XI–deficient patients (see *www.factorxi.org*), but close correlation between hemorrhagic phenotype and genotype is lacking. Most are missense or nonsense mutations and are located across all 4 apple domains and the serine protease region. In Ashkenazi Jewish individuals, factor XI deficiency is common, with a heterozygote frequency of 8 to 10%; two predominant gene mutations occur with equal frequency and are designated type II (a stop codon in exon 5) and type III (a single base defect in exon 9). The most severe clinical disease is observed in patients homozygous for type II, who usually have less than 1% factor XI activity. Homozygous type III individuals also manifest severe symptoms, but typically less severe than those of type II patients; they have slightly higher factor XI levels of about 10 to 20%. Compound heterozygotes, type II/III, make up the bulk of factor XI–deficient patients; they have clinically mild disease, with factor XI levels between 30 and 50%. In non-Jewish individuals, the mutations are more variable, although Cys128 stop has been described in several kindreds, and Cys38Arg has been found in several French Basque families. One third of those who develop inhibitors are homozygous for Glu117 stop, which results in an absent *FXI*. Genotypic identification of affected patients is determined by measuring factor XI levels rather than by defining the specific gene defect.

CLINICAL MANIFESTATIONS

The clinical bleeding tendencies in factor XI deficiency are less severe than those observed in severe hemophilia A or B and, in contrast to the hemophilias, do not correlate with the severity of the deficiency. Most individuals with less than 20% of normal factor XI activity experience excessive bleeding after trauma or surgery; however, a few do not bleed. In contrast, bleeding has been observed in approximately 35 to 50% of mildly affected patients with factor XI levels between 20 and 50% of normal. Spontaneous hemorrhagic episodes, hemarthroses, and intramuscular and intracerebral bleeds are unusual; traumatic and surgical bleeds typically involve the mucous membranes. Patients undergoing tonsillectomy, prostatectomy, or dental extraction are at highest risk for bleeding unless replacement therapy is administered. Women may experience significant menorrhagia, and it has been recommended that women with menorrhagia be screened for both VWD and factor XI deficiency. Patients with mild factor XI deficiency and coincident mild VWD have an increased risk of bleeding.

DIAGNOSIS

Factor XI deficiency is diagnosed in the laboratory by a prolonged aPTT, normal PT, and decreased factor XI activity ascertained in a specific quantitative clotting assay (normal range, 60 to 130%).

TREATMENT

Rx

Not all individuals with factor XI deficiency bleed, so it may be reasonable to monitor with no treatment, especially if there is no family history of bleeding. For surgical or other major bleeding, FFP 15 to 20 mL/kg can be used, although potential complications include fluid overload and infection risk, which can be reduced with the use of pathogen-inactivated FFP, if available. Use of factor XI concentrate, which is available in Europe but not the United States, may be complicated by thrombosis, which occurs in approximately 10% of patients, particularly in older individuals with preexisting cardiovascular disease and malignancy. Replacement dosing levels should not exceed 70% of factor XI activity. Repeat dosing with FFP or factor XI concentrate should take into consideration the long (60- to 80-hour) biologic half-life of factor XI in vivo.

The decision to treat heterozygotes with factor XI at levels greater than 20% is empirical and should be based on the individual's prior history of bleeding after trauma or surgery. Alternatively, a family medical history of bleeding complications can be considered. There is no clear evidence of benefit with the use of DDAVP. Because hemorrhagic complications originate most commonly from mucous membrane surfaces, antifibrinolytic agents such as ε-aminocaproic acid or tranexamic acid are frequently helpful as adjunctive therapy. In women with menorrhagia or postpartum hemorrhage, testing for VWD is recommended because both diseases may be present.

Alloantibody inhibitors, which neutralize the hemostatic effects of exogenously administered factor XI replacement, can develop in patients with severe factor XI deficiency who have been exposed to plasma or factor XI concentrate. Recombinant factor VIIa can prevent bleeding during or after surgery in these patients.

Deficiencies of Contact Activation Factors

Although factor XI plays an important role in the activation of factor IX in the intrinsic pathway generation of thrombin, it is only one of the four

components of the contact phase of coagulation. Deficiencies in any of the other three factors (factor XII, prekallikrein, and high-molecular-weight kininogen) produce in vitro laboratory abnormalities. Even among those with severe factor XII deficiency (<1% activity), there is no clinical bleeding; however, up to 8 to 10% with severe factor XII deficiency actually experience venous thromboembolic events, which are occasionally fatal. This finding has led to speculation that factor XII deficiency may lead to hypercoagulability through defective participation of the contact phase proteins in the activation of fibrinolysis.

DIAGNOSIS

Deficiencies of each of these factors prolong the aPTT, often markedly, which may normalize after prolonged incubation of the patient's plasma at 37° C with a negatively charged activator of the aPTT assay (i.e., kaolin or celite). Specific assays are also available to quantitate each of the contact factors.

TREATMENT Rx

Deficiencies of the contact activation factors, however severe they are and however prolonged the associated aPTT may be, do not cause clinical bleeding problems, even in response to surgery or trauma. Therefore, no therapy is indicated for factor XII deficiency, prekallikrein deficiency, or high-molecular-weight kininogen deficiency. Routine anticoagulation regimens are used to treat thrombogenic events.

Factor XIII (Fibrin-Stabilizing Factor) Deficiency

Factor XIII is a transglutaminase that is activated by thrombin and functions to cross-link fibrin to protect it from lysis by plasmin. It is also involved in wound healing and tissue repair and seems to be crucial for maintaining a viable pregnancy. Homozygous severe deficiency states are rare and are inherited in an autosomal recessive manner, with a prevalence of 1 per 3 million births. Consanguinity is common.

CLINICAL MANIFESTATIONS

Heterozygous carriers are usually asymptomatic, but homozygotes have lifelong bleeding that typically starts shortly after birth with persistent bleeding around the umbilical stump. Intracranial bleeding events, usually precipitated by minimal trauma, occur commonly enough in infants (25%) to justify the initiation of a primary prophylaxis regimen of replacement therapy. Delayed bleeding after surgery and trauma is the hallmark of the disease; however, easy bruising, poor wound healing with defective scar formation and dehiscence, and hemarthroses are characteristic. Spontaneous abortions are increased in severely affected women.

DIAGNOSIS

The diagnosis is usually suspected on clinical grounds, given that factor XIII deficiency is not detected by conventional screening coagulation assays (i.e., aPTT, PT). Most laboratories use a rapid screening assay that assesses the ability of a fibrin clot to remain intact with incubation in 5 mol/L of urea or 1% monochloroacetic acid. With factor XIII levels less than 1% of normal, the clot dissolves within 2 to 3 hours.

TREATMENT Rx

Replacement therapy for prophylaxis or the treatment of acute bleeds can be accomplished by administering cryoprecipitate, FFP, or, preferably, plasma-derived factor XIII concentrate (Fibrogammin P), which is pasteurized for viral safety. A clinical trial of Fibrogammin P for factor XIII deficiency is under way in the United States, and the product is available under compassionate investigational new drug use through ZLB-Behring Inc., Marburg, Germany, and CSL Behring Inc., King of Prussia, PA. Clinical studies are also in progress to evaluate a placentally derived product. Normal hemostasis is achieved with a factor XIII level of only 5% of normal. The dose of Fibrogammin P is 10 to 20 U/kg intravenously, and because it has a long half-life (10 days), prophylactic replacement can be given every 3 to 4 weeks. Acquired alloantibody inhibitors can develop in severely affected individuals. Autoantibodies also occur, usually in association with systemic lupus erythematosus.

Dysfibrinogenemia and Afibrinogenemia

Approximately 300 abnormal fibrinogens have been described, but few cause hemostatic symptoms. Abnormal fibrinogens are rare, autosomally inherited proteins. Quantitative fibrinogen deficiencies (afibrinogenemia and hypofibrinogenemia) may result from mutations affecting fibrinogen synthesis or processing, whereas qualitative defects (dysfibrinogenemia) are caused by mutations that lead to abnormal polymerization, defective cross-linking, or defective assembly of the fibrinolytic system.

CLINICAL MANIFESTATIONS

More than 50% of the dysfibrinogenemias are asymptomatic, 25% are associated with a mild hemorrhagic tendency (commonly caused by defective release of fibrinopeptide A), and 20% predispose individuals to thrombophilia (usually caused by impaired fibrinolysis) (Chapter 179). Concurrent bleeding and thrombosis also may occur. The prevalence of dysfibrinogenemia in patients with a history of thromboembolic episodes approaches 0.8%. A high prevalence of dysfibrinogenemia has been reported among patients with chronic thromboembolic hypertension, implicating changes in the molecular structure of fibrin in the development of this disorder. Women experience a high incidence of pregnancy-related complications, such as spontaneous abortion and postpartum thromboembolic events. Thrombin times and reptilase times (plasma-based clotting times with the substitution of reptilase snake venom for thrombin) are not helpful in predicting whether an abnormal fibrinogen will be prothrombotic, prohemorrhagic, or asymptomatic. However, clinical history, fibrinopeptide release studies, and fibrin polymerization studies may be useful. Clinically insignificant dysfibrinogenemias may be acquired in association with hepatocellular carcinoma (Chapter 202).

In contrast to the hepatic synthesis of a qualitatively abnormal protein in dysfibrinogenemia, congenital afibrinogenemia, an autosomal recessive disorder, represents the markedly deficient production of a normal protein. Severe life-threatening hemorrhagic complications can occur at any site, beginning at birth with umbilical bleeding. Intracranial hemorrhage is a frequent cause of death. Poor wound healing is characteristic. All coagulation-based assays that depend on the detection of a fibrin clot end point are markedly prolonged. Afibrinogenemia is usually detectable by specific functional or immunologic assays. Platelet dysfunction may accompany afibrinogenemia and exacerbate bleeding.

DIAGNOSIS

Abnormalities are usually detected incidentally when routine coagulation screening assays reveal decreased fibrinogen concentrations and prolonged thrombin clotting times. On further evaluation, discordance between functional and immunologic fibrinogen levels (>50 mg/dL more antigenic than functional) is observed; clotting times using snake venom (reptilase or ancrod) are variably prolonged.

TREATMENT Rx

Deficiencies of fibrinogen can be corrected by the administration of FFP or cryoprecipitate; however, viral safety remains an issue. A viral-attenuated (pasteurized), plasma-derived fibrinogen concentrate (Riastap, CSL Behring) was recently approved by the Food and Drug Administration (FDA) for use in congenital fibrinogen deficiency, with a target replacement goal of 100 mg/dL. With a circulating biologic half-life of at least 96 hours, treatment every 3 to 4 days is adequate. Primary prophylaxis regimens may be useful in afibrinogenemia, with on-demand or prophylactic replacement for trauma or surgery. Individuals with thrombophilic manifestations should receive anticoagulation long term, depending on risk-benefit assessment (Chapter 179). Riastap is not recommended for use in dysfibrinogenemia. Solvent detergent- or psoralen-treated FFP (when licensed by the FDA) may provide an alternative therapy.

Factor V Deficiency

Factor V is a component of the prothrombinase complex that assembles factors Va and Xa on the phospholipid membrane of the platelet for prothrombin (factor II) activation to thrombin (Chapter 174).

CONGENITAL FACTOR V DEFICIENCY

Deficiency of factor V is a rare, autosomal recessive disorder (1 in 1 million births). The factor V Leiden protein, which is responsible for resistance to activated protein C and thrombophilia, does not affect factor V coagulant activity (Chapter 179). The severity of plasma factor V deficiency correlates less well with the risk of clinical bleeding than does the factor V content in platelet α-granules. This observation illustrates the critical role of the platelet in promoting adequate hemostasis at bleeding sites and explains why transfusions of normal platelets may be preferred over FFP for the treatment of

hemorrhagic episodes secondary to congenital or acquired factor V deficiency. Hemostasis can be maintained without correcting plasma factor V activity (>25% of normal).

COMBINED DEFICIENCIES OF FACTORS V AND VIII

Factors V and VIII are structurally homologous proteins, and combined deficiencies of these factors occur as an autosomal recessive disorder with a prevalence of 1 in 100,000 births among Jews of Sephardic origin. The severity of bleeding is determined by the levels of these factors, which usually range from 5 to 30% of normal. Replacement therapy should be aimed at normalizing both clotting protein activities.

ACQUIRED FACTOR V DEFICIENCY

Acquired factor V deficiency has been described in individuals exposed to bovine factor V, which contaminates the thrombin preparations used topically to control bleeding during cardiovascular surgery. This abnormality probably represents the development of anti–bovine factor V antibodies that cross-react with the human factor V protein. Profuse bleeding accompanies this complication.

Deficiencies of Vitamin K–Dependent Coagulation

DEFICIENCIES OF FACTORS II, VII, AND X

PATHOBIOLOGY AND CLINICAL MANIFESTATIONS

Congenital deficiencies of factors II (prothrombin), VII, and X are rare, autosomally inherited disorders. Heterozygotes (with factor levels approximately 20% of normal) are typically asymptomatic except in the immediate newborn period, when physiologic vitamin K deficiency exacerbates the underlying clotting factor deficiency. Homozygotes with clotting factor levels less than 10% of normal manifest variable symptoms. As with other coagulopathies, these deficiencies are usually suspected after neonatal umbilical stump bleeding. Thereafter, unless replacement or prophylactic therapy is provided, these patients are subject to mucosal bleeding from epistaxis, menorrhagia, and dental extractions; hemarthroses and intramuscular hematomas; and bleeding after surgery or trauma.

Acquired factor VII deficiency has been associated with Dubin-Johnson and Gilbert's syndromes (Chapter 149). Acquired factor IX deficiency has been associated with Gaucher's disease, because factor IX binds to glucocerebroside (Chapter 215). Acquired factor X deficiency and amyloidosis are discussed later.

DIAGNOSIS

In the coagulation laboratory, factor VII deficiency is associated with a prolonged PT and a normal aPTT. This pattern localizes the deficiency to the extrinsic pathway. In contrast, deficiencies of factors II (prothrombin) and X prolong both the PT and the aPTT, with the defects localized to the common pathway of coagulation. A Russell viper venom–based clotting assay can differentiate between these two deficiencies; as a direct activator of factor X, the assay is prolonged with factor X deficiency but not with factor II deficiency. Mixing patient plasma with normal plasma results in a correction of these assays, and specific clotting assays using plasma deficient in the coagulation protein to be studied can confirm the diagnosis.

TREATMENT Rx

Replacement therapy is indicated for acute symptomatic bleeds and for prophylaxis before surgery. In addition to FFP, which has the potential to transmit blood-borne viruses, factor IX complex concentrates can be administered to achieve hemostatic levels of any of these vitamin K–dependent factors (25 to 30% of normal).

Bleeding complications caused by acquired IgG autoantibodies directed against any coagulation factor protein can be reversed rapidly, albeit temporarily, by extracorporeal immunoadsorption over a Sepharose-bound polyclonal antihuman IgG or staphylococcal A column, with concomitant replacement therapy and initiation of immunosuppression. Recombinant factor VIIa is increasingly used for surgery in those with rare congenital coagulation deficiencies, but typically at lower doses than with hemophilia inhibitors—generally 10 to 15 μg/kg/day or less, for up to several days.

FACTOR DEFICIENCY IN AMYLOIDOSIS

Severe acquired deficiency of factor X, often accompanied by deficiencies of other vitamin K–dependent factors, occasionally occurs in individuals with systemic amyloidosis (Chapter 194). Because amyloid fibrils in the reticuloendothelial system bind endogenous and exogenous sources of factor X, replacement therapy with FFP or factor IX complex concentrates, even in large quantities, may not be sufficient. Recombinant factor VIIa concentrate has been used to reverse acute bleeding. Splenectomy may ameliorate recurrent bleeding complications.

Other Acquired Coagulation Abnormalities

ANTIPHOSPHOLIPID SYNDROME AND LUPUS ANTICOAGULANT

EPIDEMIOLOGY

The antiphospholipid antibody syndrome (APS) is associated with recurrent thrombosis or recurrent pregnancy loss with autoantibodies directed against phospholipids. Antiphospholipid antibodies (APAs) may include lupus anticoagulant (LA), anticardiolipin antibody (CL), or anti-β2-glycoprotein-I (anti-β2-GPI). Thrombocytopenia is also a common finding in this prothrombotic disorder. Rarely, multiorgan failure may arise from widespread thrombosis, termed *catastrophic APS*.

PATHOBIOLOGY

Our understanding of the role of individual antibodies in diagnosing APS continues to be enhanced with clinical studies, which may also contribute to the development of better diagnostic assays. It has been suggested that the prothrombotic effects of APAs may derive from their ability to complex with β2-GPI in vivo (thereby negating their modulatory phospholipid-binding function) or through APA inhibition of protein C activation, interference with antithrombin III activity, and/or disruption of the annexin V "shield," thereby preventing normal clot breakdown (fibrinolysis). Although complement and inflammation play a role in fetal loss in a murine model of APS, the pathogenic mechanism of APS-associated pregnancy loss remains unclear. Although non-β2-GPI antibodies detected by CL enzyme-linked immunosorbent assay (ELISA) may play a role in early obstetric APS, and anti-β2-GPI antibodies with LA activity play a role in late miscarriage, additional studies are needed to better classify, understand, and manage this syndrome.

CLINICAL MANIFESTATIONS

APAs prolong coagulation in in vitro assays but are not generally associated with clinical bleeding. Rarely, clinical bleeding may occur when APA interacts with factor II (prothrombin), producing an acquired prothrombin (factor II) deficiency associated with accelerated clearance of LA-prothrombin complexes from the circulation. Bleeding tendencies also may arise when LA targets platelet membranes and produces quantitative and/or qualitative platelet abnormalities. Other clinical findings in APS include livedo reticularis (Chapter 80), valvular heart lesions, and nephropathy. Clinically, although both arterial and venous thrombosis (Chapter 179) may occur in APS, the most relevant is venous thrombosis and stroke in young adults. A diagnostic work-up in those with arterial thrombosis should include transesophageal echocardiography to exclude a cardiac source for arterial clots. In obstetric patients, other causes of miscarriage should be excluded. Nonpregnant individuals with APS-associated thrombotic manifestations have a 50% risk of experiencing recurrent events over a 5-year period. Typically, recurrent hypercoagulable episodes occur in a pattern consistent with the initial findings (e.g., venous recurrence following an initial deep vein thrombosis).

DIAGNOSIS

By international consensus, a diagnosis of APS is based on both clinical and laboratory criteria. Clinical criteria include (1) arterial, venous, or small-vessel thrombosis in any tissue or organ and (2) pregnancy morbidity. The latter includes one or more pregnancy losses before 10 weeks' gestation; one or more pregnancy losses before 34 weeks due to eclampsia, preeclampsia, or placental insufficiency; or three or more spontaneous abortions before 10 weeks. APS may be suspected in the setting of recurrent spontaneous miscarriages or pregnancy-related thromboembolic events; with the detection of cerebral arterial thromboses in young adults; in those with systemic lupus erythematosus (20 to 40%; Chapter 274) or other autoimmune diseases or lymphoproliferative malignancies; in those receiving psychotropic medications (e.g., chlorpromazine); or when incidental coagulation assays reveal aPTT prolongation.

Laboratory criteria include one or more high-titer APAs (LA, CL, anti-β2-GPI) on at least two occasions at least 12 weeks apart. APAs can be detected by three assays: the LA assay, the CL ELISA assay, and the β2-GPI

ELISA assay. The LA assay includes a screening test, based on a prolonged phospholipid-dependent clotting time; a mixing test that distinguishes the inhibitor (fails to correct in a 1 : 1 mix) from a deficiency state (corrects in a 1 : 1 mix); and a confirmatory test based on platelet neutralization to demonstrate that the inhibitor is phospholipid dependent (clotting time corrects) or a modified aPTT reagent based on the binding of hexagonal phase phospholipids to LA. The CL ELISA measures antibodies in dilute sera that bind to CL-coated plates, including those that bind to CL alone or bound to bovine β2-GPI and both IgG and IgM, but it may miss CL bound to human β2-GPI. The β2-GPI ELISA detects antibodies that bind to β2-GPI–coated irradiated plates, but it has reduced specificity owing to binding by nonpathogenic antibodies. Positivity in multiple assays is strongly associated with thrombosis and miscarriage. Of the three assays, the β2-GPI ELISA is most strongly associated with thrombosis and early recurrent miscarriage; the LA assay is associated with venous thrombosis, stroke, and late miscarriage. The greatest weight is given to a positive LA test. From a practical standpoint, testing for all three antibodies at diagnosis is recommended to guide follow-up, because oral anticoagulants may interfere with the LA test.

TREATMENT

Rx

Because of the high risk of recurrent thromboembolism, patients with APS should receive antithrombotic therapy. The approach is based on achieving a balance between thrombosis risk and bleeding complications, especially in those with thrombocytopenia. Because of the limited information from randomized clinical trials, the recommendations for APS are similar to those for patients without APS—that is, to use unfractionated heparin or low-molecular-weight heparin (LMWH), with a 4- to 5-day overlap with warfarin, for acute venous thromboembolism (VTE), followed by long-term warfarin to a target international normalized ratio (INR) of 2.0 to 3.0. This recommendation is based on a randomized trial indicating no difference in bleeding rates with high-intensity (INR >3.0) versus low-intensity (INR 2.0 to 3.0) anticoagulation.[3] In individuals with thrombocytopenia, more frequent monitoring of the INR may be warranted to avoid bleeding complications. The duration of anticoagulation in those both with and without APS is based on a balance between VTE recurrence and bleeding.

For women with APS and pregnancy loss but no past thrombosis, the goal is to prevent recurrent pregnancy loss. Based on prospective studies indicating higher birth rates with aspirin plus heparin, recommendations include low-dose aspirin (81 mg) in combination with prophylactic heparin or LMWH in the antepartum period.

Among those with APS-associated thrombocytopenia and a platelet count below 20 to 30 $\times$ 10^9/L, in the setting of bleeding or when bleeding risk exceeds bleeding with VTE treatment, management is similar to that for idiopathic thrombocytopenic purpura (Chapter 175). This includes steroids, intravenous immunoglobulin, and immunosuppressive agents (e.g., cyclophosphamide, azathioprine, off-label rituximab). Case reports indicate that danazol, dapsone, aspirin, or chloroquine may be helpful adjuncts. In pregnant women with APS-associated thrombocytopenia, treatment is advised before epidural anesthesia or cesarean section. In the latter case, early delivery under cover of intravenous immunoglobulin is recommended.

Treatment of APS-associated bleeding is dependent on the site and severity of bleeding. For anticoagulation bleeding, the anticoagulant should be withheld and an antidote (e.g., protamine) given, if available. For thrombocytopenia bleeding, platelet transfusions should be given, along with red blood cell transfusions, if necessary. If both thrombosis and bleeding occur, treatment should be directed at the component that is most life threatening. In those with a high bleeding risk, anticoagulants should be withheld or given at a lower dosage; those with a high thrombotic risk, despite thrombocytopenia, should be anticoagulated and given agents to boost platelet count. For those who receive prolonged heparin, supplemental calcium and vitamin D should be administered to minimize the risks of osteoporosis.

178 HEMORRHAGIC DISORDERS: DISSEMINATED INTRAVASCULAR COAGULATION, LIVER FAILURE, AND VITAMIN K DEFICIENCY

ANDREW I. SCHAFER

DISSEMINATED INTRAVASCULAR COAGULATION

DEFINITION

Disseminated intravascular coagulation (DIC), also referred to as *consumptive coagulopathy* or *defibrination*, is caused by a wide variety of serious disorders (Table 178-1). In most patients, the underlying process dominates the clinical picture, but in some cases (e.g., occult malignancy, envenomation), DIC may be the initial or predominant manifestation of the disorder. DIC never occurs in isolation, without an inciting cause.

PATHOBIOLOGY

DIC is primarily a thrombotic process, although its clinical manifestation may be widespread hemorrhage in acute, fulminant cases. The basic pathophysiology (Fig. 178-1), regardless of cause, is entry into the circulation of procoagulant substances that trigger systemic activation of the coagulation system and platelets with resultant disseminated deposition of fibrin-platelet

TABLE 178-1 MAJOR CAUSES OF DISSEMINATED INTRAVASCULAR COAGULATION

INFECTIONS
Gram-negative bacterial sepsis

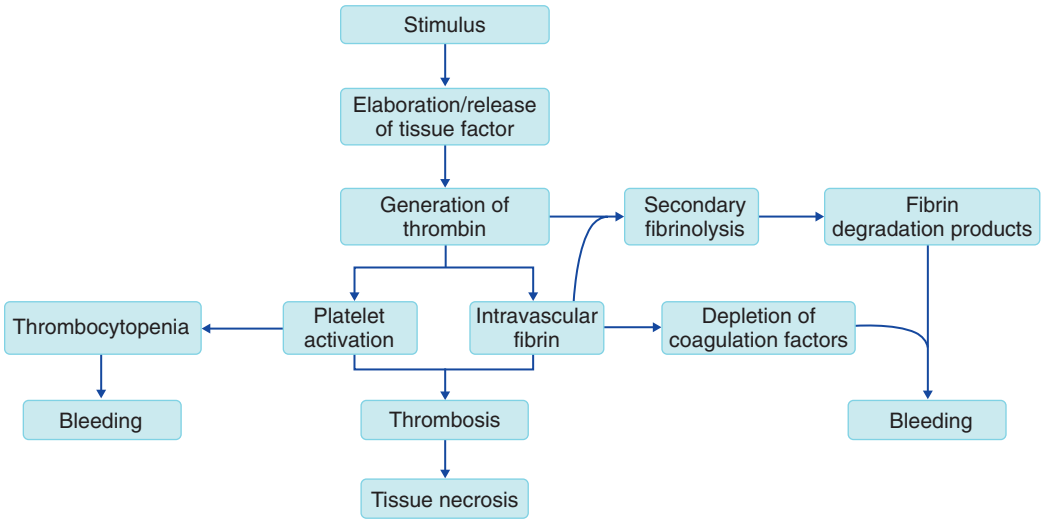

FIGURE 178-1. Pathophysiology of bleeding, thrombosis, and ischemic manifestations in patients with disseminated intravascular coagulation.

thrombi within the microvasculature. In most cases, the procoagulant stimulus is tissue factor, a lipoprotein that is not normally exposed to blood. In DIC, tissue factor gains access to blood by tissue injury, its elaboration by malignant cells, or its expression on the surface of monocytes and endothelial cells by inflammatory mediators. Components of the inflammatory response and the coagulation system are reciprocally activated in some forms of DIC, such as sepsis. Tissue factor triggers generation of the coagulation protease thrombin, which induces fibrin formation and platelet activation. In some specific cases of DIC, procoagulants other than tissue factor (e.g., a cysteine protease or mucin in certain malignancies) and proteases other than thrombin (e.g., trypsin in pancreatitis, exogenous enzymes in envenomation) provide the procoagulant stimulus.

In acute, uncompensated DIC, coagulation factors are consumed at a rate in excess of the capacity of the liver to synthesize them, and platelets are consumed in excess of the capacity of bone marrow megakaryocytes to release them. The resulting laboratory manifestations are a prolonged prothrombin time (PT) and activated partial thromboplastin time (aPTT) and thrombocytopenia. Increased fibrin formation in DIC stimulates the process of secondary fibrinolysis, in which plasminogen activators generate plasmin to digest fibrin (and fibrinogen) into fibrin(ogen) degradation products (FDPs). FDPs are potent circulating anticoagulants that further contribute to the bleeding manifestations of DIC. Intravascular fibrin deposition can cause fragmentation of red blood cells and lead to the appearance of schistocytes in blood smears; however, frank hemolytic anemia is unusual in DIC. Microvascular thrombosis in DIC can compromise the blood supply to some organs and lead to multiorgan failure, particularly when accompanied by systemic hemodynamic and metabolic derangements.

Underlying Causes

DIC always has an underlying cause that generally must be identified and eliminated if the coagulopathy is to be managed successfully. The development of DIC in many of these disorders is associated with an unfavorable outcome. Infection is the most common cause of DIC. The syndrome is particularly associated with gram-negative or gram-positive sepsis (Chapter 108), although it can be triggered by a variety of other bacterial, fungal, viral, rickettsial, and protozoal microorganisms. The placenta and uterine contents are rich sources of tissue factor and other procoagulants that are normally excluded from the maternal circulation; a spectrum of clinical manifestations of DIC may accompany obstetric complications when this barrier is breached, especially in the third trimester. These syndromes range from acute, fulminant, and often fatal DIC in amniotic fluid embolism to chronic or subacute DIC with a retained dead fetus. Other obstetric problems associated with DIC include abruptio placentae, toxemia, and septic abortion. Chronic forms of DIC are caused by a variety of malignancies, particularly pancreatic cancer (Chapter 200) and mucin-secreting adenocarcinomas of the gastrointestinal tract (Chapter 199), in which thrombotic rather than bleeding manifestations predominate. Treatment with all-*trans*-retinoic acid has greatly reduced the incidence of severe DIC in patients with acute promyelocytic leukemia (Chapter 189). It is not known whether liver failure (Chapter 157) can cause DIC or whether its coexistence merely exacerbates intravascular coagulation because of impaired clearance of activated clotting factors, plasmin, and FDPs. Snake venom contains a variety of substances that can affect coagulation and endothelial permeability. Bites from rattlesnakes and other vipers can induce profound DIC by introduction of these exogenous toxins and release of endogenous tissue factor via tissue necrosis. The likelihood and degree of DIC caused by trauma, surgery, and shock (Chapter 106) are related to the extent of tissue damage and the organs involved; the brain is a particularly rich source of tissue factor, so traumatic brain injury (Chapter 406) can precipitate acute DIC. Large aortic aneurysms (Chapter 78), giant hemangiomas, and other vascular malformations can cause subclinical or clinical DIC that is initiated locally within the abnormal vasculature but can "spill" into the systemic circulation.

CLINICAL MANIFESTATIONS

The clinical manifestations of DIC are determined by the nature, intensity, and duration of the underlying stimulus. The coexistence of liver disease exacerbates DIC of any etiology. Low-grade DIC is often asymptomatic and diagnosed only by laboratory abnormalities. Thrombotic complications of DIC occur most often with chronic underlying diseases, as exemplified by Trousseau's syndrome in cancer (Chapter 187). DIC can present as acrocyanosis and gangrene of the digits in critically ill, hemodynamically compromised patients on vasopressors. Hemorrhagic necrosis of the skin (Fig. 178-2) and purpura fulminans may also be manifestations of DIC. Bleeding is the most common clinical finding in acute, uncompensated DIC. Bleeding can be limited to sites of intervention or anatomic abnormalities, but it tends to be generalized in more severe cases, including widespread ecchymoses and diffuse oozing from mucosal surfaces and orifices.

FIGURE 178-2. Disseminated intravascular coagulation resulting from staphylococcal septicemia. Note the characteristic skin hemorrhage ranging from small purpuric lesions to larger ecchymoses. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

DIAGNOSIS

The laboratory diagnosis of severe, acute DIC is not usually difficult. Consumption and inhibition of the function of clotting factors cause prolongation of the PT, aPTT, and thrombin time. Consumption of platelets causes thrombocytopenia. Secondary fibrinolysis generates increased titers of FDPs, which can be measured by latex agglutination or D-dimer assays. Some schistocytes may be seen in the peripheral blood smear, but this finding is neither sensitive nor specific for DIC. Chronic or compensated forms of DIC are more difficult to diagnose, with highly variable patterns of abnormalities in "DIC screen" coagulation tests. Increased D-dimers and a prolonged PT are generally more sensitive measures than are abnormalities of the aPTT and platelet count. Overcompensated synthesis of consumed clotting factors and platelets in some chronic forms of DIC may actually cause shortening of the PT and aPTT or thrombocytosis (or both), even though elevated levels of D-dimers indicate secondary fibrinolysis in such cases.

The most difficult differential diagnosis of DIC occurs in patients who have coexisting liver disease. The coagulopathy of liver failure is often indistinguishable from that of DIC, partly because advanced hepatic dysfunction is accompanied by a state of DIC. In liver failure, the combination of decreased synthesis of clotting factors, impaired clearance of activated clotting factors, secondary fibrinolysis, and thrombocytopenia from portal hypertension and hypersplenism may make the coagulopathy practically impossible to differentiate from DIC. In thrombotic microangiopathies, including thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome, platelet consumption and thrombocytopenia are not accompanied by activation of clotting factors or secondary fibrinolysis; therefore the PT, aPTT, thrombin time, and D-dimers are generally normal in these disorders. Schistocytes, often with frank hemolysis, are much more prominent in the peripheral smear in thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome (Chapter 175) than in DIC.

Primary fibrinolysis is disputed as a distinct entity. Some patients with a serious clinical bleeding diathesis, however, have laboratory evidence of predominantly fibrinolysis, including high levels of FDPs (D-dimers) and severe hypofibrinogenemia, with relatively little consumption of coagulation factors and normal or near-normal platelet counts. These unusual findings, which approximate the findings expected with fibrinolytic therapy, are encountered occasionally, particularly in patients with prostate cancer.

TREATMENT Rx

Successful treatment of DIC (Table 178-2) requires that the underlying cause be identified and eliminated. All other therapies, including hemodynamic support, replacement of coagulation factors and platelets, and pharmacologic inhibitors of coagulation and fibrinolysis, are just temporizing measures. In many patients with asymptomatic, self-limited DIC who have only laboratory manifestations of the coagulopathy, no treatment may be necessary. In

TABLE 178-2 TREATMENT OF DISSEMINATED INTRAVASCULAR COAGULATION

Identify and eliminate the underlying cause
No treatment if mild, asymptomatic, and self-limited
Hemodynamic support, as indicated, in severe cases
Blood component therapy
Indications: active bleeding or high risk for bleeding
Fresh-frozen plasma
Platelets
In some cases, consider cryoprecipitate, antithrombin III
Drug therapy
Indications: heparin for DIC manifested by thrombosis or acrocyanosis; antifibrinolytic agents generally contraindicated except with life-threatening bleeding and failure of blood component therapy

DIC = disseminated intravascular coagulation.

patients with DIC who are actively bleeding or who are at high risk for bleeding, the blood component treatments of choice are transfusions of platelets to improve the thrombocytopenia and fresh-frozen plasma to replace all consumed coagulation factors and correct the prolonged PT and aPTT. Large volumes of plasma (e.g., >6 U/24 hours) may be required to ameliorate bleeding in severe cases. In some patients who have particularly profound hypofibrinogenemia, the additional transfusion of cryoprecipitate, a plasma concentrate that is enriched in fibrinogen, may be useful. The theoretical concern that these blood products could "fuel the fire" and exacerbate the DIC has not been supported by clinical experience.

The use of pharmacologic inhibitors of coagulation and fibrinolysis in DIC is controversial. Heparin is of theoretical benefit because it blocks thrombin activity and quenches intravascular coagulation and the resultant secondary fibrinolysis. In practice, heparin might exacerbate the bleeding tendency in acute DIC. Heparin is usually reserved for special forms of DIC, including those manifested by thrombosis or acrocyanosis and forms that accompany cancer, vascular malformations, retained dead fetus, and possibly acute promyelocytic leukemia. In cases of DIC in which thrombosis or acral ischemia predominates, unfractionated heparin should be used by continuous infusion owing to its short half-life and reversibility in the event of increased bleeding. Monitoring the aPTT in the presence of DIC may be problematic, so heparin infusion in this setting should be followed mainly by clinical response and improvement in other tests of coagulation (e.g., thrombocytopenia). Antifibrinolytic agents, including ε-aminocaproic acid and tranexamic acid, are generally contraindicated in DIC. By blocking the secondary fibrinolytic response to DIC, these drugs cause unopposed fibrin deposition and may precipitate thrombosis. Antifibrinolytic agents may be effective in decreasing life-threatening bleeding in DIC, however, particularly in extreme cases in which aggressive blood component replacement fails to control the hemorrhage; in such situations, simultaneous infusion of low doses of heparin may reduce the risk for thrombosis.

A 96-hour infusion of recombinant human activated protein C (rhAPC; drotrecogin alfa [activated]), which has both anticoagulant and anti-inflammatory properties, significantly reduces mortality in patients with severe sepsis and high risk of death; it should be urgently considered in such specific cases of DIC.■ However, it does not benefit septic patients with a low risk of death, such as those with only single-organ failure or Acute Physiology and Chronic Health Evaluation (APACHE) II scores of less than 25; in fact, it is associated with increased serious bleeding complications in these patients.■ Because of the increased risk for intracerebral hemorrhage with severe thrombocytopenia, rhAPC must be used cautiously in patients with DIC and in conjunction with platelet transfusion if the platelet count is less than 30,000/mm^3. Although recombinant tissue factor pathway inhibitor and antithrombin III concentrates may have some efficacy in improving laboratory parameters of DIC, the overall survival benefit with these agents in patients with DIC has not been demonstrated.

LIVER FAILURE

Bleeding complications in patients with advanced liver disease (Chapters 156 and 157) can be severe and even fatal and directly account for about 20% of the deaths associated with hepatic failure. The extent of the bleeding tendency depends on the severity and type of liver disease involved. About one third of deaths in patients undergoing liver transplantation are attributable to perioperative hemorrhage.

PATHOBIOLOGY

The pathophysiology of bleeding in liver failure is complex and multifactorial. Anatomic abnormalities resulting from portal hypertension are frequently the major cause of gastrointestinal bleeding in patients with liver disease.

TABLE 178-3 COAGULATION ABNORMALITIES IN LIVER DISEASE

ABNORMALITIES IN COAGULATION
Decreased synthesis of coagulation factors
Impaired vitamin K–dependent γ-carboxylation
Dysfibrinogenemia
Disseminated intravascular coagulation
Increased fibrinolytic activity
ABNORMALITIES IN PLATELETS
Thrombocytopenia (hypersplenism)
Abnormal platelet function

Upper gastrointestinal bleeding can be caused by esophageal varices or hemorrhagic gastritis (congestive gastropathy), whereas lower gastrointestinal bleeding, although seldom life-threatening, can be due to hemorrhoids.

The complexity of the systemic coagulopathy of liver failure is not surprising inasmuch as the liver is the principal organ site for the synthesis of coagulation and fibrinolytic factors as well as their protein inhibitors (Table 178-3). Hepatocytes produce all of the clotting factors except von Willebrand factor, and advanced parenchymal liver disease results in impaired synthesis of these proteins. Liver disease can also cause impairment in vitamin K–dependent γ-carboxylation of the procoagulant factors II, VII, IX, and X, as well as the anticoagulant proteins C and S. Functional abnormalities of fibrinogen, termed *dysfibrinogenemias,* are frequently found in various forms of liver disease, particularly in hepatocellular carcinoma. Most forms of advanced liver disease are accompanied by some degree of DIC caused by impaired synthesis of inhibitors of blood coagulation and defective hepatocellular clearance of activated coagulation factors. DIC is an especially important potential complication of LeVeen shunts used to treat intractable ascites because this procedure introduces procoagulant-rich ascitic fluid into the systemic circulation. In many of these cases, shunt ligation is required to terminate the DIC. DIC and bleeding risk are exacerbated by the enhanced fibrinolytic activity of liver disease caused by increased levels of tissue plasminogen activator accompanied by decreased synthesis of inhibitors of plasminogen activator and plasmin.

Quantitative and qualitative abnormalities of platelets also contribute to the bleeding diathesis of liver failure. Congestive splenomegaly secondary to portal hypertension causes increased pooling of platelets in the spleen (hypersplenism). The resultant thrombocytopenia, the degree of which generally correlates with spleen size, rarely causes a reduction in the platelet count to less than 50,000/mm^3. In alcoholic patients, suppression of bone marrow thrombopoiesis by the acute toxic effects of alcohol or folate deficiency may contribute to the thrombocytopenia. Qualitative platelet abnormalities have also been described in patients with liver disease.

Liver transplantation (Chapter 157) poses special problems to the coagulation system. During the anhepatic stage of surgery, which lasts about 2 hours, the complete cessation of synthesis of coagulation factors causes further prolongation of the PT and aPTT. Release of tissue plasminogen activator from the newly grafted liver leads to increased fibrinolysis and transient exacerbation of bleeding risk in the postoperative period.

CLINICAL MANIFESTATIONS

The most common hemorrhagic complication of liver disease is gastrointestinal bleeding, which is usually caused by anatomic abnormalities and exacerbated by the systemic coagulopathy of liver failure. Bleeding from other mucosal sites, extensive ecchymoses, or more serious hemorrhage into the retroperitoneum or central nervous system generally indicates more significant derangements of the coagulation system.

The severe coagulopathy in patients with liver disease makes liver biopsy a potentially hazardous procedure. The PT and platelet count are the best guides to bleeding risk. In general, liver biopsy can be performed safely if the PT and aPTT do not exceed 1.5 times control values and the platelet count is greater than 50,000/mm^3. Fresh-frozen plasma (see Treatment) can be infused to correct the prolonged PT and aPTT. Bleeding time is not a reliable predictor of bleeding risk after biopsy.

DIAGNOSIS

Although the PT and aPTT are often prolonged in patients with advanced liver disease, the former tends to be a more sensitive assay early in the course;

a disproportionate prolongation of the aPTT should raise suspicion of a coexisting coagulation abnormality, such as a lupus anticoagulant or clotting factor inhibitor. A prolonged PT is also a useful prognostic indicator of poor outcome in patients with cirrhosis, acute acetaminophen hepatotoxicity, and acute viral hepatitis; in the latter, it is a better index of prognosis than are serum albumin or transaminases. A disproportionate prolongation of the thrombin time should suggest the presence of dysfibrinogenemia. Hypersplenism (Chapter 171), possibly associated with nutritional folate deficiency or the acute toxic effects of alcohol on bone marrow, often causes mild to moderate thrombocytopenia in patients with liver disease; however, consideration should be given to other coexisting causes of thrombocytopenia if the platelet count is significantly less than 50,000/mm^3.

The coagulopathy of liver failure is often indistinguishable from that of DIC, in part because some degree of DIC is a necessary accompaniment of advanced liver disease. In general, patients with DIC have more marked decreases in levels of factor VIII and increases in D-dimer than patients with liver failure.

TREATMENT

Rx

Therapy for the coagulopathy of liver disease may be directed at preventing the hemorrhagic complications of invasive procedures or treating active bleeding. The most effective treatment is blood component therapy with fresh-frozen plasma (which contains all the coagulation factors) and platelet transfusions (Chapter 180). Some patients require large volumes of fresh-frozen plasma (15 to 20 mL/kg) to lower the prolonged PT; rarely, plasmapheresis with plasma exchange is required to avoid fluid overload in these situations. Because of the short half-lives of some clotting factors, fresh-frozen plasma may have to be administered every 8 to 12 hours to maintain acceptable coagulation test parameters. In some patients, especially those with cholestasis, parenteral administration of vitamin K can at least partially reverse the coagulation abnormalities; however, in patients with advanced hepatocellular failure, vitamin K is largely ineffective. Prothrombin complex concentrates are relatively contraindicated in patients with liver failure, as in those with DIC, because of the risk of thrombotic complications. Because of immediate pooling of transfused platelets in the enlarged spleen of patients with hypersplenism, a higher than calculated dose of platelet concentrates is usually required to increase circulating platelet counts significantly.

A recent randomized, controlled trial failed to demonstrate a beneficial effect of recombinant activated factor VII (rhVIIa) for variceal bleeding in patients with advanced cirrhosis.[3] Routine use of rfVIIa for the coagulopathy of liver disease cannot be recommended at this time. Desmopressin (DDAVP), which can shorten the bleeding time of patients with cirrhosis, may be considered as ancillary therapy in patients undergoing invasive procedures.

VITAMIN K DEFICIENCY

Vitamin K is required for γ-carboxylation of glutamic acid residues of the procoagulant factors II (prothrombin), VII, IX, and X and the anticoagulant factors protein C and protein S. This post-translational modification normally renders these proteins functionally active in coagulation. The PT is more sensitive than the aPTT in detecting vitamin K deficiency states because factor VII, the only vitamin K–dependent factor that is in the extrinsic pathway of coagulation, is the most labile of these proteins.

The two major sources of vitamin K are dietary intake and synthesis by the bacterial flora of the intestine. In the absence of malabsorption, nutritional deficiency alone rarely causes clinically significant vitamin K deficiency. The condition can arise, however, when eradication of gut flora is combined with inadequate dietary intake. This situation typically occurs in critically ill patients in intensive care units who have no oral intake and are receiving broad-spectrum antibiotics for prolonged periods. Vitamin K deficiency can also develop in patients receiving total parenteral nutrition unless the infusions are supplemented with vitamin K.

Vitamin K is absorbed predominantly in the ileum and requires the presence of bile salts. Clinically significant vitamin K deficiency occurs with malabsorption of fat-soluble vitamins secondary to obstructive jaundice (Chapter 158) or with malabsorption caused by intrinsic small bowel diseases, including celiac sprue, short-bowel syndrome, and inflammatory bowel disease (Chapters 142 and 143).

Warfarin (Chapter 37) acts as an anticoagulant by competitive antagonism of vitamin K. Rare cases of hereditary deficiency of the vitamin K–dependent coagulation factors may cause a lifelong bleeding tendency.

Correction of vitamin K deficiency, when clinically significant, can be achieved with oral supplementation, unless malabsorption is present. In the latter case, parenteral vitamin K (10 mg subcutaneously daily) should be administered. Emergency treatment of bleeding caused by vitamin K deficiency is transfusion of fresh-frozen plasma.

179 THROMBOTIC DISORDERS: HYPERCOAGULABLE STATES

ANDREW I. SCHAFER

The *hypercoagulable states,* also referred to as *thrombophilias,* encompass a group of inherited or acquired conditions that cause a risk for thrombosis.

The primary hypercoagulable states are quantitative or qualitative abnormalities in specific coagulation proteins that induce a prothrombotic state. Most of these disorders involve inherited mutations and polymorphisms that lead to either (1) a deficiency of a physiologic antithrombotic factor or (2) an increased level of a prothrombotic factor (Table 179-1). Particularly when they are combined with other inherited prothrombotic mutations (multigene interactions), these primary hypercoagulable states are associated with a lifelong predisposition to thrombosis. The secondary hypercoagulable states, a diverse group of mostly acquired conditions, cause a thrombotic tendency by more complex, often multifactorial mechanisms. The trigger for a discrete, clinical thrombotic event is often the development of one of the acquired, secondary hypercoagulable states superimposed on an inherited state of hypercoagulability.

TABLE 179-1 PRIMARY HYPERCOAGULABLE STATES

DEFICIENCY OF ANTITHROMBOTIC FACTORS

Factor IX Padua (factor IX R338L mutation)
Factors VII, XI, IX, VIII; von Willebrand's factor; fibrinogen (epidemiologic data; molecular mechanisms unknown)

PRIMARY HYPERCOAGULABLE STATES

Antithrombin III Deficiency

EPIDEMIOLOGY AND PATHOBIOLOGY

Inherited quantitative or qualitative deficiency of antithrombin III leads to increased fibrin accumulation and a lifelong propensity to thrombosis (Chapter 174). Antithrombin is the major physiologic inhibitor of thrombin and other activated coagulation factors; therefore, its deficiency leads to unregulated protease activity and fibrin formation.

The frequency of asymptomatic heterozygous antithrombin deficiency in the general population may be 1 in 350. Most of these individuals have clinically silent mutations and never have thrombotic manifestations. The frequency of symptomatic antithrombin deficiency in the general population has been estimated to be between 1 in 2000 and 1 in 5000. Among all patients seen with venous thromboembolism (VTE), antithrombin deficiency is detected in only about 1 to 2%, but it is found in approximately 2.5% of selected patients with recurrent thrombosis or onset of thrombosis at a younger age (<45 years old).

Patients with type I antithrombin deficiency have proportionately reduced plasma levels of antigenic and functional antithrombin that result from a quantitative deficiency of the normal protein. Impaired synthesis, defective secretion, or instability of antithrombin in type I antithrombin-deficient individuals is caused by major gene deletions, single nucleotide changes, or short insertions or deletions in the antithrombin gene. Patients with type II antithrombin deficiency have normal or nearly normal plasma antigen accompanied by low activity levels, characteristics indicative of a functionally defective molecule. Type II deficiency is usually caused by specific point mutations leading to single amino acid substitutions that produce a dysfunctional protein. More than 250 different mutations causing type I or type II antithrombin deficiency have been recognized to date.

The pattern of inheritance of antithrombin deficiency is autosomal dominant. Most affected individuals are heterozygotes whose antithrombin levels are typically about 40 to 60% of normal. These individuals may have the full clinical manifestations of lifelong hypercoagulability. Rare homozygous antithrombin-deficient patients generally have type II deficiency with reduced heparin affinity, a variant that is associated with a low risk for thrombosis in its heterozygous form; other forms of homozygous antithrombin deficiency are probably incompatible with life.

Protein C Deficiency

Protein C deficiency leads to unregulated fibrin generation because of impaired inactivation of factors VIIIa and Va, two essential cofactors in the coagulation cascade.

EPIDEMIOLOGY

The prevalence of heterozygous protein C deficiency in the general population is about 1 per 200 to 500. Protein C deficiency is found in 2 to 5% of all patients with VTE.

PATHOBIOLOGY

AS with antithrombin deficiency, two general forms of protein C deficiency are recognized: type I, in which quantitative deficiency of the protein is associated with a proportionate decrease in protein C antigen and activity, and type II, in which qualitative defects in protein C are associated with disproportionately reduced protein C activity relative to antigen. More than 160 mutations are known to cause protein C deficiency. In the more common type I deficiency, frameshift, nonsense, or missense mutations cause premature termination of synthesis or loss of protein C stability. In type II deficiency, different mutations can cause abnormalities in protein C activation or function. The mode of inheritance of protein C deficiency is autosomal dominant. As in antithrombin deficiency, most affected individuals are heterozygotes.

Protein S Deficiency

Protein S is the principal cofactor of activated protein C (APC), and its deficiency mimics that of protein C in causing loss of regulation of fibrin generation by impaired inactivation of factors VIIIa and Va.

EPIDEMIOLOGY

The exact prevalence of protein S deficiency in the general population is unknown but is estimated to be less than 0.5%. Its frequency in all patients evaluated for VTE (1 to 3%) is comparable to that of protein C deficiency.

PATHOBIOLOGY

Protein S circulates in plasma partly in complex with C4b binding protein; only free protein S, which normally constitutes about 35 to 40% of total protein S, can function as a cofactor of APC. As in antithrombin and protein C deficiencies, quantitative (type I) and qualitative (type II) forms of inherited protein S deficiency are known. In addition, type III protein S deficiency is characterized by normal plasma levels of total protein S but low levels of free protein S.

Relatively few specific mutations of the protein S gene have been described to date. Most involve frameshift, nonsense, or missense point mutations.

Activated Protein C Resistance (Factor V Leiden)

EPIDEMIOLOGY

The factor V Leiden mutation is remarkably frequent (3 to 7%) in healthy white populations but is far less prevalent in certain black and Asian populations. In various studies, APC resistance was found in a wide range of frequencies (10 to 64%) in patients with VTE.

PATHOBIOLOGY

Almost all subjects with functional APC resistance have a single, specific point mutation in the gene for factor V, which is a critical target of the physiologic anticoagulant action of APC. In this mutation, termed *factor V Leiden,* guanine is replaced with adenine at nucleotide 1691 (G1691A), which leads to the amino acid substitution of Arg504 by Gln and renders factor Va incapable of being inactivated by APC. Heterozygosity for the autosomally transmitted factor V Leiden mutation increases the risk for thrombosis by a factor of 5 to 10, whereas homozygosity increases the risk by a factor of 50 to 100.

Prothrombin Gene Mutation

The substitution of G for A at nucleotide 20210 of the prothrombin gene has been associated with elevated plasma levels of prothrombin and an increased risk for venous thrombosis. The allele frequency for this gain-of-function mutation is 1 to 6% in white populations, but it is much less prevalent in other racial groups. The prothrombin G20210A mutation is found in 3 to 8% of all patients with venous thromboembolism.

Other Primary Hypercoagulable States

The first X-linked thrombophilia was recently reported. A family with a gain-of-function mutation in the gene for coagulation factor IX (factor IX-R338L) had juvenile thrombophilia associated with a five- to ten-fold increase in factor IX clotting activity (with normal quantitative protein levels). Elevated levels of factor VIII coagulant activity are a significant risk factor for venous thrombosis, and family studies suggest that high factor VIII levels are often genetically determined. Increased levels of factors VII, IX, and XI, fibrinogen, von Willebrand factor, and thrombin-activatable fibrinolysis inhibitor, as well as very low levels of tissue factor pathway inhibitor, may also confer increased risk. Many other inherited abnormalities of specific physiologic antithrombotic systems may be associated with a thrombotic tendency. Most of these conditions are limited to case reports or family studies, their molecular genetic bases are less well defined, and their prevalence rates are unknown but are probably much lower than those of the disorders described earlier. The other primary hypercoagulable states include heparin cofactor II deficiency, dysfunctional thrombomodulin, and many fibrinolytic disorders that lead to impaired fibrin degradation, including hypoplasminogenemia, dysplasminogenemia, plasminogen activator deficiency, and certain dysfibrinogenemias that cause a thrombotic rather than a bleeding diathesis.

CLINICAL MANIFESTATIONS

The primary hypercoagulable states are associated with predominantly venous thromboembolic complications (see Table 174-2 in Chapter 174). Deep vein thrombosis of the lower extremities and pulmonary embolism are the most frequent clinical manifestations. Venous thromboses occurring in more unusual sites include superficial thrombophlebitis and mesenteric and cerebral venous thrombosis (see Table 174-2 in Chapter 174). Arterial thrombosis involving the coronary, cerebrovascular, and peripheral circulations is not linked to any of the primary hypercoagulable states, although some reports have described its occurrence with protein S deficiency and

homozygous antithrombin deficiency. Venous thrombosis can also result in arterial occlusion by paradoxical embolism across a patent foramen ovale.

The initial episode of VTE can occur at any age in patients with primary hypercoagulable states, but it typically takes place in early adulthood. Positive family histories of thrombosis can frequently be elicited. The risk for thrombosis varies among the individual primary hypercoagulable states and is highest in patients with deficiencies of antithrombotic factors (Table 179-2); it is markedly increased with the coexistence of multiple prothrombotic mutations. Patients with homozygous deficiency states tend to have more severe thrombotic complications. A peculiar manifestation of homozygous protein C or protein S deficiency is neonatal purpura fulminans. This serious, sometimes fatal syndrome is caused by ischemic necrosis secondary to widespread thrombosis of small cutaneous and subcutaneous vessels. Fatal purpura fulminans associated with a bleeding diathesis has also been described in a patient with an acquired immunoglobulin G (IgG) inhibitor of protein C. Warfarin-induced skin necrosis (Fig. 179-1) very infrequently complicates the initiation of oral anticoagulant therapy in patients with heterozygous protein C or protein S deficiency. Because both these proteins depend on vitamin K for normal function, their plasma levels in patients with inherited deficiency states may drop to nearly zero within a few days of starting therapy with warfarin, a vitamin K antagonist, and lead to a transient prothrombotic imbalance and skin necrosis caused by dermal vascular thrombosis. Nevertheless, oral anticoagulation provides effective long-term antithrombotic prophylaxis in these individuals.

TABLE 179-2 INHERITED HYPERCOAGULABLE STATES (THROMBOPHILIAS): EPIDEMIOLOGY AND RISK OF VENOUS THROMBOEMBOLISM (VTE)

	Prevalence (%)		*Relative Risk*	
THROMBOPHILIA	**GENERAL POPULATION***	**UNSELECTED VTE**	**FIRST VTE**	**RECURRENT VTE**
Antithrombin deficiency	0.02-0.3	1-2	5-8	2.5
Protein C deficiency	0.2-0.5	2-5	5-8	2.5
Protein S deficiency	<0.5	1-3	1.7-8	2.5
Factor V Leiden	3-7	10-65	5-10†	1.3
Factor II G20210A	1-6	3-8	1.5-3.8	1.4
FV Leiden + FII G20210A	0.01	—	20-60	2.5

*Data refer to white populations. Prevalence of FV Leiden and FII G20210A is <0.1% in African, African American, and Asian populations.
†Relative risk of first VTE with homozygous FV Leiden is up to ten-fold higher (50-100).
Modified from Coppola A, Tufano A, Cerbone AM, et al. Inherited thrombophilia: implications for prevention and treatment of venous thromboembolism. *Semin Thromb Hemostas*. 2009; 35:683-694.

FIGURE 179-1. Acute skin necrosis in a patient with protein C deficiency who was treated with heparin and warfarin for deep vein thrombosis that occurred after elective hip surgery. Warfarin treatment was withdrawn and anticoagulation continued with heparin. Skin grafting of the affected area was required. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

In most patients with primary hypercoagulable states, discrete clinical thrombotic complications appear to be precipitated by acquired prothrombotic events (e.g., pregnancy, use of oral contraceptives, surgery, trauma, immobilization), many of which are the secondary hypercoagulable states discussed subsequently. In particular, thrombosis complicates pregnancy, especially during the puerperium, in about 30 to 60% of women with antithrombin deficiency, 10 to 20% with protein C or protein S deficiency, and almost 30% with APC resistance (factor V Leiden), unless prophylactic anticoagulation is administered during this period.

DIAGNOSIS

Laboratory diagnosis (Chapter 174) of the primary hypercoagulable states requires testing for each of the disorders individually because no general screening test is available to determine whether a patient may have such a condition. Factor V Leiden can be diagnosed by a DNA-based assay or by a functional test for APC resistance: the former is required to distinguish between heterozygous and homozygous states. DNA-based assay is required to identify the prothrombin G20210A mutation. In contrast, many different mutations have been found in the genes for antithrombin, protein C, and protein S, so DNA-based tests are not practical for the diagnosis of these inherited deficiency states. Therefore, they are detected by functional and immunologic tests. Because type II ("qualitative") deficiencies of antithrombin, protein C, and protein S exhibit normal immunologic levels, functional assays for these proteins are better screening tests.

A reasonable diagnostic approach at this time is to screen at least all "strongly thrombophilic" patients after an initial episode of VTE: individuals with (1) a documented event before 50 years of age, (2) a positive family history, (3) massive or submassive pulmonary embolism, or (4) spontaneous thrombosis at an unusual site (e.g., intra-abdominal or cerebral). Analysis of results from a recent randomized trial showed that recurrent VTE was not increased in the presence of factor V Leiden, prothrombin G20210A mutation, antithrombin deficiency, or elevated levels of factor VIII, XI, or homocysteine.■ However, there have been no controlled clinical trials to date that have assessed the benefit of testing for thrombophilia on the risk of recurrent VTE.■ Although indefinite anticoagulation is recommended for patients who have had two or more VTE events, regardless of whether a primary hypercoagulable state is found, testing these individuals for thrombophilia may also be useful to guide family screening strategies. Individuals with arterial thrombosis generally should not be tested for any of these disorders because primary hypercoagulable states (see Table 179-1) are not clearly associated with an increased risk for arterial thrombosis. In contrast, some of the secondary hypercoagulable states, including hyperhomocysteinemia and the antiphospholipid syndrome (see later), are associated with an increased risk for arterial as well as venous thrombosis.

In general, testing for primary hypercoagulable states is not recommended immediately after a major thrombotic event, but rather in clinically stable patients at least 2 weeks after completing oral anticoagulation following a thrombotic episode. Active thrombosis may transiently consume and deplete some of the proteins in plasma and lead to the erroneous diagnosis of inherited antithrombin, protein C, or protein S deficiency. In addition to acute thrombosis, pregnancy, estrogen use, liver disease, and disseminated intravascular coagulation (DIC) may cause acquired deficiencies of antithrombin, protein C, or protein S. Anticoagulation may also interfere with some of the functional tests for primary hypercoagulable states. Heparin treatment can cause a decline in antithrombin levels to the deficiency range even in normal individuals. In contrast, warfarin can elevate antithrombin levels into the normal range in patients who do have an inherited deficiency state. Warfarin therapy also reduces the functional levels and, less prominently, the immunologic levels of protein C and protein S, thereby potentially leading to a misdiagnosis of inherited deficiency. When testing is indicated in patients in whom interruption of prophylactic oral anticoagulation is considered to be too risky, protein C and protein S levels can be determined after warfarin therapy has been discontinued under heparin coverage for at least 2 weeks.

As noted previously, functional assays are the best screening tests for antithrombin, protein C, and protein S deficiencies because they detect both quantitative and qualitative defects; antigenic (immunologic) assays detect only quantitative deficiencies of these proteins. Functional coagulation assays for protein C and protein S may yield spuriously low values, however, if APC resistance is present. APC resistance can be diagnosed by newer high-sensitivity and high-specificity coagulation assays or by DNA analysis of peripheral blood mononuclear cells for the factor V Leiden mutation.

TREATMENT

The initial treatment of acute venous thrombosis or pulmonary embolism in patients with primary hypercoagulable states is not different from that in patients without genetic defects (Chapters 37 and 81). As in patients without known thrombophilia, thrombolytic therapy should be considered after massive venous thrombosis or pulmonary embolism. Acute management is initiated with at least 5 days of unfractionated or low-molecular-weight heparin. Oral anticoagulation with warfarin can be started on the first day of heparin use and continued for at least 6 months in patients with VTE in the absence of triggering factors (e.g., postoperative state), with regulation of the dose to maintain an international normalized ratio (INR) of the prothrombin time between 2.0 and 3.0.

Continuing oral anticoagulant prophylaxis beyond the initial 6 to 12 months after an acute episode of VTE must be weighed against continued exposure of the individual patient to the significant risk for bleeding complications. Patients with primary hypercoagulable states who have had two or more thrombotic events should receive indefinite or lifelong prophylactic anticoagulation with warfarin (Chapter 37). Indefinite or lifelong anticoagulation is probably indicated for individuals with recurrent thrombosis even in the absence of identifiable primary hypercoagulable states.

The decision to continue prophylactic oral anticoagulation beyond the initial period after the first episode of thrombosis is more difficult (Table 179-3). After a single episode of thrombosis, patients with inherited hypercoagulable states should probably receive indefinite or lifelong anticoagulation if their initial episodes were life-threatening or occurred in unusual sites (e.g., mesenteric, cerebral venous thrombosis) or if they have more than one prothrombotic genetic abnormality. Some authorities also recommend indefinite or lifelong anticoagulation after an initial venous thromboembolic event in patients whose risk of recurrence likewise appears to be increased: those with isolated heterozygous deficiencies of antithrombin, protein C, or protein S and patients with homozygous factor V Leiden. In the absence of these characteristics, particularly if the initial episode was precipitated by a transient acquired prothrombotic situation (e.g., pregnancy, postoperative state, immobilization), it is reasonable at this time to discontinue warfarin therapy after 6 to 12 months and administer subsequent prophylactic anticoagulation only during high-risk periods.

Asymptomatic individuals with known thrombophilia who have not had previous thrombotic complications do not require prophylactic anticoagulation except during periods of high risk for thrombosis. Because about half of the first-degree relatives of a patient with a primary hypercoagulable state should be affected, these individuals should be counseled about the implications of making a diagnosis.

Management of pregnancy in women with primary hypercoagulable states requires special consideration because of the high risk for thrombosis, particularly during the puerperium. Women with thrombophilia who have previously had thrombosis—and probably also asymptomatic women with thrombophilia—should receive prophylactic anticoagulation throughout pregnancy and for 4 to 6 weeks postpartum, a particularly high-risk period. Coumarin derivatives cross the placenta and have the potential to cause both bleeding and teratogenic effects in the fetus; therefore, oral anticoagulants should not be used during pregnancy. Heparin does not cross the placenta and does not cause these fetal complications. Therefore, either unfractionated heparin or fixed-dose, low-molecular-weight heparin is the anticoagulant of choice during pregnancy. Neither warfarin nor heparin induces an anticoagulant effect in a breast-fed infant when the drug is given to a nursing mother, so either can be given safely when indicated in the postpartum period.

Because warfarin-induced skin necrosis (see Fig. 179-1) is a rare problem, screening of all patients for inherited protein C or protein S deficiency, conditions that are known to predispose to this complication, is not indicated before starting warfarin therapy. Most cases can be avoided by not initiating warfarin therapy with high loading doses and by concomitant coverage with heparin. When the complication does occur, as manifested by painful red and subsequently dark, necrotic skin lesions within a few days of starting warfarin, such therapy must be discontinued immediately, vitamin K administered, and heparin started (Chapter 37). The use of fresh-frozen plasma or purified protein C concentrate to normalize protein C levels rapidly can improve results. Despite this rare complication, warfarin is an effective, long-term prophylactic anticoagulant in patients with inherited protein C or protein S deficiency.

Antithrombin III concentrate purified from normal human plasma may be a useful adjunct to anticoagulation in "heparin-resistant" patients, who represent unusual cases of type II antithrombin deficiency, and in antithrombin-deficient patients with recurrent thrombosis despite adequate anticoagulation. Infusion of antithrombin concentrate can also be considered in some perioperative or obstetric settings in which anticoagulation poses an unacceptable bleeding risk.

TABLE 179-3 LONG-TERM MANAGEMENT OF PATIENTS WITH PRIMARY HYPERCOAGULABLE STATES

RISK CLASSIFICATION	MANAGEMENT
High risk ≥2 spontaneous thromboses 1 spontaneous life-threatening thrombosis 1 spontaneous thrombosis at an unusual site (e.g., mesenteric, cerebral venous) 1 spontaneous thrombosis in the presence of antiphospholipid syndrome, antithrombin deficiency, or more than a single hypercoagulable state	Indefinite anticoagulation or lifelong chronic anticoagulation
Moderate risk 1 thrombosis with an acquired prothrombotic stimulus	Vigorous prophylaxis during high-risk situations
Asymptomatic	

Modified from Bauer K. Approach to thrombosis. In: Loscalzo J, Schafer AI, eds. *Thrombosis and Hemorrhage,* 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2003:330-342.

SECONDARY HYPERCOAGULABLE STATES

DEFINITION

The secondary hypercoagulable states (Fig. 179-2) are diverse, mostly acquired disorders that predispose patients to thrombosis by complex, multifactorial pathophysiologic mechanisms. Many of these conditions also represent the acquired precipitating stimuli for clinical thrombotic events in individuals with a genetic predisposition (primary hypercoagulable states). Although each disorder causes thrombosis primarily through abnormalities in blood flow (rheology), the composition of blood (coagulation factors and platelet function), or the vessel wall, multiple overlapping mechanisms are operative in many of them.

Hyperhomocysteinemia

Hyperhomocysteinemia is an elevated blood level of homocysteine, a sulfhydryl amino acid derived from methionine by a transmethylation pathway (E-Fig. 179-1). Homocysteine is remethylated to methionine or catabolized to cystathionine. The major remethylation pathway requires folate and cobalamin (vitamin B_{12}) and involves the action of methylenetetrahydrofolate reductase (MTHFR); a minor remethylation pathway is mediated by betaine-homocysteine methyltransferase. Alternatively, homocysteine is converted to cystathionine in a trans-sulfuration pathway catalyzed by cystathionine β-synthase (CBS), with pyridoxine used as a cofactor.

Homozygous CBS deficiency states that lead to severe hyperhomocysteinemia (homocystinuria) (Chapter 216) cause premature arterial atherosclerotic disease and VTE, as well as mental retardation, neurologic defects, lens ectopy, and skeletal abnormalities. By comparison, adults with heterozygous CBS deficiency, with resultant mild to moderate hyperhomocysteinemia, may have only venous or arterial thrombotic manifestations. Hyperhomocysteinemia resulting from inherited remethylation pathway defects usually involves reduced activity of MTHFR. In homozygous individuals with the autosomal recessive C677T mutation of the *MTHFR* gene, which occurs in 15% of certain populations, moderate hyperhomocysteinemia may occur and is correctable with folic acid, but it does not appear to be related to risk of venous thrombosis. Acquired causes of hyperhomocysteinemia in adults most commonly involve nutritional deficiencies of the cofactors required for homocysteine metabolism, including pyridoxine, cobalamin, and folate.

Acquired and inherited hyperhomocysteinemia is a probable risk factor for both arterial and venous thrombosis. The mechanism of homocysteine-induced thrombosis and atherogenesis involves complex, probably multifactorial effects on the vessel wall. Homocysteine can cause vascular endothelial injury, conversion of the endothelial surface of blood vessels from an antithrombotic to a prothrombotic state, and smooth muscle cell proliferation. These toxic effects of homocysteine on the vessel wall may be mediated by oxidant stress.

Vitamin supplementation with folate, pyridoxine, and cobalamin can normalize elevated blood levels of homocysteine. However, several prospective

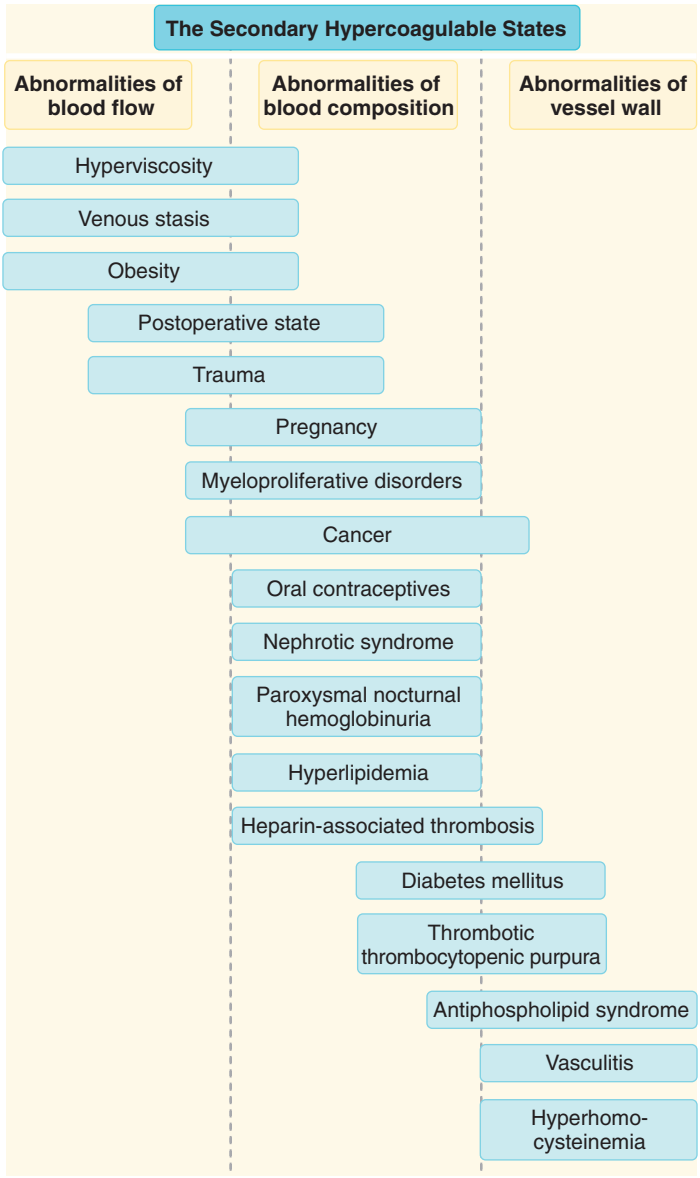

FIGURE 179-2. Secondary hypercoagulable states. The pathophysiologic basis of thrombotic risk in these diverse disorders is complex and multifactorial. Predominant mechanisms of thrombosis for the different secondary hypercoagulable states shown are based on Virchow's triad of thrombogenesis: abnormalities in blood flow, abnormalities in blood composition, and abnormalities of the vessel wall. (Modified from Schafer AI. The primary and secondary hypercoagulable states. In: Schafer AI, ed. *Molecular Mechanisms of Hypercoagulable States.* New York: Chapman & Hall; 1997:16.)

clinical trials of homocysteine-lowering therapy have failed to show reduced rates of vascular events in patients with established vascular disease. It remains to be determined whether this disappointing lack of clinical benefit with homocysteine-lowering vitamin therapy indicates that homocysteine is not a direct atherogenic factor, or that vitamin therapy in this setting might have other, offsetting deleterious effects, or that possibly other mechanisms are operative.

Malignancy

Multiple abnormalities of hemostasis are involved in the hypercoagulable state in cancer patients, many of which initiate a systemic process of chronic DIC (Chapter 178). The thrombotic tendency of patients with cancer may also be related to mechanical factors, such as immobility, indwelling central venous catheters, or a bulky tumor mass compressing vessels, and to comorbid conditions, such as sepsis, surgery, liver dysfunction secondary to metastases, and the prothrombotic effects of certain antineoplastic agents.

The incidence of thrombotic complications in cancer patients depends in part on the type of malignancy. Hypercoagulability is most prominent in patients with pancreatic cancer (Chapter 200), adenocarcinoma of the gastrointestinal tract (Chapters 198 and 199) or lung (Chapter 197), ovarian cancer (Chapter 205), and hematologic malignancies. The presence of underlying malignancy compounds the independent risk for thrombosis in the postoperative state. Thrombosis most commonly occurs in patients with established or concurrently diagnosed malignancy. In these patients, the risk of venous thrombosis has been found to be highest in the first few months after the diagnosis of malignancy, then decreases progressively over the subsequent 15 years. The same large case-control study showed that the risk of venous thrombosis in cancer patients is approximately 12- to 17-fold increased in those who also have the factor V Leiden or the prothrombin G20210A mutation.■

The most frequent thrombotic manifestations in patients with neoplasms are deep vein thrombosis and pulmonary embolism, but more unusual and distinctive thrombotic complications are also found. Trousseau's syndrome, characterized by migratory superficial thrombophlebitis of the upper or lower extremities, is strongly linked to cancer. Nonbacterial thrombotic endocarditis involves fibrin-platelet vegetations on heart valves, which produce clinical manifestations by systemic embolization (Chapter 60). Of patients with nonbacterial thrombotic endocarditis, 75% have underlying malignancies at autopsy. Trousseau's syndrome and nonbacterial thrombotic endocarditis are highly associated with adenocarcinomas. The occurrence of either syndrome in patients without known cancer demands a more vigorous search for occult malignancy than in patients with deep vein thrombosis or pulmonary embolism. Thrombotic microangiopathy (Chapter 175), characterized by hemolysis with red blood cell fragmentation, thrombocytopenia, and microvascular thrombosis with involvement of target organs, occurs in about 5% of patients with metastatic carcinomas, most commonly those with gastric (Chapter 198), lung (Chapter 197), and breast (Chapter 204) primary sites.

TREATMENT Rx

Treatment of acute VTE in cancer patients should be initiated as in other patients, but subsequent prophylactic anticoagulation should be continued while active malignancy is present. Anticoagulation can be difficult in many cancer patients; these patients may be resistant to warfarin prophylaxis. Anticoagulation can also be complicated by bleeding into tumors. Long-term treatment of cancer patients with low-molecular-weight heparin after VTE (Chapter 37) reduces recurrences and possibly decreases bleeding complications when compared with treatment with warfarin.■

Myeloproliferative Disorders and Paroxysmal Nocturnal Hemoglobinuria

Thrombosis and, apparently paradoxically, bleeding are major causes of morbidity and mortality in patients with myeloproliferative disorders (Chapter 169) and the related stem cell disorder paroxysmal nocturnal hemoglobinuria (Chapter 163). In uncontrolled polycythemia vera (Chapter 169), increased whole blood viscosity contributes to the thrombotic tendency. Thrombocytosis, abnormal platelet function, and other less well understood factors are also probably involved in the hemostatic defect of the myeloproliferative disorders and paroxysmal nocturnal hemoglobinuria.

In addition to deep vein thrombosis and pulmonary embolism, some distinctive thrombotic manifestations are seen. Hepatic vein thrombosis (Budd-Chiari syndrome) and portal and other intra-abdominal venous thromboses (Chapter 145) are associated with myeloproliferative disorders and paroxysmal nocturnal hemoglobinuria (Chapter 163) and may be the initial manifestations of the disease. Myeloproliferative disorders, particularly polycythemia vera (Chapter 169) and essential thrombocythemia (Chapter 169), may cause erythromelalgia, a syndrome of microvascular thrombosis manifested by intense pain accompanied by warmth, duskiness, and mottled erythema, sometimes resembling livedo reticularis, in a patchy distribution in the extremities, most prominently in the feet; digital microvascular ischemia progressing to vascular insufficiency and gangrene may ensue (Chapter 80). A wide spectrum of neurologic manifestations may be caused by cerebrovascular ischemia, especially in patients with essential thrombocythemia.

TREATMENT Rx

Treatment of VTE in patients with the myeloproliferative disorders and paroxysmal nocturnal hemoglobinuria should be initiated as in patients without these hematologic disorders. In patients with thrombosis associated with polycythemia vera, the hematocrit should be maintained in the normal range with

phlebotomies or chemotherapy, or with both (Chapter 169). Low-dose aspirin (100 mg daily) can prevent thrombotic complications without increasing the incidence of major bleeding in patients with polycythemia vera who have no contraindications to such treatment. In patients with essential thrombocythemia, cytoreduction of the elevated platelet count should be achieved with chemotherapy (Chapter 169).

Antiphospholipid Syndrome

Antiphospholipid syndrome (Chapter 177) is characterized by venous and arterial thrombosis, recurrent spontaneous abortions (which may also be due to thrombosis), thrombocytopenia, and a variety of neuropsychiatric manifestations. The syndrome is associated with a heterogeneous group of autoantibodies that bind to anionic phospholipid-protein complexes, a protein cofactor of which is β_2-glycoprotein I. Patients with this syndrome have any combination of positive tests to detect different plasma antiphospholipid-protein antibodies (e.g., anticardiolipin antibodies) and phospholipid-based clotting tests (lupus anticoagulants) (Chapter 265). The predominant prothrombotic effects of these antibodies are probably directed to the vessel wall.

Deep vein thrombosis and pulmonary embolism are the most frequent venous thrombotic events in these patients. Cerebrovascular events are the most common arterial thrombotic complications and are manifested as stroke, transient ischemic attacks (Chapter 414), multi-infarct dementia (Chapter 409), or retinal artery occlusion. Peripheral and intra-abdominal vascular occlusion is encountered more rarely. About one third of these patients have nonbacterial heart valve vegetations (Libman-Sacks endocarditis). The most prominent obstetric complications are recurrent spontaneous abortions and fetal growth retardation, which are probably due to thrombosis of placental vessels. Patients are occasionally seen with "catastrophic" antiphospholipid syndrome involving a series of acute and sometimes fatal vascular occlusive events, or "thrombotic storm." Thrombotic complications are limited largely to patients with primary antiphospholipid syndrome and patients in whom the antibodies are associated with collagen vascular disease, not with drugs or infections.

TREATMENT Rx

Acute management of thrombosis in these patients is essentially the same as in other individuals. Monitoring of heparin anticoagulation is difficult in patients with a lupus anticoagulant because they already have a prolonged activated partial thromboplastin time at baseline; the use of low-molecular-weight heparin, which does not require monitoring, can circumvent this problem. Warfarin is effective in preventing recurrent thrombosis but usually requires prolonged or indefinite therapy with doses to achieve an INR of 2.0 to 3.0. No established treatment of women with antiphospholipid syndrome has been shown to prevent recurrent fetal loss. Treatment with prednisone and aspirin during pregnancy is not effective in promoting live birth and may increase the risk for prematurity.

Pregnancy, Oral Contraceptives, and Hormone Replacement Therapy

The pathophysiology of hypercoagulability associated with pregnancy (Chapter 247) involves a progressive state of DIC throughout the course of pregnancy. Activation of the coagulation system is initiated locally in the uteroplacental circulation, where the placenta is the source of increased thrombin generation. Platelet activation and increased platelet turnover also occur during normal pregnancy, and about 8% of healthy women have mild thrombocytopenia at term. Simultaneously, the fibrinolytic system is progressively blunted throughout pregnancy because of the action of placental plasminogen activator inhibitor type 2. The net effect of these coagulation changes is creation of a state of hypercoagulability that makes pregnant women vulnerable to thrombosis, particularly in the puerperium. These systemic alterations are compounded by prothrombotic mechanical and rheologic factors in pregnancy, including venous stasis in the legs caused by the gravid uterus, pelvic vein injury during labor, and the trauma of cesarean section. Oral contraceptives induce a prothrombotic state by increasing procoagulant effects and decreasing physiologic anticoagulant effects. The use of oral contraceptives is associated with an increased risk for venous thrombosis, myocardial infarction, stroke, and peripheral arterial disease, particularly during the first year of use (Chapter 246). Unexpectedly, third-generation oral contraceptives, which contain less estrogen and a different progestin, double the risk for venous thromboembolism in comparison to second-generation preparations. Postmenopausal hormone replacement increases the risk for deep venous thromboembolism by a factor of 2 to 3.5, at least during the first year. Hormone replacement therapy has no beneficial and possibly even a detrimental effect on the risk for arterial disease (Chapter 248).

Deep vein thrombosis and pulmonary embolism are the most common thrombotic complications of pregnancy and the use of oral contraceptives or hormone replacement therapy. Coexisting primary hypercoagulable states are an additive risk factor in all these settings. In the absence of a clear family history of venous thromboembolism, there is little justification, however, to screen for prothrombotic mutations with pregnancy or before starting hormone replacement therapy or oral contraceptives. Increasing age, increasing parity, cesarean delivery, prolonged bedrest or immobilization, obesity, and previous thromboembolism are additional prothrombotic risk factors in pregnant women. Most thrombotic events associated with pregnancy occur in the peripartum period, especially after delivery. Special considerations for anticoagulation in the setting of pregnancy are noted in the section on treatment of primary hypercoagulable states.

Postoperative State, Immobilization, and Trauma

Postoperative thrombosis (Chapter 441) is caused by a combination of local mechanical factors, including decreased venous blood flow in the lower extremities, and systemic changes in coagulation (Chapter 81). The level of risk for postoperative thrombosis depends largely on the type of surgery performed. It is probably compounded by coexisting risk factors, such as an underlying inherited primary hypercoagulable state or malignancy, advanced age, and prolonged procedures. Postoperative deep vein thrombosis and pulmonary embolism, the most common thrombotic complications, are often asymptomatic but detectable by noninvasive studies. The incidence of deep vein thrombosis after general surgical procedures is about 20 to 25%, with almost 2% of these patients having clinically significant pulmonary embolism. The risk for deep vein thrombosis after hip surgery and knee reconstruction ranges from 45 to 70% without prophylaxis, and clinically significant pulmonary embolism occurs in 20% of patients undergoing hip surgery. Postoperative thrombosis risk after urologic and gynecologic surgery more closely approximates that found after general surgery. Although the process of thrombosis generally begins intraoperatively or within a few days of surgery, the risk for this complication can be protracted beyond the time of discharge from the hospital, particularly in hip replacement patients.

Patients who are bedridden or experiencing prolonged air travel are at increased risk for VTE. VTE is also one of the most common causes of morbidity and mortality in survivors of major trauma, and asymptomatic deep vein thrombosis of the lower extremities has been detected by venography in more than 50% of hospitalized trauma patients (Chapter 112). The risk for venous thrombosis after trauma is increased by advanced age, need for surgery or transfusions, and the presence of lower extremity fractures or spinal cord injury.

Mechanical methods of prophylaxis against VTE should be considered in high-risk postoperative patients and bedridden patients with medical conditions, either in combination with anticoagulant prophylaxis or instead of it in patients who have an unusually high risk for bleeding with anticoagulation. Such methods include graduated compression stockings, intermittent pneumatic compression devices, and venous foot pumps. For long-distance travelers with thrombophilia, either properly fitted below-knee graduated compression stockings or a single prophylactic dose of low-molecular-weight heparin injected before departure is recommended in addition to general measures such as avoidance of dehydration and frequent stretching of calf muscles.

180 TRANSFUSION MEDICINE

LAWRENCE T. GOODNOUGH

DEVELOPMENT OF TRANSFUSION MEDICINE

Issues in blood transfusion and blood conservation include the safety of blood, the formation of guidelines and consensus statements on the use of blood components and products, new strategies in blood conservation, emerging alternatives to blood transfusion, and informed consent for transfusion. The broad-based constituency of transfusion medicine includes blood collection facilities, hospital-based transfusion services, research laboratories, and the commercial sector.

THE TRANSFUSION MEDICINE SPECIALIST

Medical management of the blood bank involves issues related to blood inventory and safety, as well as the oversight of laboratory policies and procedures (Fig. 180-1). Management of the transfusion service includes coordinating blood transfusion and blood conservation activities and serving as a consultant to clinicians whose patients are undergoing massive transfusions, apheresis, or transplantation or who are having difficulty finding compatible blood products. Finally, the transfusion medicine specialist supervises quality assurance to satisfy regulatory and accreditation requirements.

TRANSFUSION

Worldwide, more than 75 million units of whole blood are estimated to be donated every year. In the United States, the yearly transfusion of more than 13 million units corresponds to the transfusion of 1 unit of blood every 0.39 second.

Blood Availability

Blood centers must be able to supply blood in response to acute crises. Sporadic shortages of blood and blood products (e.g., packed red cells, platelet products, albumin, intravenous immunoglobulin, and clotting factor concentrates) are potentially life threatening. Such shortages have been attributed to disruptions in production, increasingly strict criteria for accepting donors, product recalls, increased use (including off-label use), and stockpiling or other market issues.

In the United States, the Department of Health and Human Services monitors sentinel community blood services and hospital transfusion services to track blood collection and transfusion activity. Blood transfusion and collection activities peaked in 1986 and then declined until 1994. However, blood transfusion and collection subsequently increased 8.0% in 1997, 10.2% in 1999, and an estimated 4% to 5% annually thereafter.

Within the American Red Cross, which supplies about half of all blood products in the United States, a 3- to 4-day supply of red blood cell products is typical, but some independent centers have higher reserves. Use of frozen red cells as a hedge against inventory shortages has generally not been practical because the shelf life of thawed units is only 24 hours; however, an automated, functionally closed system for the glycerolization and deglycerolization processes allows a 2-week post-thaw shelf life. With such a system, many blood centers and transfusion services can expand their available red cell inventories as reserves. After disasters—human or natural—on-hand blood supplies are adequate in the short term and can be rapidly mobilized over great distances. Because of the need to maintain reserves, blood collection must routinely surpass the anticipated need for blood transfusion.

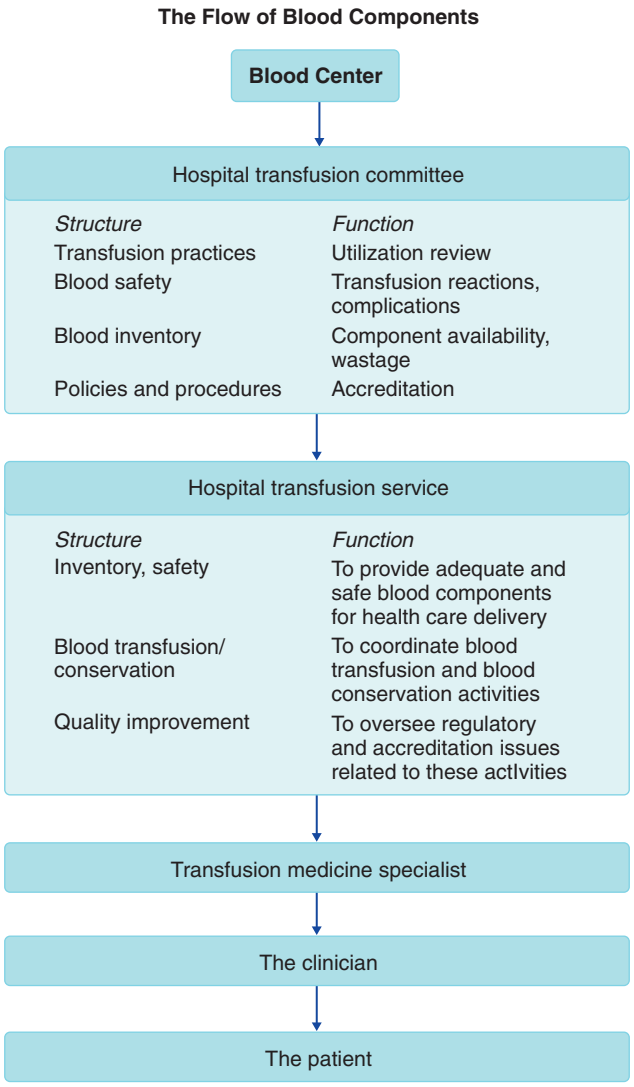

FIGURE 180-1. A hospital's transfusion committee and transfusion service can help clinicians manage the availability, safety, and use of blood products. (From Goodnough LT. What is a transfusion medicine specialist? *Transfusion.* 1999;39:1031-1033.)

Red Blood Cell Transfusion

Whole Blood

A unit of blood is collected as a donation of 450 mL ± 10% into a citrate anticoagulant that also contains phosphate and dextrose. The red cell and hemoglobin content is variable and dependent on the donor's hematocrit and the precise volume bled.

Whole blood is stored at 4 ± 2° C to diminish red cells' utilization of adenosine triphosphate and to preserve their viability, which should be at least 70% at the end of a shelf life of 35 days. After 10 days of storage, all predonation 2,3-diphosphoglycerate content in red cells is lost, but up to 50% is regenerated within 8 hours after transfusion.

In Western countries, whole blood is rarely used because within a few hours or days, some coagulation factors (especially factors V and VIII) and platelets decrease in quantity or lose viability. After a 7-day hold at 4° C, factor VIII levels fall to 0.32 ± 0.09 IU/mL, and factor V levels fall to 0.78 ± 0.15 IU/mL. At 4° C, platelets undergo a shape change from discoid to spherical that is irreversible after 8 hours, and their in vivo survival is reduced to 2 days.

Red Cell Components

Red cells are provided in various formats that differ with respect to the presence of additive solutions and the extent to which white cells are removed. Solutions that contain combinations of saline, adenine, phosphate, bicarbonate, glucose, and mannitol provide better red cell viability during storage and allow up to a 42-day shelf life. Red cells and red cells in additive solution can be

used interchangeably, with the exception that red cells in additive solution are not recommended for exchange or massive transfusions in neonates.

Red cells should be refrigerated until the time of the transfusion because of the risk for bacterial proliferation within the pack at room temperature. Red cells that have been out of refrigeration for 30 minutes or longer cannot be returned to stock. A unit of red cells should be infused over a maximum period of 4 hours.

Irradiated Cellular Blood Components

Gamma-irradiated cellular blood components are used to prevent the occurrence of transfusion-associated graft-versus-host disease (see later).

Leukocyte-Reduced Blood Components

Blood components are depleted of leukocytes by means of filtration. A leukocyte-reduced component is defined as one with less than 5×10^6 residual white cells per liter, and 100% of tested units should meet this standard. Leukocyte removal should be performed while the cells are still intact by filtering the blood as soon as possible after collection.

Leukocyte reduction reduces the incidence of human leukocyte antigen (HLA) alloimmunization in multitransfused recipients, but immunization rates of 10 to 25% are still seen in women who have already been exposed to HLA alloantigens through previous pregnancy. Leukocyte reduction has less impact on refractoriness to random platelet donations because of the importance of nonimmune factors in the poor response to transfused platelets.

Leukocyte reduction also lowers the risk for nonhemolytic febrile reactions after the transfusion of red cells or platelets. Several, but not all, studies suggest that leukocyte reduction has a beneficial impact on the rate of postoperative infection. The impact of leukocyte reduction on the incidence of transfusion-associated graft-versus-host disease is unknown.

Preventing Transmission of Cytomegalovirus

A small number of studies of prestorage leukocyte reduction have suggested its efficacy in preventing transfusion-transmitted cytomegalovirus (CMV) infection (Chapter 384), which occurs in 4% of cases, even with seronegative components. Prestorage leukocyte depletion reduces the infection rate to less than 1%, suggesting that this technology may be at least equivalent to serologic testing for CMV antibodies for the prevention of CMV transmission; however, CMV testing of leukocyte-reduced components continues to be performed by most transfusion services. Indications for CMV-seronegative components include transfusion in pregnancy, intrauterine transfusion, transfusions to neonates less than 37 weeks' gestation, transfusions to CMV-seronegative patients who are potential or actual recipients of allogeneic bone marrow or peripheral blood progenitor transplants when the donor is also CMV seronegative, and patients infected with human immunodeficiency virus (HIV).

Immunomodulatory Effects

Previous transfusion has an immunomodulatory benefit for the survival of renal allografts, even with the use of potent immunosuppressive drugs, although the exact mechanism of this benefit remains unknown. Retrospective studies suggest an adverse effect of transfusion on the rate of perioperative infections or recurrent cancers.

Typing and Crossmatching

Blood and blood components for transfusion must be compatible with the same blood type as the patient. Obtaining an accurate ABO/Rh grouping for a patient is the most significant serologic test performed before transfusion. When type-specific blood and components are unavailable or emergency circumstances do not allow their identification or use, type O-negative red cells should be used. Group O is the only choice for group O recipients and is the alternative choice for groups A, B, and AB.

Red cell antigens other than ABO and D are not routinely considered when selecting *donor* blood products for transfusion; the exception is when unexpected, clinically significant red cell antibodies are present in the patient, as determined by an antibody screen or previous identification. Red cell alloantibodies are produced by exposure to foreign red cell antigens via previous transfusion, pregnancy, or both. For an antibody to be considered clinically significant, it must be associated with a hemolytic transfusion reaction or decreased survival of transfused incompatible red cells. Most of the clinically significant antibodies are optimally reactive at 37° C or are detected by the antiglobulin test. If an antibody screen is negative in the *recipient,* the probability is greater than 99% that an ABO and Rh crossmatch will also be compatible. If no unexpected, clinically significant antibodies are detected and there is no record of their previous detection, only serologic testing for ABO incompatibility is required (i.e., antiglobulin testing is not required when the crossmatch is performed).

Red Blood Cell Transfusion

If a transfusion is appropriate, a benefit should occur. In a large study of Jehovah's Witnesses (whose religious beliefs preclude the use of blood transfusion), the risk of death was higher in surgical patients with cardiovascular disease than in those without. A follow-up analysis of a subset of these patients reported that the odds of death in patients with a postoperative hemoglobin level less than 7 g/dL increased 2.5 times for each gram decrease in the hemoglobin level; although no deaths occurred in 98 patients with postoperative levels of 7.1 to 8.0 g/dL, 34.4% of 32 patients with postoperative levels of 4.1 to 5.0 g/dL died. These data suggest that in surgery-induced anemia, survival is improved if blood transfusion is administered to maintain the hemoglobin concentration at greater than 7 g/dL. In a large, retrospective study of elderly patients who underwent surgical repair of hip fractures, the use of perioperative transfusion in those with hemoglobin levels as low as 8 g/dL did not appear to influence 30- or 90-day mortality.

In a multi-institutional study, 418 critical care patients received red cell transfusions when their hemoglobin levels dropped below 7 g/dL and had their levels maintained between 7 and 9 g/dL, whereas another 420 patients received transfusions when their hemoglobin levels dropped below 10 g/dL and had their levels maintained between 10 and 12 g/dL. Thirty-day mortality rates were not significantly different in the two groups, suggesting that a transfusion threshold as low as 7 g/dL may be as safe as a higher threshold of 10 g/dL in critically ill patients.[1] A follow-up analysis found that the more restrictive strategy of red blood cell transfusion also appeared to be safe in most patients with cardiovascular disease.

A retrospective study analyzed the relationships among anemia, blood transfusion, and mortality in nearly 80,000 patients older than 65 years hospitalized for acute myocardial infarction. Anemia, defined as a hematocrit below 39%, was present on hospital admission in 44% of patients and was 33% or less in 10% of patients; blood transfusion in patients with hematocrit levels lower than 33% at admission was associated with a significantly lower 30-day mortality. On the basis of this study, transfusion to maintain hematocrit levels above 33% has been recommended in patients with acute myocardial infarction. In patients with heart failure, transfusion to maintain a hemoglobin level above 10 g/dL appears to improve outcomes. Among patients undergoing cardiac surgery, a restrictive perioperative transfusion strategy is as good as a more liberal strategy.[2]

Guidelines

Guidelines from several professional groups recommend that blood not be transfused prophylactically in patients without risk factors until the hemoglobin level is 6 to 8 g/dL; a threshold of 8 g/dL seems appropriate in surgical patients with no risk factors for ischemia, whereas a threshold of 10 to 11 g/dL can be justified for patients considered to be at risk: those with myocardial ischemia or infarction, heart failure, chronic lung disease, or chronic kidney disease. With substantial improvements in blood safety, now the concern is that some patients may be at risk for undertransfusion.

Platelet Transfusion

The use of intensive chemotherapy regimens and bone marrow or stem cell transplantation has increased the demand for platelet products, particularly in patients with severe thrombocytopenia or bleeding complications. The use of apheresis platelet transfusions (i.e., a platelet unit collected from a dedicated donor via an apheresis procedure) has increased substantially, driven by the need for platelet inventories to support cardiac surgery, oncology, and stem cell transplantation programs. Emerging issues in platelet transfusion therapy include re-evaluation of the platelet threshold for prophylactic transfusion and modification of the dose of platelet transfusions.

Threshold for Platelet Transfusion

The appropriate threshold for platelet transfusion depends on the clinical situation (Fig. 180-2). Prospective, randomized studies indicate that a platelet transfusion threshold of 10,000 cells/μL is as safe and effective as higher thresholds in patients undergoing chemotherapy or stem cell transplantation.[3]

For consumptive thrombocytopenias such as disseminated intravascular coagulation (Chapter 178), platelet therapy is supportive but not effective

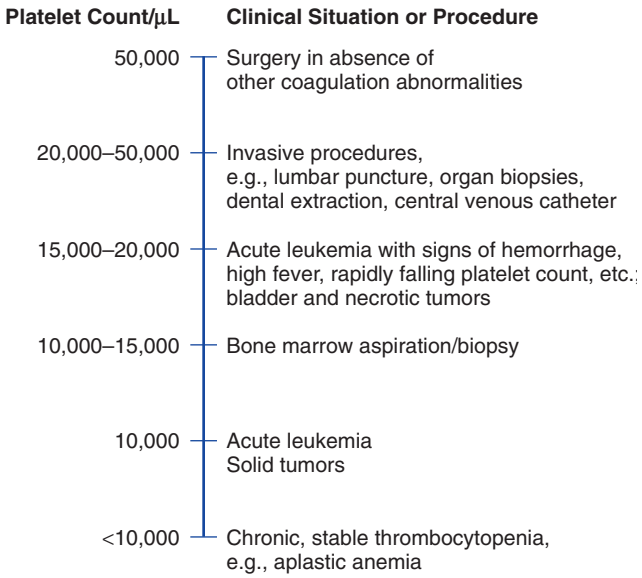

FIGURE 180-2. Threshold for providing platelet transfusions in thrombocytopenic patients.

until the underlying cause is treated. Platelet transfusions are generally not indicated in patients with idiopathic thrombocytopenic purpura or the thrombotic microangiopathies such as thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome (Chapter 175).

Platelet Dose

American Association of Blood Bank (AABB) standards require that 75% of apheresis platelet products contain more than 3×10^{11} platelets; however, no consensus exists for a standardized platelet dose, and clinical trials have used a broad range of doses. In general, higher platelet doses result in greater incremental increases in the platelet count and prolonged time to the next transfusion; however, the estimated platelet half-life is similar, and there are no other differences in outcomes.

Low-dose platelet therapy (i.e., <1 platelet unit) may be more beneficial in thrombocytopenic patients who are receiving prophylactic platelet transfusions. The fixed platelet requirement for hemostasis is estimated to be 7100/μL^3/day, and platelet needs above this threshold are mainly a result of platelet consumption. For patients who become thrombocytopenic as a result of myeloablative therapy, platelet survival decreases with increasing severity of thrombocytopenia. A trial of prophylactic platelet transfusions in patients with hypoproliferative thrombocytopenia found that low doses (1.1×10^{11} per square meter) of platelets led to a decreased number of transfusions but an increased number of platelets transfused (and donor exposures).■ At doses between 1.1×10^{11} and 4.4×10^4 platelets per square meter, no effect on the incidence of bleeding was demonstrated.

Plasma Transfusion

Plasma therapy provides a source of clotting factors for patients with inherited or acquired coagulation disorders. Patients with inherited disorders such as hemophilia (Chapter 177) or von Willebrand disease (Chapter 176) are now treated primarily with clotting factor concentrates, which are blood derivatives from processed and treated commercial lots from pooled donors. For patients with acquired coagulopathies, there is little systematically derived, evidence-based guidance to inform plasma transfusion decisions. For patients with mild prolongation of coagulation assays such as prothrombin time and partial thromboplastin time (Chapter 174), plasma therapy has little or no value in prophylaxis for invasive procedures. Plasma therapy is indicated in patients undergoing massive hemorrhage (trauma, postpartum hemorrhage, or gastrointestinal bleeding) or for emergent reversal of warfarin-associated coagulopathy (Chapter 37), such as in patients with intracranial hemorrhage. Recommended dosage in these settings is 15 to 30 mL/kg.

BLOOD SAFETY

Adverse reactions associated with transfusion are listed in Table 180-1.

Errors in Transfusion Medicine

The mistransfusion rate (blood transfused to other than the intended recipient) is about 1 in 14,000 to 28,000 units. About two thirds of the errors occur in the clinical arena (patient misidentification and/or specimen mislabeling at time of drawing blood for type and screen/crossmatch, incorrect identification of the recipient of the blood unit, and failure to recognize a transfusion reaction). About half of mistransfusions are ABO incompatible, and about 10% of these are fatal. The frequency of death as a result of ABO error can therefore be estimated at approximately 1 per 600,000 blood units, a risk that is higher than the risk of transmitting HIV or hepatitis C virus.

TABLE 180-1 TRANSFUSION-ASSOCIATED ADVERSE REACTIONS

ADVERSE REACTION	RISK PER UNIT INFUSED
ABO-incompatible blood transfusions	1 in 30,000–60,000
Symptoms	40%
Fatalities	1 in 600,000
Delayed serologic reactions	1 in 1600
Delayed hemolytic reactions	1 in 6700
Transfusion-related acute lung injury	1 in 8000
Graft-versus-host disease	Rare
Fluid overload	Underestimated
Febrile, nonhemolytic transfusion reactions	
Red blood cells (non–leukocyte reduced/ leukocyte reduced)	1 in 200/1 in 300
Platelets (non–leukocyte reduced/leukocyte reduced)	1 in 5–20/1 in 25–50
Allergic reactions	1 in 30–100
Anaphylactic reactions	1 in 150,000
Iron overload	After 80–100 U
Post-transfusion purpura	Rare
Immunosuppressive effects	Unknown

Modified from Goodnough LT. Current issues in transfusion medicine. *Clin Adv Hematol Oncol.* 2005;3:614-616.

Transfusion Reactions

Acute Hemolytic Transfusion Reaction

An acute hemolytic transfusion reaction is most commonly defined as hemolysis of donor red cells within 25 hours of transfusion by preformed alloantibodies in the recipient's circulation. Life-threatening acute hemolytic transfusion reactions are most commonly due to ABO-incompatible blood being transfused to a recipient with naturally occurring ABO alloantibodies (anti-A, anti-B, anti-A, B). Clerical errors (mislabeling blood or misidentifying patients) account for 80% of such reactions.

Signs and symptoms of an acute intravascular hemolytic transfusion reaction may develop when as little as 10 to 15 mL of ABO-incompatible blood has been infused. Fever, which is the most common initial manifestation, is frequently accompanied by chills. The patient may complain of a general sense of anxiety or uneasiness or pain at the infusion site or in the back or chest (or both). The most serious sequela is acute renal failure. In an unconscious or anesthetized patient, diffuse bleeding at the surgical site may be the first indication of intravascular hemolysis and may be accompanied by hemoglobinuria and hypotension.

Treatment begins with immediate cessation of the transfusion. The risk for renal failure may be reduced by the administration of crystalloid fluids, including sodium bicarbonate (250 to 500 mg intravenously over a 1- to 4-hour period), to maintain urine pH at 7.0 and by diuresis with 20% mannitol (100 mL/m^2 in 30 to 60 minutes, followed by 30 mL/m^2/hour for 12 hours) or furosemide (40 to 120 mg intravenously).

Febrile Nonhemolytic Transfusion Reactions

Febrile nonhemolytic transfusion reactions are common and are estimated to occur in 0.5% of all red cell transfusions and up to 30% of platelet transfusions. A febrile transfusion reaction is defined as a rise in temperature greater than 1° C, which may be accompanied by chills, rigor, or both.

These reactions are thought to be due to a reaction of HLA or leukocyte-specific antigens (or both) on transfused lymphocytes, granulocytes, or platelets in the donor unit with antibodies in previously alloimmunized recipients. Multiply transfused individuals and multiparous women are most likely to experience this type of transfusion reaction. Febrile nonhemolytic transfusion reactions, especially those associated with platelet transfusions, may be caused by the infusion of biologic response modifiers, such as cytokines, that have accumulated in the platelet concentrate during storage.

Symptoms may occur during the transfusion or may not manifest until 1 to 2 hours after its completion. The diagnosis of a febrile nonhemolytic transfusion reaction is generally made by excluding other causes of fever (e.g., bacterial contamination of blood, acute hemolytic transfusion reaction).

Febrile nonhemolytic transfusion reactions in susceptible populations can often be prevented by administering antipyretics before the transfusion of blood components. Prestorage leukocyte reduction is recommended to prevent reactions resulting from the accumulation of cytokines during storage.

Allergic Reactions

Allergic reactions can be mild, moderate, or life threatening and are associated with the amount of plasma transfused. From 1 to 5% of all blood transfusion recipients experience mild allergic reactions.

Anaphylactic transfusion reactions are sometimes associated with antibodies to immunoglobulin (Ig) A, which are common and have an incidence of approximately 1 in 700 individuals. However, the incidence of anaphylactic transfusion reactions is much lower—1 in 20,000 to 50,000.

Urticarial reactions are not well understood but are believed to be an interaction between antibodies in the recipient's plasma and plasma proteins in the donor blood. There is usually no specific identifiable antigen to which the patient is reacting. Symptoms are generally mild and include localized urticaria, erythema, and itching.

Anaphylactic or anaphylactoid reactions, which can occur after the transfusion of only a few milliliters of blood or plasma, include skin flushing, nausea, abdominal cramps, vomiting, diarrhea, laryngeal edema, hypotension, shock, cardiac arrhythmia, cardiac arrest, and loss of consciousness. Fever is notably absent. In some cases, there may be symptoms indicative of airway involvement, such as hoarseness, wheezing, dyspnea, and substernal pain. Management begins with discontinuation of the transfusion. Treatment is diphenhydramine (25 to 50 mg intravenously), but more severe episodes may require aggressive therapy (Chapters 260 and 261).

Patients who experience recurrent allergic or urticarial reactions can be treated with antihistamines before transfusion. Washed red blood cells may be indicated for patients who experience repeated severe urticarial reactions.

Bacterial Contamination

Bacterial contamination may be introduced into a unit of blood through skin contaminants during venipuncture or from donors with asymptomatic bacteremia. Multiplication of bacteria can occur in blood and blood components stored at refrigerated temperatures but is more likely to occur in platelets stored at room temperature.

Bacterial contamination of red cells is most often due to *Yersinia enterocolitica,* followed by *Serratia liquefaciens,* whereas platelets are most often contaminated with *Staphylococcus* and Enterobacteriaceae. The incidence of bacterial contamination of red cells has been estimated to be 1 in 60,000, with an overall fatality rate of 1 in 1 million. The incidence of bacterial contamination of platelets was estimated to be 1 in 5000 before the initiation of bacterial detection systems in 2004, but it is now estimated to be 50% lower (1 in 10,000).

Recipients of units with low bacterial counts may have relatively mild symptoms such as fever and chills, but those receiving units with high bacterial counts may have severe or fatal reactions. Clinically, the patient may experience high fever, shock, hemoglobinuria, renal failure, and disseminated intravascular coagulation. The blood transfusion must be stopped immediately, the patient's blood and any untransfused blood must be cultured, and broad-spectrum antibiotics (Chapter 108) should be started.

Circulatory Overload

Acute pulmonary edema, caused by the circulatory system's inability to handle an increased fluid volume, can occur in any patient who is transfused too rapidly. Although the true frequency of this type of transfusion reaction is unknown, it is believed to be a common occurrence. Susceptible populations are primarily the very young, the elderly, and patients with a small total blood volume or cardiopulmonary disease. Treatment is the same as for heart failure (Chapter 59).

Delayed Reactions

A delayed hemolytic transfusion reaction generally occurs 3 to 7 days after transfusion of the implicated unit. Hemolysis is usually extravascular, and red cells are destroyed in the recipient's circulation by antibody produced as a result of an immune response to the transfusion. These reactions are most commonly due to an anamnestic response (secondary exposure to a red cell antigen) in a patient with a negative antibody screen despite a low level of antibody as a result of previous exposure to a foreign red cell antigen through either pregnancy or transfusion. Exposure to the same antigen a second time may cause IgG antibody to reappear within hours or days of the transfusion. This subsequent exposure to the antigen produces an anamnestic antibody response, resulting in increased production of IgG antibodies that are capable of reacting with any transfused cells present.

In most cases, anamnestic production of antibody does not result in acute hemolysis, but red cell destruction does occur between 3 days and 2 weeks after the transfusion. Patients are generally asymptomatic, and hemolysis may be noted only by a more rapid decline than usual in the patient's hemoglobin level or by an absence of the expected rise in hemoglobin. Fever, the most common initial symptom, is occasionally noted, along with jaundice; renal failure is rare. Prednisone (1 to 2 mg/kg/day) is indicated for more severe reactions.

Transfusion-Associated Graft-versus-Host Disease

Transfusion-associated graft-versus-host disease results from the transfusion of immunologically competent lymphocytes into an immunologically incompetent host. An individual's risk depends on whether the recipient is immunocompromised (and to what degree), the degree of HLA similarity between the transfusion donor and recipient, and the number of transfused T lymphocytes capable of multiplying and engrafting. The engrafted lymphocytes mount an immunologic response against the recipient's tissue, resulting in pancytopenia with bleeding and infectious complications. Symptoms usually appear within 12 days of transfusion. Transfusion-associated graft-versus-host disease is rare, but it is fatal in approximately 90% of affected patients.

Transfusion-Related Acute Lung Injury

Transfusion-related acute lung injury (TRALI; Chapter 94) is an acute respiratory distress syndrome (Chapter 104) that occurs within 6 hours after transfusion and is characterized by dyspnea and hypoxia secondary to noncardiogenic pulmonary edema. Although the actual incidence is almost certainly underreported, the estimated frequency is approximately 1 in 8000 transfusions. In a prospective nested case control study, 16 of 668 (2.4%) of cardiac surgery patients developed TRALI, suggesting that the incidence of TRALI is particularly high in this population. In approximately 50% of cases, blood donor antibodies with HLA or neutrophil antigenic specificity can be shown to react with the recipient's leukocytes, leading to increased permeability of the pulmonary microcirculation.

Most recently, reactive lipid products from donor blood cell membranes that arise during the storage of blood products have been implicated in the pathophysiology of TRALI. Such substances are capable of neutrophil priming, with subsequent damage to the pulmonary-capillary endothelium of the recipient, particularly in patients who receive massive transfusions during cardiac surgery or for trauma or in patients receiving chemotherapy for malignancy. In each of these settings, the true incidence of TRALI may be underreported because the findings may be blamed on the underlying disease process or the surgical procedure. Similar to other causes of acute respiratory distress syndrome, therapy is supportive, and 90% of patients recover. Ongoing initiatives to reduce TRALI risks include recruiting male plasma donors or female donors with no prior history of pregnancy, and screening female apheresis platelet donors for HLA antibodies and limiting donation to those who are HLA antibody negative.

Transmission of Viral Pathogens

Categories of transfusion-transmitted agents, as well as those currently screened, are listed in Table 180-2. The implementation of nucleic acid testing of multiple minipools (donation samples, test well) from blood donations has markedly reduced the transmission of HIV and hepatitis C virus during the infectious window period. Current estimates of the risk per unit of blood are 1 in 1.4 million to 2.4 million for HIV and 1 in 872,000 to 1.7 million for hepatitis C virus (Fig 180-3).

Only 43% of the World Health Organization's 191 member states test blood for HIV, hepatitis C virus, and hepatitis B virus, so at least 13 million units of blood donated every year are not tested for these transmissible viruses. In the poorest countries, the cost of testing ($40 to $50 per blood donation) is prohibitive. Every year, unsafe transfusions are estimated to account for 8 million to 16 million hepatitis B infections, 2.3 million to 4.7 million hepatitis C infections, and 80,000 to 160,000 HIV infections.

TABLE 180-2 CATEGORIES OF TRANSFUSION-TRANSMITTED AGENTS

AGENTS CAUSING TRANSFUSION-TRANSMITTED DISEASE FOR WHICH DONORS ARE ROUTINELY SCREENED
Hepatitis B virus
Human immunodeficiency virus
Hepatitis C virus
Human T-cell lymphotropic virus
West Nile virus
Bacteria
Trypanosoma cruzi
Cytomegalovirus
AGENTS THAT ARE TRANSFUSION TRANSMISSIBLE BUT HAVE NOT CAUSED ANY KNOWN DISEASE WHEN ACQUIRED THROUGH TRANSFUSION
Agents initially thought to cause hepatitis
Human herpesvirus 8
AGENTS CAUSING TRANSFUSION-TRANSMITTED DISEASE FOR WHICH DONORS ARE NOT ROUTINELY SCREENED
Hepatitis A virus
Parvovirus B19

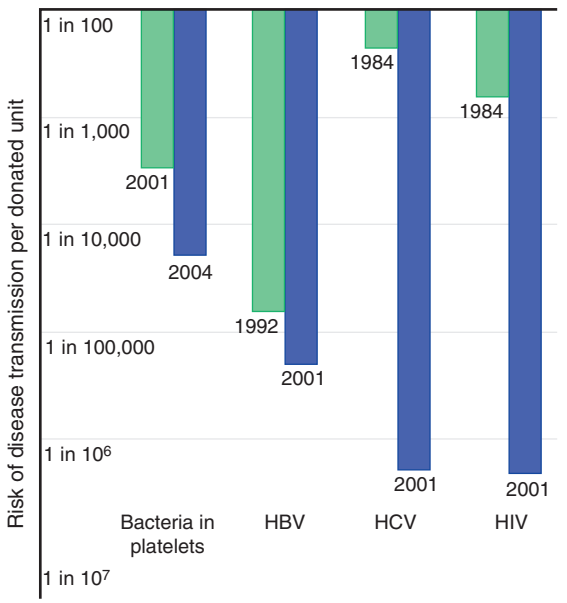

FIGURE 180-3. Risk of transmission of potentially fatal transfusion-acquired infections in the United States. The figures plotted pertain to risk reduction documented between 2001 and 2004 for bacteria in platelets, 1992 and 2001 for hepatitis B virus (HBV), and 1984 and 2001 for hepatitis C virus (HCV) and human immunodeficiency virus (HIV). The risk of bacteria in platelets today is considered to be the same as in 2004, and the risk of HBV, HCV, and HIV is considered to be the same as in 2001, because no further measures to protect the blood supply from these pathogens have been introduced. (From Vamvakas EC, Blajchman MA. Transfusion-related mortality: the on-going risks of allogeneic blood transfusion and the available strategies for their prevention. *Blood.* 2009;113:3406-3417.)

EMERGING ISSUES AND EVOLVING TECHNOLOGIES

Problems related to blood component storage have long been known, such as depletion of 2,3-diphosphoglycerate in red cell units during storage at 4° C for longer than 35 to 42 days. Recent evidence suggests that in patients undergoing cardiac surgery, transfusion of red cells stored for more than 14 days is associated with a significantly increased risk of postoperative complications, as well as reduced short-term and long-term survival. A prospective, randomized multicenter trial comparing the transfusion of blood less than 10 days old versus blood 21 days or older in adult patients undergoing cardiac surgery is currently under way in the United States. Erythropoiesis-stimulating agents, including recombinant human erythropoietin, modified erythropoietin molecules, and erythropoietin receptor agonists, along with artificial oxygen carriers, can potentially decrease the need for red cell transfusion. It is important that oversight of these biotechnology products and other specialized blood products (e.g., solvent- or detergent-treated plasma, leukoreduced blood products, irradiated blood components, CMV-negative blood components) be placed under the auspices of standing hospital medical committees, such as a transfusion medicine committee. Otherwise, promotion of such products by the commercial sector directly to consumers could undermine both institutional oversight and evidence-based rationales for their use.

HEMATOPOIETIC STEM CELL TRANSPLANTATION

JULIE M. VOSE

Hematopoietic stem cell transplantation is the process of collecting and infusing hematopoietic stem cells obtained from bone marrow (bone marrow transplantation) or peripheral blood (peripheral blood stem cell transplantation). High-dose chemotherapy followed by bone marrow or peripheral blood stem cell transplantation is increasingly used for the treatment of many hematologic, immunologic, and neoplastic diseases. Hematopoietic stem cells can be obtained directly from bone marrow by multiple aspirations from the pelvic bones while the patient is under general anesthesia. Alternatively, hematopoietic stem cells can be obtained from peripheral blood, after stimulation with hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF), followed by leukapheresis, or they can be

obtained from cord blood sources. The availability of hematopoietic stem cell transplantation permits the administration of supralethal chemotherapy or combined chemotherapy and radiation therapy to patients with malignancies or, in selected cases, with nonmalignant diseases in an attempt to increase the destruction of the affected cells. Additionally, the healthy transplanted cells may reconstitute the patient's immune system to provide an antitumor effect or, in the case of bone marrow transplantation for congenital diseases, to provide cells that are no longer deficient in certain vital components.

ALLOGENEIC AND SYNGENEIC TRANSPLANTATION

Allogeneic bone marrow or peripheral blood stem cell transplantation involves the transfer of stem cells from a donor to another person. Syngeneic transplantation, which occurs in only about 1% of transplant procedures, is the special case of a donor and recipient who are genetically identical twins. Myeloablative allogeneic transplants are usually considered only for patients younger than 55 to 60 years; however, older patients are occasionally treated. Results tend to be poorer in older patients because of the increasing incidence of graft-versus-host disease (GVHD) with age. More recently, reduced-intensity nonmyeloablative allogeneic transplants have been used, especially in older patients and others who might not be good candidates for fully myeloablative transplants. In all cases, the decision whether to transplant must take into account all factors, including not only the patient's chronologic age but also his or her physiologic age.

The donor and recipient must be matched for human leukocyte antigens (HLAs); the most important gene pairs include HLA-A, HLA-B, HLA-C, HLA-DR, and HLA-DQ loci, all of which are closely linked on chromosome 6 and inherited in haplotypes. The chance of having an HLA match from a sibling is 25%; however, because of the relatively small size of families in the United States, only about 30% of patients have HLA-matched siblings. For patients who lack HLA-identical sibling donors, other possible solutions include identifying an unrelated but closely HLA-matched person through the National Marrow Donor Program (NMDP), using a partially matched related donor, or identifying one or more cord blood units from a cord blood bank. The genes encoding HLAs are numerous, and the odds that any two unrelated individuals are HLA identical for main loci are less than 1 in 10,000. About 10 million volunteer donors have been HLA-typed through the NMDP registry, however, and a donor can be found for about 50% of patients for whom a search is initiated. It usually takes about 4 months to locate an unrelated donor, which may be too long for some patients with rapidly progressive malignancies.

An allogeneic partially matched sibling or placental or umbilical cord blood is an alternative source of stem cells. Umbilical cord blood stem cells are already stored in cord blood banks, and no additional harvest procedures are needed. Because of the unique immature biology of umbilical cord blood stem cells, these transplants are associated with less GVHD; consequently, the HLA matching requirements are less strict. However, cord blood cells must be partially matched to the recipient, as well as to each other if more than 1 unit is given. The small volume of cord blood stem cells often makes these transplants unsuitable for adult recipients. The time to engraftment and immune reconstitution may also be different for this type of transplant, which sometimes causes late engraftment and an increased rate of post-transplant infection.

When an adequate donor has been identified, the patient is prepared for the allogeneic or syngeneic transplant with high doses of chemotherapy, alone or combined with radiation therapy. This treatment is designed to destroy any remaining malignant cells, provide sufficient immunosuppression to allow engraftment of the new cells, and clear the marrow space for engraftment of the new cells. The preparative agents must have few toxicities at high doses; for this reason, high doses of anthracyclines are often impractical because of their cardiac toxicities. Most regimens consist of total body irradiation combined with alkylating agents, etoposide, or cytarabine. With nonmyeloablative transplants, less intense chemotherapy and/or radiation is used, which is less damaging to the patient. However, acute and chronic GVHD is still a possibility, and in fact, the risk of chronic GVHD may be slightly higher.

An integral component of the regimens for allogeneic transplantation is immunosuppression to prevent GVHD and graft rejection (Chapter 48). Because the recipient's immune system is ablated with high-dose chemotherapy and radiation therapy, graft rejection is a rare event with related donors and a fully ablative transplant. However, reduced-intensity regimens can have a higher risk of nonengraftment. Drugs commonly used to prevent GVHD include tacrolimus, mycophenolate mofetil, rapamycin, and the combination of cyclosporine and methotrexate. For allogeneic hematopoietic stem cell transplantation, prophylactic immunosuppression is not lifelong; when immunologic tolerance is established, immunosuppressive agents can be slowly withdrawn and discontinued. Another strategy to prevent GVHD is to deplete the donor's T cells from the graft; the disadvantage of this approach is its association with increased rates of disease relapse and infection, and overall survival does not seem to be improved. To accelerate engraftment, hematopoietic growth factors such as G-CSF are administered after transplantation until the neutrophil count recovers. Allogeneic transplantation regimens also include prophylactic antiviral drugs (acyclovir, ganciclovir), antifungal drugs (fluconazole, voriconazole), broad-spectrum antibiotics (cephalosporins, fluoroquinolones), and anti-*Pneumocystis* drugs (trimethoprim-sulfamethoxazole, dapsone, pentamidine).

Leukemias and some indolent lymphomas that relapse after allogeneic stem cell transplantation can sometimes be controlled by further infusions of lymphocytes from the same allogeneic donor. The donor T lymphocytes destroy malignant cells by an immune mechanism called the *graft-versus-tumor effect.* For solid tumors, a graft-versus-tumor effect can sometimes be demonstrated. These observations led to the development of nonmyeloablative transplantation regimens, based on the concept that allogeneic stem cell transplantation is a form of immunotherapy by which the donor lymphocytes eradicate the malignant disease, with high-dose chemotherapy and irradiation not being necessary for success.

AUTOLOGOUS BONE MARROW TRANSPLANTATION

In autologous bone marrow transplantation, the patient's own hematopoietic cells are infused to reestablish bone marrow function after the administration of high-dose chemotherapy, with or without total body irradiation. These reinfused hematopoietic cells can come from the patient's bone marrow, peripheral blood, or both. Because a major limitation of allogeneic bone marrow transplantation is that only a few patients have HLA-matched sibling donors, the use of autologous hematopoietic cells greatly increases the number of patients eligible for transplantation (Table 181-1). Autologous transplantation can also be used safely in older patients because of the absence of GVHD, which is a major concern in this population. Disadvantages of autologous hematopoietic cell transplantation include the risk of contaminating the graft with viable tumor cells and the lack of graft-versus-tumor effects. Although patients undergoing autologous transplantation have higher relapse rates than those undergoing allogeneic transplantation, the lower rate of other complications seems to translate into similar long-term outcomes. A variety of methods have been developed to decrease the contamination of autologous grafts with tumor cells (graft "purging"), but no prospective data have yet confirmed that these interventions are beneficial because most relapses originate from incompletely eradicated disease in the host.

INDICATIONS FOR TRANSPLANTATION

For many diseases, hematopoietic stem cell transplantation is now part of standard therapy (Table 181-2). In the United States, more than 17,000 allogeneic and autologous transplants are performed each year for various diseases (Fig. 181-1).

Lymphoproliferative Malignancies

Non-Hodgkin's Lymphoma

As first-line treatment, autologous transplantation results in a higher rate of complete response but not better survival in patients with aggressive

TABLE 181-1 COMPARISON OF ALLOGENEIC AND AUTOLOGOUS TRANSPLANTATION

FEATURE	ALLOGENEIC	AUTOLOGOUS
Upper age limits	55–75 yr	Physiologic status limits
Availability	40–60% of patients	Only limitation may be the ability to collect enough stem cells
Main cause of failure	Graft-versus-host disease Infections	Disease relapse

TABLE 181-2 RESULTS OF STANDARD-OF-CARE ALLOGENEIC OR AUTOLOGOUS STEM CELL TRANSPLANTATION IN SPECIFIC DISEASES*

	Three-Year Survival (%)	
DISEASE	**ALLOGENEIC**	**AUTOLOGOUS**
HEMATOLOGIC MALIGNANCIES		
Acute myelogenous leukemia	32–50	43–50
Chronic myelogenous leukemia	28–54	NU
Myelodysplastic syndrome	40–46	NU
Acute lymphocytic leukemia	25–51	NU
Chronic lymphocytic leukemia	35–45	66
Hodgkin's disease	NU	78
Follicular lymphoma	60	76
Diffuse large cell lymphoma	19–30	60
Multiple myeloma	12–40	66
Neuroblastoma	NU	60
NONMALIGNANT CONDITIONS		
Aplastic anemia	33–82	NA
Fanconi's anemia	16–81	NA
Thalassemia major	91 (1 yr)	NA
Sickle cell anemia	91	NA
Severe combined immunodeficiency	59.3	NA

*Information based on the Center for International Bone Marrow Transplant Research report for patients who underwent transplantation between 2000 and 2007. Results are typically better in patients younger than 20 years, patients in earlier stages of the disease, and recipients of HLA-identical sibling transplants.
NA = not applicable; NU = not routinely used.

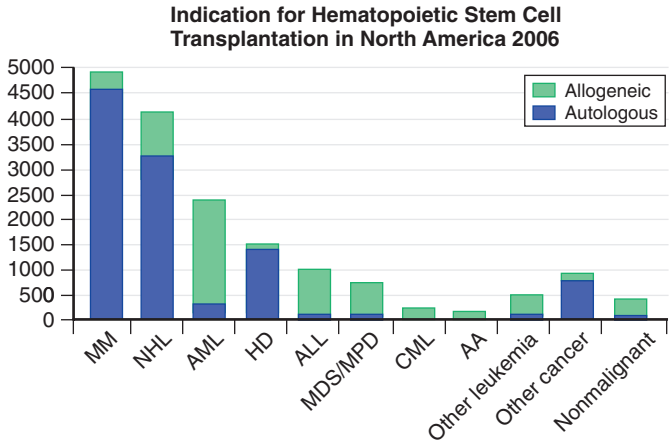

FIGURE 181-1. Indications for autologous and allogeneic blood and marrow transplantation in North America. AA = aplastic anemia; ALL = acute lymphocytic leukemia; AML = acute myelogenous leukemia; CML = chronic myelogenous leukemia; HD = Hodgkin's disease; MDS = myelodysplastic syndrome; MM = multiple myeloma; MPD = myeloproliferative disease; NHL = non-Hodgkin's lymphoma. (Information reprinted with permission from the Center for International Bone Marrow Transplant Research [CIBMTR], 2010.)

non-Hodgkin's lymphoma (Chapter 191).■ Patients with relapsed disease seem to benefit most from this therapy if they undergo transplantation when they still have chemotherapy-sensitive disease. High-risk patients who undergo transplantation early in the course of the disease, during their first partial or complete response, may have a better outcome than similar patients treated with conventional therapy; however, this is considered controversial. The use of high-dose chemotherapy, radiation therapy, and autologous transplantation in patients with indolent disease is associated with a failure-free survival rate of 40 to 60% at a median follow-up of 3 years; because late relapses are common, much longer follow-up is necessary to assess the long-term results of this treatment. Allogeneic stem cell transplantation is typically used for patients who have relapsed after an autologous stem cell transplant or for some lymphomas in which an autologous transplant is not possible owing to circulating lymphoma cells.

Hodgkin's Disease

High-dose chemotherapy followed by autologous hematopoietic stem cell transplantation has been widely accepted for patients with relapsed Hodgkin's disease (Chapter 192). Allogeneic transplantation has not been used as extensively because of increased morbidity and mortality. The outcome is poorer in patients who have received multiple chemotherapy regimens than in those who have undergone less pretreatment. Autologous transplantation during the first remission is being evaluated in patients with "B" symptoms, disseminated disease with bone marrow or pulmonary involvement, and other high-risk features.

Multiple Myeloma

Autologous and allogeneic transplant procedures have been performed successfully in patients with multiple myeloma (Chapter 193). The major concern with conventional myeloablative allogeneic transplantation was its high mortality rate; however, with improvements in supportive care, the transplant-related mortality associated with autografts for multiple myeloma has been reduced to 1%, and randomized trials confirm better progression-free survival but not overall survival after autologous stem cell transplantation compared with conventional chemotherapy.■ Autologous transplantation for multiple myeloma is more successful in patients who undergo less pretreatment and have a smaller tumor burden. Multiple myeloma is now the most common indication for autologous stem cell transplantation in North America. Studies using autologous tandem transplantation, or an autologous transplant followed by a nonmyeloablative transplant, have shown early promising results.

Lymphoid Leukemias

The results of conventional induction and consolidation chemotherapy for acute lymphoblastic leukemia (ALL) in children are excellent, except for ALL associated with the Philadelphia chromosome (Ph) (Chapter 189). Therefore, in children with ALL, transplantation is generally reserved for these high-risk patients and those who relapse after initial therapy. A much higher percentage of adults fail to respond to initial therapy and have higher-risk disease; therefore, allogeneic stem cell transplantation, which improves overall survival when performed in adults during a first complete remission,■ should be considered in adult ALL patients, particularly those who are Ph positive.

Selected younger patients with B-cell chronic lymphocytic leukemia (B-CLL) that is refractory or who have relapsed more than once might benefit by transplantation from a related or unrelated donor; durable disease-free survival rates are 40 to 60% (Chapter 190). Because the allogeneic graft-versus-leukemia effect seems to be especially important against B-CLL, this disease is a common indication for nonmyeloablative allogeneic transplantation. Autologous transplantation also yields high rates of remission in pretreated B-CLL patients, but relapse rates are significant.

Myeloproliferative Malignancies

Myeloid Leukemias

Because patients with good-risk or average-risk acute myelogenous leukemia (AML) can be cured with conventional chemotherapy, most centers use transplantation only for relapsed AML in adults or as part of the initial therapy in patients with known poor prognostic characteristics, such as certain high-risk chromosomal abnormalities, including complex abnormalities or deletions (Chapter 189). In these intermediate- and high-risk patients, allogeneic transplantation improves progression-free survival and overall survival when performed during first complete remission.■

Most patients with chronic myelogenous leukemia (CML) are treated with tyrosine kinase inhibitors rather than allogeneic stem cell transplantation (Chapter 190). If the medications fail, allogeneic transplantation from an HLA-matched sibling donor produces long-term disease-free survival in 55 to 75% of patients with Ph-positive CML. The results seem to be better when younger patients undergo transplantation within the first year of diagnosis. When an HLA-matched related donor is not available, use of alternative donors can yield a cure in about 50% patients with chronic phase CML. However, the development of effective, nontoxic tyrosine kinase inhibitors for the treatment of *BCR-ABL*–positive CML is tempering enthusiasm for allogeneic transplantation in CML patients, so this procedure is rarely performed.

Myelodysplastic Syndromes

Myelodysplastic syndromes in young, otherwise healthy patients are best treated with an allogeneic transplant (Chapter 188). However, most patients

with myelodysplastic syndromes are elderly, which often precludes the use of this therapy.

Solid Tumors

High-dose chemotherapy for the treatment of metastatic breast cancer can result in a higher complete response rate than conventional treatment (Chapter 204). The reported disease-free survival rate in chemotherapy-sensitive stage IV breast cancer is only 10 to 25%, however, and no overall survival benefit has been shown in several randomized trials. As a result, transplantation has lost favor in this condition.

High-dose chemotherapy plus transplantation has had success in the treatment of some chemotherapy-sensitive solid tumors, including testicular cancer (Chapter 206), ovarian carcinoma (Chapter 205), and childhood tumors such as neuroblastoma and Wilms' tumor. Other solid tumors that are refractory to chemotherapy, such as melanoma or many gastrointestinal malignancies, are poor targets for this therapy. Limited reports of a high rate of regression of metastatic renal carcinoma (Chapter 203) after nonmyeloablative allogeneic peripheral blood stem cell transplantation hold promise for its wider use.

Nonmalignant Conditions

Disorders such as Wiskott-Aldrich syndrome or severe combined immunodeficiency syndrome have been treated successfully with HLA-matched sibling transplants or transplants from alternative donors (Chapter 258).

Genetic disorders such as osteopetrosis (Chapter 256), Gaucher's disease (Chapter 215), and Hurler's syndrome (Chapter 268) can be treated successfully with an allogeneic transplant. Other indications for allogeneic transplantation include hemoglobinopathies such as sickle cell anemia (Chapter 166) and thalassemia (Chapter 165) and acquired blood disorders such as paroxysmal nocturnal hemoglobinuria (Chapter 163). The transplant must be performed before the onset of secondary organ failure.

Allogeneic transplantation can lead to long-term disease-free survival in more than 50% of patients with severe aplastic anemia (Chapter 168). When compared with standard immunosuppressive therapy, allogeneic transplantation is more likely to produce a complete and durable reversal of the hematologic abnormalities. Patients with aplastic anemia who are less heavily transfused have better outcomes with allogeneic transplantation. For patients with less severe aplastic anemia, patients older than 40 years, and those without a matched sibling donor, a trial of immunosuppression therapy is usually appropriate before consideration of allogeneic transplantation.

Autologous stem cell transplantation to engraft a tolerant immune system has had promising results in selected patients with systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and multiple sclerosis. Randomized prospective trials comparing conventional treatments are currently under way.

Much attention has focused on the possible use of autologous bone marrow–derived or circulating peripheral blood stem cells to promote the recovery of myocardial function after acute myocardial infarction. To date, the infusion of such cells, usually directly into the relevant coronary artery after successful percutaneous coronary intervention, has shown promising results in improving regional but not necessarily global myocardial function. Further research is required to define the appropriate clinical role for such approaches.

COMPLICATIONS

Infections

Infections are a major cause of morbidity and mortality after hematopoietic stem cell transplantation, especially allogeneic transplantation, because of prolonged immunosuppression for the prevention or treatment of GVHD. Bacterial infections are frequently related to central venous catheters. Among fungal infections, *Aspergillus* infections typically occur in patients receiving prolonged high-dose steroids for the treatment of GVHD. Viral infections include reactivation cytomegalovirus (Chapter 384), human herpesvirus 6, and Epstein-Barr virus (Chapter 385) infections. These patients are also susceptible to seasonal respiratory viruses. Prophylactic use of G-CSF and granulocyte-macrophage colony-stimulating factor is helpful but does not improve survival.

At 1 year after allogeneic or autologous transplantation, patients should receive the following vaccinations: diphtheria, tetanus, *Haemophilus influenzae* type b, hepatitis A virus, hepatitis B virus, 23-valent pneumococcal polysaccharide, seasonal influenza virus, inactivated poliovirus, and, only in areas of outbreaks, meningococcal vaccine (Chapter 17). Live vaccines against measles, mumps, and rubella should not be administered until 2 years after transplantation, and only in the absence of chronic GVHD and immunosuppressive therapy. Family members can receive routine vaccines, including influenza virus vaccine, but patients should avoid contact with a child who has received oral poliovirus vaccine for about 1 month after vaccination. Despite these recommendations, vaccines may not always induce protective immunity in an immunodeficient patient who has chronic GVHD or is taking immunosuppressive drugs.

Cardiac Toxicity

Most transplant centers screen potential patients for underlying cardiac abnormalities that would place them at increased risk during the procedure. Nevertheless, a few patients experience cardiotoxicity, either acutely during the transplant procedure or later. Pericardial effusion can develop in patients who have disease near the pericardium or are receiving radiation therapy in that area (Chapter 77). An idiosyncratic cardiomyopathy can occur after high doses of cyclophosphamide. Viral cardiomyopathies can also develop.

Pulmonary Toxicity

Pulmonary toxicities include infections from bacterial, fungal, or viral sources during the transplant. In addition, in patients receiving certain chemotherapy agents, such as carmustine, chemotherapy-induced lung damage may develop, but this can usually be treated with steroids. Patients undergoing allogeneic transplantation are at increased risk for pneumonitis caused by cytomegalovirus and fungal infections, for adult respiratory distress syndrome, and for interstitial pneumonia of unknown cause. Chronic GVHD can also manifest in the lung as bronchiolitis obliterans, with or without obstructive pneumonia.

Liver Toxicity and Veno-occlusive Disease

The most frequent liver complication associated with transplantation is veno-occlusive disease of the liver (also called sinusoidal obstruction syndrome). The pathogenesis of this syndrome is damage to hepatic sinusoids, often with occlusion of hepatic venules, associated with chemotherapy drugs and total body irradiation used in conditioning regimens. Symptoms associated with this complication include jaundice, tender hepatomegaly, ascites, and weight gain. Total serum bilirubin is a sensitive but nonspecific test for veno-occlusive disease. Imaging studies may demonstrate hepatomegaly, ascites, periportal edema, and attenuated hepatic venous flow. The diagnosis can be made most definitively by transvenous liver biopsy and hepatic venous pressure measurements. Progressive hepatic failure and multiorgan system failure can develop, but at least 70% of patients recover spontaneously. Predisposing factors seem to be previous hepatic injury, the use of estrogens, and perhaps the use of HLA-mismatched donors.

Renal Toxicity

Acute renal failure requiring dialysis occurs infrequently during the transplant procedure. The judicious use of nephrotoxic agents can decrease the incidence of this complication. Idiopathic or cyclosporine-induced hemolytic-uremic syndrome (Chapter 175) can be a serious complication after allogeneic stem cell transplantation, with a high risk for end-stage renal disease or death.

Graft-versus-Host Disease

In the allogeneic transplant setting, acute GVHD manifests with symptoms in the skin, gastrointestinal tract, and liver within the first 100 days after transplantation. Skin involvement ranges from a maculopapular rash to generalized erythroderma or desquamation. The severity of liver disease is based on bilirubin levels, and the severity of the gastrointestinal disease is graded by the quantity of daily diarrhea. Patients who receive transplants from unrelated donors are at increased risk, and the incidence and severity of GVHD rise with the age of the patient. Other risk factors include a female donor (particularly a multiparous donor), advanced age, and cytomegalovirus seropositivity of the donor or patient. Prophylaxis with cyclosporine or tacrolimus, with or without methotrexate, corticosteroids, or mycophenolate mofetil, reduces the incidence and severity. Treatment of acute GVHD includes high-dose corticosteroids, antithymocyte globulin, or various monoclonal antibodies.

Chronic GVHD occurs more than 100 days after transplantation and is most likely to develop in older patients who also had acute GVHD. Symptoms include the sicca syndrome, chronic sinusitis, rashes, scleroderma-like

skin thickening, diarrhea, wasting syndrome, and liver abnormalities. Patients are also at greatly increased risk for infectious complications resulting from either GVHD itself or treatment for it. Adverse prognostic factors for survival include thrombocytopenia, progressive clinical manifestations, involvement of more than 50% of the skin, poor performance status, and elevated bilirubin. Treatment of chronic GVHD includes corticosteroids, cyclosporine, tacrolimus, mycophenolate mofetil, ultraviolet light, and other immunosuppressive agents.

Graft Rejection

Graft rejection occurs when immunologically competent cells of host origin destroy the transplanted cells of donor origin. This complication is rare after fully matched, related donor transplants and occurs more commonly in patients who receive transplants from alternative donors or T-cell–depleted transplants. Graft rejection is less likely in nontransfused patients with aplastic anemia.

Late Complications

As the number of long-term post-transplant survivors increases, complications that develop years later are beginning to be recognized.

Secondary Malignancies

One complication of the chemotherapy or radiation therapy (or both) used to treat malignancy is the development of a secondary malignancy. There have been several reports of the development of secondary AML or myelodysplastic syndrome after autologous transplantation. Some studies have suggested that total body irradiation may increase the risk for these complications. After allogeneic transplantation, the overall incidence of secondary malignancies is 2.2% at 10 years and 6.7% at 15 years after transplantation. Within the first 1 to 2 years, the most common malignancies are Epstein-Barr virus–related lymphoproliferative disorders; solid tumors are more likely to occur more than 3 years after transplantation. Risk factors include the use of antithymocyte globulin to treat GVHD, the use of a T-cell–depleted graft, HLA incompatibility, and perhaps total body irradiation.

Infertility and Hypogonadism

The risk of gonadal failure is likely to be lower with nonmyeloablative preparative regimens. The use of total body irradiation is almost always associated with sterility, but successful pregnancies have occurred in some patients after other regimens. Gynecomastia (sometimes tender) occasionally occurs in males. To address all the complexities of functional castration from high-dose therapy, a reproductive endocrinologist should be consulted before transplantation in patients for whom future fertility is an issue.

Endocrine Dysfunction

Iatrogenic Cushing's syndrome is commonly due to long-term steroid therapy in patients with chronic GVHD (Chapter 34). Particularly disabling are steroid-induced myopathy, avascular necrosis of the hip, and osteoporosis. Because many patients take steroids for many months, tapering can be associated with malaise, nausea, hypotension, and musculoskeletal pains. In these situations, slower tapering over several months or reintroduction of physiologic replacement doses (e.g., 7.5 to 10 mg/day of prednisone) is appropriate. Hypothyroidism (Chapter 233) is typically related to the use of total body irradiation or local irradiation of the head and neck for lymphoma or other cancer. Osteoporosis (Chapter 251) occurs in 50 to 60% of patients after hematopoietic stem cell transplantation. The major contributing causes include hypogonadism, secondary hyperparathyroidism caused by low serum calcium, and post-transplant steroid therapy. Bone mineral density should be evaluated before and after transplantation; osteopenia should be treated as appropriate with bisphosphonates, calcium, vitamin D, estrogen, and testosterone.

Other Complications

The long-term incidence of cataracts is about 20 to 50%; the risk is related to the use of total body irradiation and corticosteroids (Chapter 431). About 50% of patients with cataracts require surgical therapy. Alopecia is typically reversible, but in rare cases it may be irreversible, especially after the use of busulfan-containing preparative regimens.

FUTURE DIRECTIONS

The safety and efficacy of transplantation may be improved by the use of hematopoietic cytokines to stimulate immunologic reconstitution, ex vivo expansion of progenitors, genetic modulation of cells, improved supportive care for transplant patients, better prophylaxis against GVHD, better HLA typing, and newer anticancer agents. Whether stem cells can be infused to improve the function of adult organs is an area of active investigation.

APPROACH TO THE PATIENT WITH CANCER

MICHAEL C. PERRY

DIAGNOSIS

Few diagnoses produce such emotional responses as *cancer* or *leukemia,* and in the first few moments after those words are uttered, the patient often experiences a storm of feelings that limit useful discussion. When the time is right, however, the physician and the patient must discuss the diagnosis, its implications, and the therapeutic alternatives. It is often best for the patient if family members or close friends are present in the consulting room, both to provide emotional support and to be another "set of ears." It is often useful to ask, "What do you understand about your diagnosis?"

If the physician is not familiar with the latest treatments, consultation in advance with, for example, the National Cancer Institute's Physician Data Query will make the interview more meaningful. Prompt referral to a specialist, whether a surgical oncologist, radiation oncologist, or medical oncologist, is imperative. The generalist should not be a therapeutic nihilist unless he or she is intimately involved in the field and knows about all the current therapies and clinical trials.

The consulting medical oncologist, often advised by a local tumor board comprising medical, surgical, and radiation oncologists, usually outlines the prognosis and the alternatives: standard therapy, possible clinical trials, a second opinion, or no treatment. Many oncologists actively participate in clinical trials and may have investigational drugs available, or they may suggest referral to a tertiary cancer center as appropriate.

Diagnostic Procedures

In most settings, a lesion has been found on physical examination or by abnormal laboratory or radiographic studies, and a biopsy has confirmed the diagnosis. It is critical that the biopsy be representative of the entire tumor and that appropriate investigations (e.g., special stains, flow cytometry, cytogenetics, hormone assays) be performed before treatment is initiated. If there is a question whether the lesion is benign or malignant or about its proper classification, consideration should be given to additional biopsies, and consultation with a reference pathologist may be indicated. There is seldom a need for such rapid therapy that appropriate pretreatment evaluations cannot be performed. For many tumor sites, such as the colon (Chapter 199), there is one predominant histology; in others, such as the lung (Chapter 197), the distinction between small cell lung cancer and non–small cell lung cancer is critical for treatment. For breast cancer (Chapter 204), the treating physician is interested in a variety of factors, such as histology, tumor grade, the presence or absence of estrogen and progesterone receptors, and the presence of ERBB2 (HER2/neu) overexpression.

Staging and Work-up

After a diagnosis has been established, staging is next. The American Joint Committee on Cancer staging system is considered the standard in the United States and is based on the TNM (tumor, node, metastasis) system. The approach to staging depends on the type of cancer, but it commonly includes plain films such as chest radiographs, computed tomography (CT), magnetic resonance imaging (MRI), radionuclide scans, and, increasingly, positron emission tomography (PET). These studies are typically supplemented by routine hematologic and chemistry profiles, tumor markers, and, in some cases, bone marrow aspiration and biopsies.

The keys to the work-up are to identify sites of metastases and to establish an indicator lesion or lesions to monitor therapy. Thus, for most solid tumors, a CT scan and perhaps a bone scan can accomplish both goals, with brain CT or MRI reserved for cases in which central nervous system metastases are most likely (e.g., small cell lung cancer). PET scans supplement CT scans by establishing that a given lesion is likely to be malignant and by clarifying other sites of disease. In patients with known, established advanced disease, they are seldom needed.

TREATMENT

Development of a Treatment Plan

For cancers amenable to surgery, resection is usually the best alternative if the patient is a suitable candidate for anesthesia (Chapter 440) and is otherwise in acceptable condition in terms of concomitant or comorbid illnesses. A joint discussion among the internist, oncologist, surgeon, and anesthesiologist is often very useful in this regard. Determination of the patient's performance score (Table 182-1) is a simple means of assessing functional status. If life expectancy is limited or if the patient is not a good candidate for surgery, radiation therapy is usually considered the next best "local" therapy, with chemotherapy reserved for patients whose disease is extensive or metastatic. The increasing effectiveness of chemotherapy has resulted in its earlier incorporation into therapy, often as part of an "organ-sparing" approach. Ideally, the discussion of treatment with the patient should take a multidisciplinary approach, with clarification of the diagnosis, prognosis, treatment goals, alternatives, side effects, and risks and benefits.

Surgical Therapy

Surgery is used to biopsy a suspected lesion, to remove the primary tumor, to bypass obstructions, and to provide palliation. A preoperative discussion may determine the requirement for placement of a venous access device at the time of surgery, thus eliminating the need for a second anesthesia.

Surgery remains the most common method to cure localized cancers, such as breast cancer (Chapter 204), colorectal cancer (Chapter 199), and lung cancer (Chapter 197), but it is limited by the location of the tumor, its extension, and distant metastases. Even if a tumor cannot be removed, a biopsy provides confirmation of the diagnosis. Occasionally, an obstructing lesion can be bypassed to provide palliation.

Surgical staging also establishes the extent of the disease. For ovarian cancer (Chapter 205), surgical "debulking" aims to remove all visible disease, leaving minimal residual disease, to enhance chemotherapy.

In rare circumstances when the primary tumor is controlled, removal of a single metastasis (metastasectomy) can result in long-term survival; an example is resection of a single liver metastasis found at the time of colectomy for colorectal cancer. A variety of surgical techniques, such as radio frequency ablation or cryoablation, can treat hepatic metastases in carefully selected patients. Adjuvant chemotherapy is often given after surgery in this situation to treat microscopic metastases.

Reconstruction after a disfiguring procedure is critical to long-term physical and emotional functioning. Examples include post-mastectomy breast reconstruction (Chapter 204) and plastic surgery procedures to correct deformities after head and neck surgery (Chapter 196).

Radiation Therapy

Ionizing radiation (Chapter 19) can be delivered using high-energy rays, known as *teletherapy*, via a linear accelerator; by brachytherapy, through the application of radioactive implants, seeds, wires, or plaques; and intravenously by using radioisotopes. Radiation interacts with molecular oxygen, inducing the formation of superoxide, hydrogen peroxide, or hydroxyl radicals that damage DNA, leading to cell death. Like chemotherapy, radiation therapy is most effective against rapidly dividing cells.

As "local" therapies, both surgery and radiation therapy are limited in their effectiveness by the inapparent extension of disease, the location of tumors next to normal structures that must be preserved, and the presence of distant metastases. Normal tissue tolerance, which varies among the different organs and tissues, often prevents the use of radiation doses that could uniformly eradicate cancers. Radiation therapy is also limited by tumor hypoxia: large, bulky tumors are frequently relatively radioresistant, whereas well-oxygenated tumors can be more effectively treated at lower doses.

Radiation therapy can be used as the primary treatment, as part of multimodality therapy, in the adjuvant setting, and for palliation. As a single modality, radiation therapy can be curative for early-stage malignancies such as laryngeal cancer (Chapter 196), cervical cancer (Chapter 205), and prostate cancer (Chapter 207). Breast-conserving surgery (Chapter 204) requires the use of radiation to treat the remaining breast. Partial irradiation techniques using three-dimensional planning with external beam radiation or with a balloon catheter have recently been developed and used in selected patients with appropriately placed and sized breast cancers. For localized prostate cancer (Chapter 207), implanted radioactive seeds of gold or palladium offer an alternative to surgery or external beam radiation therapy, again in carefully selected patients.

It is important to note that the combination of chemotherapy and radiation therapy may result in synergistic toxicities, such as esophagitis (Chapter 140) in the treatment of lung cancer (Chapter 197) or mucositis in the treatment of head and neck cancer (Chapter 196).

Newer techniques, such as intensity-modulated radiation therapy, permit more exact tailoring of the dose to the target, thereby reducing damage to the surrounding normal tissues. Stereotactic radiation therapy or gamma knife techniques allow the treatment of primary or metastatic brain tumors (Chapter 195) measuring up to 3 cm with pinpoint accuracy, minimizing damage to normal brain. Proton therapy has only limited applicability at this time; it is

TABLE 182-1 KARNOFSKY AND ZUBROD PERFORMANCE SCALES

Karnofsky Performance Status Scale	
VALUE	**LEVEL OF FUNCTIONAL CAPACITY**
100	Normal, no complaints, no evidence of disease
90	Able to carry on normal activity, minor signs or symptoms of disease
80	Normal activity with effort, some signs or symptoms of disease
70	Cares for self, unable to carry on normal activity or to do active work
60	Requires occasional assistance but is able to care for most needs
50	Requires considerable assistance and frequent medical care
40	Disabled, requires special care and assistance
30	Severely disabled, hospitalization is indicated although death is not imminent
20	Hospitalization is necessary, very sick, active supportive treatment necessary
10	Moribund, fatal processes progressing rapidly
0	Dead
Eastern Cooperative Oncology Group (Zubrod) Performance Scale	
PERFORMANCE STATUS	**DEFINITION**
0	Asymptomatic
1	Symptomatic; fully ambulatory
2	Symptomatic; in bed <50% of day
3	Symptomatic; in bed >50% of day
4	Bedridden

used for some uveal melanomas, skull base tumors, and a few pediatric malignancies.

Low- to moderate-dose palliative radiation is used to ameliorate symptomatic cancer when cure is no longer the goal. For instance, radiation therapy can improve brain metastases (Chapter 195), relieve pain from bone lesions (Chapter 208), relieve obstructing lesions, and sometimes relieve hemoptysis caused by lung cancer (Chapter 197) or bleeding from a gynecologic malignancy (Chapter 205). Bone-seeking radioisotopes such as samarium or strontium may relieve pain from bone metastases in prostate cancer (Chapter 207) or breast cancer (Chapter 204).

Systemic Therapy

Chemotherapy

Pharmacogenomics, the study of inherited interindividual differences in drug disposition and effects, is becoming important in cancer therapy because genetic polymorphisms in drug-metabolizing enzymes are often responsible for the variations in efficacy and toxicity observed with many chemotherapeutic agents. Drugs potentially affected by polymorphisms identified to date include the thiopurines, 5-fluorouracil, irinotecan, and the platinum agents. In patients who are heterozygous or homozygous for deficiencies in metabolizing enzymes, toxicity can be dramatically enhanced.

Currently available tests cannot reliably assess the likelihood of response to therapy, so treatment is largely empirical and based on predictive factors from the tumor itself. Gene expression microarrays currently under development may reliably predict responses in the future. Gene profiles are increasingly used to determine the necessity of therapy, such as the adjuvant therapy of breast or lung cancer.

Assessing Treatment

Assessment of the response to therapy depends largely on tumor size, determined by either direct measurement or diagnostic imaging studies. The categories of response are complete response, with total absence of tumor and correction of tumor-associated changes; partial response, defined as greater than 50% reduction in tumor size; stable disease, defined as greater than 25% but less than 50% reduction in tumor size; and progressive disease, characterized by either tumor growth or the development of new tumors. Leukemias can be assessed by bone marrow aspirates, and multiple myeloma is typically assessed by the measurement of monoclonal proteins, peripheral blood counts, and percentages of malignant plasma cells in bone marrow samples, as well as radiographs of bone lesions.

Chemotherapy is now used in a variety of settings with or without and before, during, or after surgery and radiation therapy (Table 182-2). Considerable experimental evidence suggests that cancers are most sensitive to

TABLE 182-2 EXAMPLES OF TIMING OF CHEMOTHERAPY

ADJUVANT THERAPY	NEOADJUVANT THERAPY	ORGAN-SPARING THERAPY	COMBINATION CHEMOTHERAPY

Stage III melanoma		Esophageal cancer	
Stage I–III lung cancer			

*Usually palliative.

chemotherapy during the early stages of growth, as a result of the high growth fraction and shorter cell cycle times. Thus, a given dose of drug exerts a greater therapeutic effect against a rapidly growing tumor than against a larger, quiescent tumor.

Neoadjuvant Chemotherapy

Neoadjuvant therapy, also called *primary* or *induction chemotherapy*, is used before surgery or radiation therapy to decrease the size of locally advanced cancers, thereby permitting better surgical resection, and to eradicate undetectable metastases. It also affords an opportunity to evaluate the effectiveness of treatment by histologic analysis of resected tissue. This approach is most often used for locally advanced breast cancer (Chapter 204), although other primary tumors can be targeted. Disadvantages include the initially incomplete pathologic staging and the possibility that ineffective chemotherapy will permit the tumor to grow beyond the point of resection.

Organ-sparing therapy is the use of chemotherapy, radiation therapy, or both to salvage organs that would have been surgically removed if cure were the intended result. This technique is often effective in patients with cancers of the larynx (Chapter 196), esophagus (Chapter 198), bladder (Chapter 203), and anus (Chapter 199).

Adjuvant Chemotherapy

Adjuvant chemotherapy is used in patients whose primary tumor and all evidence of cancer (e.g., regional lymph nodes) have been surgically removed or treated definitively with radiation but in whom the risk of recurrence is high because of involved lymph nodes or certain morphologic or biologic characteristics of the cancer. Common examples include cancers of the breast (Chapter 204) and colon (Chapter 199). The typical end points of clinical chemotherapy, such as shrinkage of measurable tumor on serial radiographic studies, are not available in this situation; instead, relapse-free survival and overall survival are the principal measures of treatment effect. For an individual patient receiving adjuvant therapy, there is no way to determine whether such therapy is beneficial or necessary, so decisions are generally based on evidence from clinical trials.

Adjuvant therapy has been used in a wide variety of tumors, with variable success. In the case of breast cancer (Chapter 204) and colon cancer (Chapter 199), the number of lives saved by the use of adjuvant therapy is significant because of the large number of affected patients, despite the modest absolute differences between treated and control patients with current treatment programs. Resectable lung cancer (Chapter 197) has recently been added to this list.

Palliative Chemotherapy

Chemotherapy rarely cures cancers that remain after surgical or radiation treatment or that recur after such therapy. Pancreatic cancer (Chapter 200) is perhaps the best example of this scenario, because few patients are deemed eligible for surgery, and most have recurrent cancer after surgery. Most adult patients with recurrent or metastatic disease are considered for palliative therapy if there is no realistic chance of cure but the potential for prolongation of useful life and/or relief of tumor-related symptoms makes such therapy reasonable.

Combination Chemotherapy

Virtually all the curative chemotherapy regimens developed for hematologic malignancies or solid tumors use combinations of active agents. Combination chemotherapy is usually superior to the use of single agents in adjuvant and neoadjuvant therapy as well. The improved results achieved by combination chemotherapy can be explained in several ways. Resistance to any single agent is almost always present at diagnosis, even in clinically responsive tumors. Tumors that are initially "sensitive" to chemotherapy rapidly acquire resistance to single agents, either as a result of selection of a preexisting clone of resistant tumor cells or because of an increased rate of mutation leading to drug resistance. Combination chemotherapy theoretically addresses both phenomena by providing a broader range of coverage against initially

resistant clones of cells and preventing or slowing the development of resistant clones.

Combination chemotherapy follows a set of principles. All drugs must be active against the tumor, and all drugs must be given at an optimal dose and on an optimal schedule. The drugs should have different mechanisms of antitumor activity as well as different toxicity profiles, and the drugs should be given at consistent intervals for the shortest possible treatment time.

Hormonal Therapy

Endocrine or hormonal therapy for cancer (Table 182-3), the earliest form of systemic therapy, is almost entirely limited to breast cancer (Chapter 204) and prostate cancer (Chapter 207). Many premenopausal breast cancers are thought to be under the influence of estrogens, and hormonal deprivation (ablation) may produce long-term responses in properly selected patients (those with estrogen and/or progesterone receptor positivity who have predominantly soft tissue or bone disease). This hormonal ablation may take the form of surgical removal of the ovaries, ablative radiation therapy, or the use of luteinizing hormone–releasing hormone antagonists. The antiestrogen tamoxifen is effective against breast cancer, and it may decrease the incidence of contralateral breast cancers in both premenopausal and postmenopausal women with breast cancer. It also has an estrogen-like activity that is responsible for an increased rate of endometrial cancers. Somewhat paradoxically, postmenopausal women who are candidates for hormonal therapy may also respond to tamoxifen.

Aromatase Inhibitors

Patients who have experienced a prolonged objective response or stable disease with hormonal therapy may be candidates for second-, third-, or fourth-line hormonal therapy. However, such responses tend to become less frequent and shorter, and many patients eventually need chemotherapy. Recently, aromatase inhibitors (e.g., anastrozole, letrozole, exemestane), which decrease the conversion of metabolites in fat and muscle into estrogen, have been found to be more effective than tamoxifen as first-line therapy in both the adjuvant and metastatic settings, although the optimal schedule for tamoxifen and the aromatase inhibitors in the adjuvant setting is still under study (Chapter 204).

Prostate cancer (Chapter 207) is androgen dependent, and androgen deprivation through castration or antiandrogens can produce meaningful responses. Estrogen therapy is now used infrequently because of its cardiovascular side effects and the availability of better alternatives. Once prostate cancer becomes androgen independent, second-line hormonal therapy rarely produces useful responses.

Corticosteroids

The corticosteroids (Chapter 34), typically prednisone or dexamethasone, are widely used in the treatment of hematologic and oncologic cancers. In Hodgkin's disease (Chapter 192), the non-Hodgkin's lymphomas (Chapter 191), and multiple myeloma (Chapter 193), corticosteroids have antitumor activity. In solid tumors, they are used as antiemetics and, rarely, for the treatment of hypercalcemia of cancer (Chapter 186), for symptomatic relief of cerebral edema in cases of central nervous system metastases (Chapter 195), or as an adjunct to radiation therapy for spinal cord metastases. Megestrol acetate (Megace) is often used in an attempt to relieve anorexia, which is common among cancer patients.

Immunotherapy

Two cancers characterized by often unpredictable clinical behavior, melanoma (Chapter 210) and renal cell carcinoma (Chapter 203), are treated with interferon, interleukin-2, or both (Table 182-4). Dramatic responses are uncommon, and immunotherapy is only a minor component of cancer therapy.

Molecularly Targeted Agents

Targeted agents (Table 182-5) are drugs directed at a specific molecular point, such as a protein tyrosine kinase, or at the presence of a specific antigen on a tumor cell. The first tyrosine kinase inhibitors were imatinib and erlotinib. The best example of the success of tyrosine kinase inhibitor therapy is the dramatic response of chronic myelogenous leukemia (Chapter 190) to imatinib (Gleevec). Imatinib also has activity against gastrointestinal stromal cell tumors.

Erlotinib, directed against the epidermal growth factor receptor (EGFR), has antitumor effects in patients whose non–small cell lung cancers (Chapter 197) have EGFR mutations. Current research aims to identify the specific types of mutations so that patients can be prospectively selected for therapy, analogous to the measurement of estrogen receptors to select breast cancer patients for hormonal therapy.

The vascular endothelial growth factor receptor (VEGFR) stimulates the formation of new blood vessels that are critical for tumor growth. Anti-VEGFR agents, such as the monoclonal antibody bevacizumab, prevent VEGF from transducing its signal in endothelial cells, thereby preventing their division. Bevacizumab has antitumor effects in metastatic colorectal cancer, non–small cell lung cancer, and breast cancer. Thalidomide inhibits angiogenesis through an unknown mechanism and is used against multiple myeloma (Chapter 193).

Bortezomib (Velcade), a unique drug, is a reversible inhibitor of the proteasome pathway that normally regulates the intracellular concentration of specific proteins, thus controlling homeostasis. It has been effective in the treatment of refractory multiple myeloma (Chapter 193) and non-Hodgkin's lymphomas (Chapter 191).

The development of monoclonal antibodies directed against antigens found on cancer cells represents an additional treatment modality, often complementary to conventional chemotherapy. Examples include alemtuzumab, cetuximab, rituximab, and trastuzumab. Trastuzumab has recently been shown to add significantly to disease-free survival time in patients positive for HER2/neu who receive adjuvant therapy for early-stage breast cancer (Chapter 204). These monoclonal antibodies can be used alone ("naked") or, in some cases,

labeled with a radioactive molecule to enhance cell killing. This radioimmunoconjugate approach has been most effective in the treatment of non-Hodgkin's lymphomas (Chapter 191) and chronic lymphocytic leukemia (Chapter 190). The effectiveness of monoclonal antibodies is limited by changes in the antigenic composition of neoplastic cells, called *antigenic drift*.

Individual Agents

A list of the most commonly used chemotherapeutic agents (Table 182-6) can help in understanding the key issues each one raises. In all cases, the most current information from the manufacturer should be sought before therapy is initiated. The number of new drugs continues to increase, and some older drugs included in previous editions of this textbook have been omitted.

The administration of chemotherapy is best done by specifically trained individuals because of the dual risks of hypersensitivity reactions and extravasation. No doses or schedules are suggested because these agents are often used in combination, and the doses must be reduced in many cases. End-organ function also affects dosing. The administration of chemotherapy during pregnancy is an especially difficult circumstance and requires a particularly high level of expertise.

Unless otherwise specified, all chemotherapeutic agents are capable of producing some degree of nausea and vomiting, myelosuppression, alopecia, mucositis, and/or diarrhea after treatment. Most agents are also teratogenic, mutagenic, and carcinogenic, so these toxicities are not repeated for each agent. Drugs used routinely to offset agent-specific toxicities are also included in Table 182-6.

Bone Marrow or Stem Cell Transplantation

Because the major dose-limiting toxicity of most chemotherapeutic agents is myelosuppression, approaches have been developed to harvest the pluripotent stem cells found in bone marrow, peripheral blood, or, less often, cord blood before marrow-damaging chemotherapy so that the stem cells can be reinfused later (Chapter 181). This technique is most effective for acute leukemias (Chapter 189), relapsed lymphomas (Chapter 191), and germ cell tumors (Chapter 206). The effectiveness of this approach is limited more by the inability to eradicate cancer cells than by the inability to achieve engraftment. Transplants may be syngeneic (from an identical twin), autologous (from oneself), allogeneic (from a matched donor, such as a sibling or parent), or from a matched unrelated donor. Nonablative hematopoietic transplants that do not completely abolish myelopoiesis reduce toxicity and allow the treatment of older and medically infirm patients.

Special Circumstances: Pregnant and Geriatric Patients

Pregnancy

Cancer during pregnancy is not uncommon, with breast, cervical, ovarian, melanoma, thyroid, and hematologic malignancies being most common. This is obviously an emotionally charged time, as the joy of a new birth is contrasted with the possible loss of the mother. Clinical decision making is complicated by ethical, moral, cultural, and religious issues. This is not an area for the inexperienced. If surgery can be safely accomplished, this may be the best course, even if it is only a temporizing measure. Radiation therapy carries the very real risk of radiation exposure to the fetus, and staging is almost always suboptimal and confined to ultrasound examinations. When the disease requires chemotherapy, changes in both the mother and the fetus must be taken into account; for instance, there are major changes is pharmacokinetics during pregnancy, along with changes in renal function and plasma volume, plasma protein levels, hepatic metabolism, gastrointestinal absorption, and placental transfer, not to mention fetal pharmacokinetics and placental excretion. Many of the commonly used chemotherapeutic drugs are classified by the Food and Drug Administration as category D (positive human fetal risk, but the benefits in pregnant women may be acceptable despite the risk) or category X (studies in humans and animal have shown fetal malformations or there is evidence of fetal risk based on human evidence). If the mother's condition permits, it is advisable to defer chemotherapy during the first and perhaps the second trimesters and to treat life-threatening situations during the third trimester after extensive counseling with the parents.

Geriatrics

The aging U.S. population has brought an increasing number of older patients with cancer to the attention of oncologists, and the field of geriatric oncology is a new area of specialization. An increasing proportion of cancers occurs in the older population. The changes that develop with age are covered in another chapter, but they can be briefly summarized here as decreased excretion of drugs and metabolites from the kidneys, decreased volume of distribution of water-soluble drugs, and increased susceptibility to myelosuppression, cardiomyopathy, and neuropathy. Many older adults also have comorbid illnesses that must be taken into account. As a general rule, the suitability of an older patient for therapy can be determined by a comprehensive geriatric assessment (CGA) that evaluates the patient's function, comorbidity, nutrition, medications, and resources. By itself, age is not a barrier to surgery; rather, the patient's performance status and the CGA should determine the likelihood of a good recovery. Tolerance of radiation therapy seems to remain largely intact with increasing age. Chemotherapy decisions are also based on the performance status and CGA, with the use of growth factors to increase the white blood cell count and to maintain a hemoglobin sufficient to minimize symptoms. Dosage adjustments are also made for individual glomerular filtration rates for patients aged 65 and older. The use of lower chemotherapy doses based on age alone is probably not advisable and may result in ineffective therapy.

Management of Complications

Supportive Care

Nutrition is always a concern for patients newly diagnosed with cancer, even if they have not experienced weight loss. In fact, significant weight loss is an adverse prognostic factor for several cancers, especially lung cancer. Patients are often concerned about whether their diet contributed to development of the cancer and whether diet can influence the results of therapy. In most settings, neither of these scenarios is the case. Malnourished patients should be evaluated by a dietitian to determine whether they are ingesting sufficient calories and whether dietary supplements might be needed. Some patients, such as those with head and neck cancers (Chapter 196) or esophageal cancers (Chapter 198), may require parenteral nutrition through a percutaneous endoscopic gastrostomy tube. Total parenteral nutrition (Chapter 224) is rarely indicated, is not particularly helpful, and is likely to produce an ethical dilemma when therapy fails and the decision to discontinue it must be discussed. Corticosteroids increase appetite but have many undesirable side effects. Megestrol acetate (Megace) at a dose of 800 mg/day improves appetite and allows weight gain in many patients; it is expensive, although the suspension is less costly than the tablets. The synthetic cannabinoid dronabinol (Marinol) stimulates appetite and reduces nausea in some patients, but it can produce dysphoria, particularly in older patients. A multiple vitamin with zinc may help with abnormal taste and provide trace minerals. Larger than recommended doses of vitamins are not helpful and may be toxic. It is always useful to inquire what over-the-counter and alternative medications (Chapter 38) are being contemplated or used by the patient.

Symptom Management

Symptom management is key to successful treatment and the patient's quality of life. Pain control (Chapter 29) can be accomplished with a variety of analgesics, both non-narcotic and narcotic. Oncologists use a 10-point scale for evaluating pain control (Fig. 182-1) and start with nonsteroidal anti-inflammatory drugs (NSAIDs) such as aspirin and acetaminophen, progress through ibuprofen and related drugs, and then through combinations of NSAIDs and narcotics to stronger narcotics.[1] Newer narcotics are available in both short-duration and long-duration forms; some patches last 72 hours, which are ideal for patients who have severe pain and are unable to take oral medications. Oral transmucosal fentanyl is more effective than standard-release morphine in this setting. Oral mucositis, a common complication of intensive therapy for hematologic malignancies, can be treated with local measures or with recombinant human keratinocyte growth factor.[2,3] Oral anti-*Candida* drugs that are absorbed or partially absorbed from the gastrointestinal tract can help prevent oral candidiasis.[4]

Many patients still fear chemotherapy because of the risk of nausea and vomiting. New antiemetics, used in combination, have made this side effect much less common. Chemotherapeutic drugs can be ranked according to their probability of causing nausea and vomiting, with prophylactic treatment given accordingly. The availability of the serotonin 5-hydroxytryptamine type 3 (5-HT_3) receptor antagonists (dolasetron, granisetron, ondansetron) has dramatically improved the ability to completely control nausea and vomiting. Although prochlorperazine may be adequate for mildly emetogenic chemotherapy, more emetogenic regimens require combination therapy with a corticosteroid (usually dexamethasone), a 5-HT_3 antagonist, and a benzodiazepine (e.g., lorazepam). A newer antiemetic, aprepitant, is particularly useful for the treatment of delayed nausea and vomiting. Treating patients before the development of nausea and vomiting is much more effective and helps patients adhere to their treatment schedules.

Growth factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), permit the more rapid recovery of white blood cell nadirs, thus permitting chemotherapy to be given on schedule, without reducing the dosage in many cases.[5] However, such therapy does not decrease hospitalizations or improve survival. It is possible to determine which individuals are at greatest risk for febrile neutropenia (Chapters 170 and 289) and treat them in advance, based on published guidelines.[6,7] Anemia induced by chemotherapy can be alleviated, the need for transfusions reduced, and quality of life improved by the use of either erythropoietin (Procrit) or darbepoetin (Aranesp).

The bisphosphonates pamidronate (Aredia) and zoledronate (Zometa) are very effective not only to treat tumor-induced hypercalcemia (Chapter 186) but also to reduce pathologic fractures in bones with metastatic lesions, particularly from breast cancer (Chapter 204), prostate cancer (Chapter 207), and myeloma (Chapter 193). They are also used to treat osteoporosis caused by chemotherapy-induced premature menopause in young women with breast cancer. Denosumab (Xgeva) is a human monoclonal antibody that binds to

TABLE 182-6 CHEMOTHERAPEUTIC AGENTS

AGENT	CLASS	ACTION	EXCRETION	UNIQUE SIDE EFFECTS	DRUG INTERACTIONS	INDICATIONS
ALKYLATING AGENTS						
Bendamustine (Treanda)	Alkylating agent	Bifunctional with both alkylating and purine-like antimetabolite action	Biotransformation in liver	None	Synergistic with rituximab	CLL, myeloma, Hodgkin's and non-Hodgkin's lymphoma
Carboplatin (Paraplatin)	Platinum coordination compound	Produces interstrand DNA cross-links, similar to those with bifunctional alkylating agents; cell cycle nonspecific	Renal	Nephrotoxicity, ototoxicity, neuropathy, hypomagnesemia, hypersensitivity reactions, hepatotoxicity	Avoid other nephrotoxic or ototoxic drugs	Ovarian cancer, testicular cancer, lung cancer, head and neck cancer, breast cancer
Chlorambucil (Leukeran)	Bifunctional alkylating agent	Formation of interstrand DNA cross-links with resultant inactivation of DNA; cell cycle nonspecific	Hepatic biotransformation, renal excretion	Hepatotoxicity, pulmonary toxicity	None	CLL, Waldenström's macroglobulinemia, Hodgkin's and non-Hodgkin's lymphomas, myeloproliferative disorders, ovarian cancer
Cisplatin (Platinol)	Platinum coordination compound	Produces interstrand DNA cross-links similar to bifunctional alkylating agents; cell cycle nonspecific	Renal	Nephrotoxicity, ototoxicity, neuropathy, hypomagnesemia, hypersensitivity reactions, hemolytic anemia, SIADH	Avoid other nephrotoxic or ototoxic drugs	Testicular cancer, other germ cell tumors, ovarian cancer, bladder cancer, prostate cancer, lung cancer, sarcomas, cervical cancer, endometrial cancer, gastric cancer, breast cancer, adrenal cancer, head and neck cancer
Cyclophosphamide (Cytoxan, Neosar)	Alkylating agent of nitrogen mustard type	Cross-linking of DNA and RNA, inhibits protein synthesis; cell cycle nonspecific	Hepatic biotransformation, renal excretion	Hemorrhagic cystitis, SIADH	Phenobarbital increases rate of metabolism and leukopenia; cyclophosphamide potentiates effects of succinylcholine and may increase oral anticoagulant activity	Breast cancer, ovarian cancer, Hodgkin's and non-Hodgkin's lymphomas, leukemias, neuroblastoma, retinoblastoma, other sarcomas, bladder cancer, lung cancer, cervical cancer, endometrial cancer, prostate cancer, osteogenic sarcoma, Wilms' tumor
Dacarbazine (DTIC-Dome)	Nonclassic alkylating agent	Inhibits DNA and RNA synthesis via formation of carbonium ions; cell cycle nonspecific	Hepatic biotransformation, renal excretion	Pain on injection, flu-like syndrome, hepatic veno-occlusive disease, photosensitivity	Heparin, lidocaine, hydrocortisone, phenytoin, phenobarbital, interleukin-2	Melanoma, Hodgkin's disease, sarcomas
Ifosfamide (Ifex)	Alkylating agent of nitrogen mustard type	Alkylated metabolites interact with DNA; cell cycle nonspecific	Hepatic biotransformation, renal elimination	Hemorrhagic cystitis, nephrotoxicity, CNS toxicity	None	Germ cell tumors, sarcomas, non-Hodgkin's lymphomas, cervical cancer, Ewing's sarcoma, lung cancer
Mechlorethamine, nitrogen mustard (Mustargen)	Bifunctional alkylating agent	Cross-links strands of DNA and RNA, inhibits protein synthesis; cell cycle nonspecific	Rapidly deactivated in body fluids and tissues	Extravasation	None	Hodgkin's disease, intracavitary treatment of effusions; topically for mycosis fungoides
Melphalan (Alkeran)	Alkylating agent of nitrogen mustard type	Forms interstrand, intrastrand, or DNA protein cross-links; cell cycle nonspecific	Deactivated in body fluids and tissues, renal elimination 50%	Pulmonary toxicity	Cimetidine decreases oral bioavailability; cyclosporine enhances risk of renal toxicity	Multiple myeloma, breast cancer, ovarian cancer, rhabdomyosarcoma, bone marrow ablation for stem cell transplantation
Mitomycin (Mutamycin)	Antitumor antibiotic	Acts as bifunctional alkylating agent, inhibiting DNA synthesis; cell cycle nonspecific, but most active in G and S phases	Hepatic biotransformation, renal elimination	Cumulative myelosuppression, extravasation, renal toxicity, pulmonary toxicity, cardiac toxicity, hemolytic-uremic syndrome	Prior treatment with vinca alkaloids may predispose to pulmonary toxicity; if used with doxorubicin, may potentiate cardiotoxicity	Gastric cancer, pancreatic cancer, anal cancer, lung cancer, head and neck cancer, cervical cancer

Oxaliplatin (Eloxatin)	Platinum coordination compound	Produces interstrand DNA cross-links similar to bifunctional alkylating agents; cell cycle nonspecific	Renal	Nephrotoxicity, neurotoxicity (worse with cold), allergic reactions	Avoid other nephrotoxic drugs, incompatible with 5-fluorouracil	Colorectal cancer
Procarbazine (Matulane)	Nonclassic alkylating agent and MAO inhibitor	Unknown; metabolism produces highly active free radicals that may alkylate and methylate DNA; cell cycle specific, S phase	Renal 70% after hepatic biotransformation	Disulfiram (Antabuse)-like side effects with alcohol ingestion; patients should avoid foods containing tyramine due to the drug's MAO inhibitory effects; central and peripheral neurotoxicity, hepatotoxicity, pulmonary toxicity	>100, including alcohol, antihistamines, anticoagulants, anticonvulsants, hypoglycemics, certain antihypertensives, caffeine-containing preparations, narcotics, methyldopa, metrizamide, sympathomimetics, tyramine or other high pressor amine-containing foods	Hodgkin's disease, brain tumors
Streptozocin (Zanosar)	Nitrosourea	Inhibits DNA synthesis	Renal	Cumulative, dose-related renal toxicity, hepatotoxicity, glucose intolerance	None	Islet cell tumors of pancreas, carcinoid tumors
Temozolomide (Temodar)	Nonclassic alkylating agent	Inhibits DNA and RNA synthesis via formation of carbonium ions; cell cycle nonspecific	Hepatic biotransformation, renal excretion	Photosensitivity	None	Melanoma, brain tumors
DIFFERENTIATING AGENTS						
All-*trans*-retinoic acid (ATRA)	Retinoid	Induces differentiation and/or inhibition of clonogenicity	Conjugation to glucuronic acid with subsequent biliary excretion and enterohepatic circulation	Mucocutaneous toxicity, ocular toxicity, musculoskeletal toxicity, neurologic toxicity, hepatotoxicity, lipid toxicity	None	Acute progranulocytic leukemia
Arsenic trioxide (Trisenox)	Natural product	Induces differentiation of acute progranulocytic leukemia cells	Hepatic metabolism, excreted in urine	Prolonged QT interval, acute progranulocytic leukemia differentiation syndrome, leukocytosis, peripheral neuropathy	Medications that increase QT interval, such as antiarrhythmics and amphotericin	Acute progranulocytic leukemia
ENZYMES						
L-Asparaginase (Elspar)	Enzyme	Hydrolyzes 1-asparagine to aspartic acid and ammonia, resulting in cellular deficiency of 1-asparagine; sensitive tumor cells lack asparagine synthetase; interferes with protein, DNA, and RNA synthesis; cell cycle specific for G1 phase of cell division	Metabolized in liver	Hypersensitivity reactions, inhibitory effects on protein synthesis with resultant decreases in hepatic synthesis of coagulation factors, pancreatitis, hyperglycemia, CNS depression, hepatotoxicity	Abolishes effects of methotrexate on malignant cells; concurrent vincristine may enhance hyperglycemic effects of asparaginase and increase risk of neuropathy	Acute lymphoblastic leukemia
ANTIMETABOLITES						
5-Azacitidine (Vidaza)	Antimetabolite; pyrimidine nucleoside analogue of cytidine	Causes hypomethylation of DNA and direct cytotoxicity on abnormal hematopoietic cells	Hepatic metabolism, excreted in urine	Renal toxicity, low serum bicarbonate levels	None	Myelodysplasia
Capecitabine (Xeloda)	Antimetabolite of pyrimidine analogue type	Fluoropyrimidine carbamate prodrug form of 5-fluorouracil; given orally; inactive as itself; inhibits DNA and RNA synthesis; cell cycle specific, S phase	Hepatic catabolism	Hand and foot syndrome, angina	Warfarin potentiation, phenytoin, antacids, leucovorin, thymidine	Breast cancer, colorectal cancer

TABLE 182-6 CHEMOTHERAPEUTIC AGENTS—cont'd

AGENT	CLASS	ACTION	EXCRETION	UNIQUE SIDE EFFECTS	DRUG INTERACTIONS	INDICATIONS
Cladribine (Leustatin), 2-chloro-2-deoxy-D-adenosine	Antimetabolite	Purine nucleoside analogue, inhibits both DNA synthesis and repair	Uncertain	Bone marrow suppression, fever, paralysis, and/or acute renal failure when used at very high doses for BMT	None known	Hairy cell leukemia
Clofarabine (Clofar)	Purine nucleoside antimetabolite	Inhibits DNA synthesis and DNA repair	Excreted in urine and other?	Bone marrow suppression, hepatotoxicity	Other renal and hepatotoxic drugs	Relapsed acute lymphoblastic leukemia
Cytarabine (Cytosar-U, Tarabine PFS)	Antimetabolite	Activated to cytarabine triphosphate in tissues, inhibits DNA synthesis; cell cycle specific, S phase	Deaminated in blood and tissues	Pancreatitis; with high doses, cerebral dysfunction, GI damage, hepatotoxicity, pulmonary edema, corneal damage, "Ara-C syndrome"	With high-dose cyclophosphamide, may increase cardiotoxicity	Acute granulocytic leukemia and its variants, non-Hodgkin's lymphoma, myelodysplasia*
Fludarabine phosphate (Fludara)	Antimetabolite of purine type	2-Fluoro-ara-ATP inhibits DNA synthesis by inhibition of ribonucleotide reductase and the DNA polymerases; cell cycle specific, S phase	Renal	Neurologic, pulmonary toxicity	None	CLL
Fluorouracil (5-FU, Adrucil)	Antimetabolite of pyrimidine analogue type	Inhibits DNA and RNA synthesis; cell cycle specific, S phase	Respiratory, small renal elimination	Cerebellar ataxia, myocardial ischemia	None	Breast cancer, GI cancers, head and neck cancer, bladder cancer, ovarian cancer, endometrial cancer, effusions
Floxuridine (FUDR)	Antimetabolite of pyrimidine analogue type	Inhibits DNA and RNA synthesis; cell cycle specific, S phase	Respiratory, small renal elimination	Cerebellar ataxia, myocardial ischemia, hepatotoxicity	Leucovorin enhances activity and toxicity; thymidine rescues toxic effects	Intra-arterial therapy for hepatic malignancies
Hydroxyurea (Hydrea)	Antimetabolite	Inhibits ribonucleotide reductase, causing inhibition of DNA synthesis; cell cycle specific, S phase	Renal after hepatic biotransformation	Megaloblastosis	May enhance effects of anti-HIV drugs	Myeloproliferative neoplasms, ovarian cancer, head and neck cancer, cervical cancer (with radiation therapy)
Mercaptopurine (Purinethol, 6-MP)	Antimetabolite of purine analogue type	Inhibits DNA synthesis; cell cycle specific, S phase	Metabolic alteration by xanthine oxidase, renal excretion	Hepatotoxicity, skin rashes	Dose must be reduced when used with allopurinol; concomitant methotrexate enhances bioavailability of 6-MP; inhibits warfarin (Coumadin) effects	Acute lymphoblastic leukemia
Methotrexate (Folex, Mexate)	Antimetabolite of folic acid analogue type	Inhibits DNA, RNA, thymidylate, and protein synthesis as a result of binding to dihydrofolate reductase; cell cycle specific, S phase	Renal	Hepatotoxicity, lung disease; in high doses, acute renal failure, acute neurologic dysfunction; avoid use with ascites, pleural effusions	Salicylates, NSAIDs, folic acid–containing vitamins, oral nonabsorbable broad-spectrum antibiotics, trimethoprim/sulfamethoxazole, other nephrotoxic drugs	Breast cancer, head and neck cancer, choriocarcinoma, acute lymphoblastic leukemia, non-Hodgkin's lymphomas, osteosarcoma, intrathecal treatment of meningeal leukemia, bladder cancer, lung cancer
Pemetrexed (Alimta)	Antimetabolite of folic acid analogue type	Inhibits thymidylate synthetase, dihydrofolate reductase, and de novo purine synthesis; cell cycle specific, S phase	Renal, after hepatic metabolism	Must be given with folic acid and vitamin B_{12}; avoid use with ascites, pleural effusions	Salicylates, NSAIDs	Mesothelioma, breast cancer, lung cancer
Pentostatin (Nipent)	Purine antagonist	Inhibits adenosine deaminase; also inhibits RNA synthesis	Renal	Fever, fatigue, rash, pain, hepatotoxicity, chronic immunosuppression	Enhances effects of vidarabine, a purine nucleoside with antiviral activity; must not be given with fludarabine because of fatal pulmonary toxicity	Hairy cell leukemia, CLL
Pralatrexate (Fotolyn)	Antimetabolite type		Renal	Requires vitamin B_{12} and folate supplementation	Myelosuppression	Relapsed peripheral T-cell lymphomas

NONCOVALENT DNA-BINDING DRUGS						
Bleomycin (Blenoxane)	Antitumor antibiotic	Inhibition of DNA synthesis; most effective in G2 phase of cell division	Renal	Dose-related pulmonary fibrosis, hypersensitivity reactions, skin and mucocutaneous toxicity, including Raynaud's phenomenon (in combination with other agents), fever, chills; usually considered nonmyelosuppressive	Cisplatin may decrease renal clearance; high oxygen concentrations may enhance pulmonary toxicity, even after therapy	Testicular cancer and other germ cell tumors; Hodgkin's and non-Hodgkin's lymphomas; mycosis fungoides; squamous cell carcinomas of head and neck, cervix, and vulva; pleural effusions
Daunorubicin (Cerubidine)	Antitumor antibiotic	Binds to DNA by intercalation between base pairs and inhibits DNA and RNA synthesis by template disordering and steric obstruction; most active in S phase but not cell cycle phase specific	Hepatic biotransformation with 40% biliary excretion	Dose-related cardiotoxicity, extravasation, red urine	None	Acute granulocytic leukemia and its variants, acute lymphoblastic leukemia
Doxorubicin (Adriamycin, Rubex)	Antitumor antibiotic	Binds to DNA by intercalation between base pairs and inhibits DNA and RNA synthesis by template disordering and steric obstruction; cell cycle specific, S phase	Hepatic biotransformation with 50% biliary excretion	Dose-related cardiotoxicity, extravasation, red urine	None	Acute granulocytic leukemia and its variants, acute lymphoblastic leukemia, breast cancer, bladder cancer, ovarian cancer, thyroid cancer, lung cancer, Hodgkin's and non-Hodgkin's lymphomas, sarcomas, gastric cancer, multiple myeloma, endometrial cancer, bladder cancer, prostate cancer, Wilms' tumor, neuroblastoma
Doxorubicin liposomal (Doxil)	Anthracycline antibiotic	Topoisomerase inhibitor	Liver	Dose-related cardiotoxicity, extravasation, hand-foot syndrome	None	Ovarian cancer, myeloma, Kaposi's sarcoma
Epirubicin (Ellence)	Antitumor antibiotic	Intercalates with DNA	Liver	Dose-related cardiotoxicity	None	Breast cancer adjuvant therapy
Idarubicin (Idamycin)	Anthracycline glycoside	Intercalates DNA and inhibits DNA synthesis, interacts with RNA polymerases, and inhibits topoisomerase II	Hepatic biotransformation, biliary excretion	Dose-related cardiotoxicity, extravasation	None	Acute granulocytic leukemia and its variants
Mitoxantrone (Novantrone)	Antitumor antibiotic	Binds to DNA by intercalation between base pairs and nonintercalative electrostatic interaction, resulting in inhibition of DNA and RNA synthesis; not cell cycle specific, but most active in late S phase	Hepatic biotransformation, biliary/fecal excretion	Dose-related cardiotoxicity, extravasation, blue-green urine	None	Prostate cancer, acute myelogenous leukemia and its variants, breast cancer, non-Hodgkin's lymphomas
INHIBITORS OF CHROMATIN FUNCTION						
Docetaxel (Taxotere)	Mitotic spindle poison	Unique mitotic spindle inhibitor; cell cycle specific, M phase	Hepatic metabolism, biliary	Hypersensitivity reactions, fluid retention syndrome, nail discoloration, neuropathy, arthralgias	Inhibitors or activators of liver cytochrome P-450 CYP34A enzyme system may affect metabolism	Breast cancer, prostate cancer, lung cancer, ovarian cancer, esophageal cancer, gastric cancer, head and neck cancer, bladder cancer
Etoposide (VP-16, VePesid)	Epipodophyllo toxin	Inhibits DNA synthesis; cell cycle dependent and phase specific, with maximum effect in S and G2 phases	Hepatic biotransformation, renal elimination	Allergic reactions, hepatotoxicity, CNS toxicity, hypotension	None	Testicular cancer, lung cancer, Hodgkin's and non-Hodgkin's lymphomas, choriocarcinoma, Ewing's sarcoma, acute granulocytic leukemia
Irinotecan (Camptosar)	Topoisomerase I inhibitor	Binds to topoisomerase I–DNA complex and prevents relegation of these single-strand breaks	Metabolized in liver	Early and late diarrhea may be severe	None	Colorectal cancer, small cell lung cancer

TABLE 182-6 CHEMOTHERAPEUTIC AGENTS—cont'd

AGENT	CLASS	ACTION	EXCRETION	UNIQUE SIDE EFFECTS	DRUG INTERACTIONS	INDICATIONS
Paclitaxel (Taxol)	Mitotic spindle poison	Unique mitotic spindle inhibitor; cell cycle specific, M phase	Hepatic metabolism, biliary	Hypersensitivity reactions, neuropathy, arthralgias, cardiotoxicity	Enhanced myelosuppression with doxorubicin	Lung cancer, ovarian cancer, breast cancer, esophageal cancer, gastric cancer, head and neck cancer
Paclitaxel protein-bound particles (Abraxane)	Mitotic spindle poison	Unique mitotic spindle inhibitor; cell cycle specific, M phase	Hepatic metabolism, biliary	Hypersensitivity reactions, neuropathy, arthralgias/myalgias, cardiotoxicity	Enhanced myelosuppression with doxorubicin	Metastatic breast cancer
Topotecan (Hycamtin)	Topoisomerase I inhibitor	Binds to topoisomerase I–DNA complex and prevents relegation of these single-strand breaks	Excreted unchanged in urine	—	None	Relapsed ovarian cancer, small cell lung cancer
Vinblastine (Velban)	Vinca alkaloid	Blocks mitosis by arresting cells in metaphase; cell cycle specific, M phase	Biliary/fecal	Extravasation, neurotoxicity	None	Testicular cancer, breast cancer, choriocarcinoma, Hodgkin's and non-Hodgkin's lymphomas, Kaposi's sarcoma, bladder cancer, neuroblastoma, renal carcinoma
Vincristine (Oncovin)	Vinca alkaloid	Blocks mitosis by arresting cells in metaphase; cell cycle specific, M phase	Biliary/fecal	Extravasation, neurotoxicity, constipation, SIADH	Concurrent use with L-asparaginase may increase neurotoxicity	Acute lymphocytic leukemia, neuroblastoma, Wilms' tumor, Hodgkin's and non-Hodgkin's lymphomas, rhabdomyosarcoma, Ewing's sarcoma, breast cancer, small cell lung cancer, multiple myeloma
Vinorelbine (Navelbine)	Vinca alkaloid	Inhibits tubulin polymerization, disrupting formation of microtubule assembly during mitosis; cell cycle specific, M phase	Biliary/fecal	Extravasation, neurotoxicity, constipation, SIADH	Drugs metabolized by liver P-450 system, phenytoin	Non–small cell lung cancer, breast cancer, non- Hodgkin's lymphomas
HORMONAL AGENTS						
Anastrozole (Arimidex)	Nonsteroidal aromatase inhibitor	Inhibits synthesis of estrogens by inhibiting conversion of adrenal androgens to estrogens	Metabolized in liver	Hot flashes, arthralgias	None	Adjuvant and metastatic breast cancer in postmenopausal women
Bicalutamide (Casodex)	Nonsteroidal antiandrogen	Binds to androgen receptors in prostate	Hepatic metabolism	Worsening bone pain, gynecomastia, hot flashes	None	Prostate cancer (usually in conjunction with LHRH antagonist)
Degarelix (Firmagon)	GnRH receptor antagonist	Binds to GnRH receptors in pituitary		Injection site reactions, increased LFTs, QT interval prolongation	None	Prostate cancer
Dexamethasone (Decadron)	Corticosteroid	Multiple	Renal excretion of inactive metabolites	Cushingoid appearance, hyperglycemia, fluid retention, osteoporosis, muscular weakness, peptic ulcer disease, cataracts, psychosis, aseptic necrosis	Efficacy impaired by phenytoin	Acute lymphoblastic leukemia, Hodgkin's and non-Hodgkin's lymphomas, CLL, multiple myeloma, Waldenström's macroglobulinemia, cerebral edema, hypercalcemia, lymphangitic metastases, antiemetic
Diethylstilbestrol (DES)	Estrogen	Stimulation of autocrine growth factors	Renal	Feminization in men, fluid retention, thromboembolic phenomena, induction of endometrial cancer	None	Breast cancer, prostate cancer

Estradiol	Estrogen	Stimulation of autocrine growth factors	Renal	Feminization in men, fluid retention, thromboembolic phenomena, induction of endometrial cancer	None	Breast cancer, prostate cancer
Estramustine (Emcyt)	Phosphorylated combination of estradiol and nitrogen mustard	Inhibits microtubule structure and function; cell cycle specific, M-phase	Biliary/fecal	Feminization, fluid retention	None	Prostate cancer
Estrogens (conjugated or esterified)	Estrogen	Stimulation of autocrine growth factors, inhibition of pituitary secretion of LH, resulting in decreased serum testosterone concentration	Primarily renal	Feminization in men, fluid retention, thromboembolic phenomena, induction of endometrial cancer	None	Breast cancer, prostate cancer
Exemestane (Aromasin)	Steroidal aromatase inhibitor	Permanently binds to and irreversibly inhibits aromatase, inhibits synthesis of estrogens by inhibiting conversion of adrenal androgens to estrogens	Metabolized in liver	Hot flashes, arthralgias	None	Metastatic breast cancer in postmenopausal women
Fluoxymesterone (Halotestin)	Androgen	Suppresses GnRH, LH, and FSH through negative feedback mechanism involving hypothalamus and anterior pituitary	Renal	Masculinization in women, hepatotoxicity	May increase anticoagulant effects of warfarin (Coumadin); decreased blood glucose, resulting in potential for hypoglycemia in diabetics	Breast cancer
Flutamide (Eulexin)	Antiandrogen	Inhibition of androgen uptake and/or inhibition of nuclear binding of androgen in target tissues; its interference with testosterone at cellular level complements "medical castration" produced by LHRH analogues	Renal	Worsening bone pain, hot flashes, gynecomastia	None	Prostate cancer (usually in conjunction with LHRH antagonist)
Fulvestrant (Faslodex)	Estrogen receptor antagonist	Competitively binds to estrogen receptor and downregulates estrogen receptor protein in breast cancer cells	Cleared by hepatobiliary route	Arthralgias	None	Recurrent breast cancer in postmenopausal women
Goserelin (Zoladex)	Synthetic decapeptide analogue of LHRH	Suppresses pituitary gonadotropins, with fall of serum testosterone into castrate range	Metabolism	Worsening bone pain, hot flashes	None	Breast cancer, prostate cancer
Letrozole (Femara)	Nonsteroidal competitive inhibitor of aromatase	Inhibits synthesis of estrogens by inhibiting conversion of adrenal androgens to estrogens	Metabolized in liver	Hot flashes, arthralgias	None	Adjuvant and metastatic breast cancer in postmenopausal women
Leuprolide (Lupron, Lupron Depot)	Synthetic LHRH analogue	Suppresses secretion of GnRH, with resultant fall in testosterone secretion, producing "medical castration"	Metabolized in liver	Increased bone pain, hot flashes, thromboembolic phenomena	None	Prostate cancer, breast cancer
Medroxyprogesterone (Provera, Depo- Provera)	Progestational drug	Inhibition of pituitary gonadotropin production with resultant decrease in estrogen secretion	Renal	Weight gain, thromboembolic phenomena, fetal hazard	None	Breast cancer, endometrial cancer
Megestrol acetate (Megace)	Progestational drug	Inhibition of pituitary gonadotropin production, with resultant decrease in estrogen secretion	Renal	Weight gain, thromboembolic phenomena, fetal hazard	None	Breast cancer, endometrial cancer

TABLE 182-6 CHEMOTHERAPEUTIC AGENTS—cont'd

AGENT	CLASS	ACTION	EXCRETION	UNIQUE SIDE EFFECTS	DRUG INTERACTIONS	INDICATIONS
Nilutamide (Nilandron)	Nonsteroidal antiandrogen	Binds to androgen receptors in prostate, inhibiting androgen uptake and binding in nucleus	Hepatic metabolism	Worsening bone pain, gynecomastia, hot flashes, visual disturbances, interstitial pneumonitis	Increased warfarin effect; inhibits liver cytochrome P-450 system; increased risk of alcohol intolerance	Prostate cancer (usually in conjunction with LHRH antagonist)
Octreotide (Sandostatin)	Synthetic octapeptide analogue of somatostatin	Suppresses secretion of serotonin and GI peptides; blocks carcinoid flush, decreases serum 5-HIAA, and controls other symptoms associated with carcinoid syndrome	Renal	Hyper/hypoglycemia, hepatic dysfunction	None	Palliative treatment of carcinoid tumors and vasoactive intestinal peptide tumors (VIPomas)
Prednisone (Deltasone)	Corticosteroid	Multiple	Renal excretion of inactive metabolites	Cushingoid appearance, hyperglycemia, fluid retention, osteoporosis, muscular weakness, peptic ulcer disease, cataracts, psychosis, aseptic necrosis	Efficacy impaired by phenytoin	Acute lymphoblastic leukemia, Hodgkin's and non-Hodgkin's lymphomas, CLL, multiple myeloma, Waldenström's macroglobulinemia, cerebral edema, hypercalcemia, lymphangitic metastases, antiemetic
Tamoxifen (Nolvadex)	Nonsteroidal antiestrogen	Competes with estradiol for estrogen receptor protein	In feces, mainly as conjugates	Hot flashes, nausea/vomiting, vaginal bleeding or discharge, hypercalcemia, visual disturbances, thrombocytopenia, endometrial cancer, rare liver dysfunction	When used with coumarin anticoagulants, significant increase in anticoagulant effect may be seen	Adjuvant and metastatic breast cancer
BIOLOGIC RESPONSE MODIFIERS						
Aldesleukin (Human Recombinant IL-2, Proleukin)	Lymphokine	Supports T-cell proliferation, augments natural killer cytotoxicity, induces lymphokine-activated killer (LAK) cell development, and participates in activation of monocytes and B cells	Renal	Cardiovascular toxicity, nephrotoxicity, pulmonary toxicity, GI toxicity, endocrine toxicity, dermatologic complications, CNS toxicity, hematologic toxicity, fever and chills, infection, capillary leak syndrome	May potentiate effects of psychotropics, nephrotoxic drugs, and antihypertensive agents; corticosteroids may reduce effectiveness	Renal cancer, melanoma
Erythropoietin (Aranesp, Epogen, Procrit)[†]	Hematopoietic growth factor	Stimulates division and differentiation of committed erythroid progenitors in bone marrow	Metabolized in liver	Headache, hypertension, possible seizures, allergic reactions	None	Correction of anemia in chronic renal failure, azathioprine-treated HIV infection, myelodysplasia, multiple myeloma, chemotherapy-induced anemia
Filgrastim (G-CSF, Neupogen)	Class II hematopoietic growth factor (acts on progenitor cells capable of forming only one differentiated cell type, the neutrophil)	CSFs bind to specific cell surface receptors and stimulate proliferation and differentiation	Metabolized in liver	Pain at site of subcutaneous injection, allergic reactions, arthralgias, bone pain	None	Decreases incidence of infection after myelosuppressive chemotherapy, enhances myeloid engraftment after BMT, enhances peripheral progenitor cell yield
Interferon-α (Intron-A, Roferon)[‡]	Interferon	Antiviral, antiproliferative, and immunomodulatory properties	Renal	Fever, flu-like symptoms, cardiotoxicity, neurotoxicity	None	Hairy cell leukemia, Kaposi's sarcoma, renal cancer, non-Hodgkin's lymphoma

Sargramostim (GM-CSF, Leukine, Prokine)	Class I hematopoietic growth factor (stimulates formation of granulocytes and macrophages and is not lineage specific)	CSFs bind to specific cell surface receptors and stimulate proliferation and differentiation	Metabolized in liver	Fever, capillary leak syndrome, pain at site of subcutaneous injection, allergic reactions, arthralgias, bone pain	None	Decreases incidence of infection after myelosuppressive chemotherapy, enhances myeloid engraftment after BMT, enhances peripheral progenitor cell yield
TARGETED AGENTS						
Alemtuzumab (Campath)	Humanized monoclonal antibody	Targets CD52 antigen present on surface of most normal lymphocytes and malignant B and T lymphocytes	Metabolism unclear	Hypersensitivity reactions, immunosuppressive	None	Relapsed B-cell CLL, T-cell prolymphocytic leukemia
Bevacizumab (Avastin)	Recombinant humanized monoclonal antibody to VEGF; inhibits angiogenesis	Binds to all human forms of VEGF, preventing it from binding to its receptors, reducing blood vessel formation	Metabolized	Hemorrhage, hypertension, proteinuria, thrombophlebitis	SN-38 metabolite of irinotecan is higher with concurrent use	Metastatic colorectal cancer, lung cancer, breast cancer
Bortezomib (Velcade)	Targeted agent	Reversible inhibitor of 26S proteasome; inhibits breakdown of ubiquitinated intracellular proteins and disrupts ubiquitin-proteasome pathway, eventually leading to apoptosis	Undergoes oxidative metabolism via cytochrome P-450 enzymes	Myelosuppression, peripheral neuropathy, asthenia, hypotension	Unknown	Relapsed multiple myeloma
Cetuximab (Erbitux)	Chimeric monoclonal antibody targeted against EGFR	Blocks growth factor from binding to EGFR, preventing cell signaling by tyrosine kinase phosphorylation	Metabolized	Hypersensitivity reactions, rash, diarrhea	None	Metastatic colorectal cancer
Dasatinib (Sprycel)	Multitargeted TKI	Inhibits multiple kinases	Metabolized by P-450 microenzyme CYP3A4	Myelosuppression	Multiple	Resistant/refractory CML
Erlotinib (Tarceva)	Targeted agent	Inhibits tyrosine kinase domain of EGFR	Metabolized	Rash, diarrhea, interstitial lung disease	CYP3A4 inducers and inhibitors may alter metabolism	Second- or third-line non–small cell lung cancer
Everolimus (Affinitor)	mTOR inhibitor	Inhibits mTOR	Metabolized by CYP3A4 in liver		CYP3A4 inhibitors/inducers, grapefruit juice	Renal cell carcinoma
Imatinib (Gleevec)	Targeted agent; signal transduction inhibitor	Inhibits BCR-ABL tyrosine kinase	Hepatic metabolism, excreted in feces	Myelosuppression, hypophosphatemia, fluid retention	Drugs inhibiting/stimulating liver microsomal CYP3A4 enzyme	CML, GISTs
Lapatinib (Tykerb)	Tyrosine kinase inhibitor	TKIs of EGFR and HER2/neu inhibitors/inducers	Metabolized by CYP3A4	Diarrhea, hand-foot syndrome	Capecitabine, CYP3A4	HER2/neu+ breast cancer
Lenalidomide[§] (Revlimid, CC-5013)	Targeted agent	Induces apoptosis	Renal excretion	Neutropenia, thrombocytopenia, diarrhea, pruritus, rash, fatigue, leg cramps	Other myelosuppressive agents	Myelodysplasia, myeloma
Nexavar (Sorafenib)	Targeted agent	Multikinase inhibitor, inhibits RAF kinase, VEGF, and PDGF receptors	Hepatic	Rash, hand-foot syndrome, fatigue, diarrhea, hair loss	CYP2C9 inducers, UGT1A1 pathway-excreted agents	Renal cell carcinoma
Nilotinib (Tasigna)	Tyrosine kinase inhibitor	Inhibits ATP site of ABL	Metabolized in liver	Prolonged QTc interval	CYP3A 4 inhibitors/inducers (irinotecan)	Resistant/intolerant CML
Ofatumumab (Arzerra)	Monoclonal antibody	Anti-CD20 antibody	Metabolized	Infusion reactions, infections	None	Resistant CLL
Pazopanib (Votrient)	Tyrosine kinase inhibitor	Inhibits multiple TKIs	Metabolized	Hepatotoxicity	CYP3A4 inducers/inhibitors	Renal cell cancer
Rituximab (Rituxan)	Chimeric anti- CD20 antibody	Targets CD20 antigen expressed on lymphocytes	Metabolized	Hypersensitivity reactions, lymphopenia	None	Relapsed low-grade non- Hodgkin's lymphomas

TABLE 182-6 CHEMOTHERAPEUTIC AGENTS—cont'd

AGENT	CLASS	ACTION	EXCRETION	UNIQUE SIDE EFFECTS	DRUG INTERACTIONS	INDICATIONS
Sunitinib (Sutent)	Multitargeted TKI	Inhibits TKIs and angiogenesis	Metabolized by P-450	Bleeding, CHF, prolonged QTc	CYP3A4 inhibitors/inducers	GIST, renal cell cancer
Temosirolimus (Torisel)	mTOR inhibitor	Inhibits mTOR kinase responsible for cell division	Metabolized in liver	Bowel perforation, interstitial lung disease	Affected by CYP3A4 inhibitors/inducers	Renal cell cancer
Thalidomide (Thalomid)	Immunomodulatory agent, antigenic agent	Inhibits TNF-α, may inhibit angiogenesis through inhibition of bFGF and VEGF	Nonenzymatic hydrolysis	Teratogenicity, sedation, constipation, peripheral neuropathy, rash	Sedation enhanced with alcohol, other sedatives	Multiple myeloma
Trastuzumab (Herceptin)	Recombinant humanized monoclonal antibody against HER2/neu	Downregulates expression of ERBB2 pathways	Metabolized	Hypersensitivity reactions	Increased risk of cardiotoxicity when used with anthracyclines or taxanes	Metastatic or adjuvant HER2/neu+ breast cancer
DRUGS TO OFFSET SIDE EFFECTS OF CHEMOTHERAPY						
Amifostine (Ethyol)	Cytoprotectant	Free thiol metabolites	Metabolized	Nausea/vomiting,	Hypertension	Reduces renal toxicity from cisplatin
Dexrazoxane (Zinecard)	Cardioprotector	Unclear	Excreted in urine	Myelosuppression		Reduces cardiotoxicity
Leucovorin (folinic acid, citrovorum factor, Wellcovorin)	Water-soluble folate vitamin	Increases general body pool of reduced folates	Metabolized in liver	None	In large amounts may counteract action of anticonvulsives	Prophylaxis and treatment of hematopoietic side effects of folic acid antagonists
Kepivance (Palifermin)	Keratinocyte growth factor	Stimulates growth of epithelial cells?		Rash	Heparin, myelotoxic chemotherapy	Decreases mucositis after BMT
Mesna (Mesnex)	Synthetic sulfhydryl compound	Only metabolite, mesna disulfide, reacts chemically with urotoxic ifosfamide metabolites, resulting in their detoxification	Renal	Bad taste, diarrhea	None	Prophylaxis of cyclophosphamide/ifosfamide-induced hemorrhagic cystitis

*An intrathecal formulation, DepoCyt, is used for the treatment of carcinomatous meningitis.
†Dosing differs among agents.
‡Dosages differ among brands.
§An analogue of thalidomide, which is a severe human teratogen; restricted prescribing.

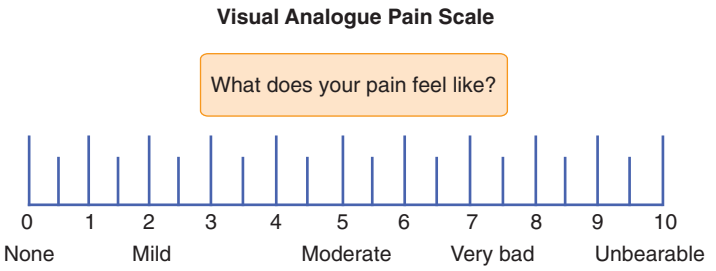

FIGURE 182-1. Grading pain in cancer patients.

RANK ligand, a protein found on osteoclasts and involved in bone breakdown. It is administered subcutaneously. Some clinical trials have found denosumab to be superior to zoledronic acid for the prevention of skeletal-related events in cancer patients with bone metastases.■

Hematologic malignancies and chemosensitive solid tumors should be treated with prophylactic allopurinol to prevent gout and renal colic from hyperuricemia. The acute tumor lysis syndrome can be defined by laboratory findings—elevated levels of uric acid, potassium, and phosphorus and decreased levels of calcium—or clinically—elevated creatinine, cardiac arrhythmias or sudden death, and seizures. The effects can be minimized by the use of allopurinol, vigorous hydration, and rasburicase and by the careful assessment of serum electrolytes, but anticipating the possibility of its occurrence is the best strategy.

EPIDEMIOLOGY OF CANCER

MICHAEL J. THUN AND AHMEDIN JEMAL

EPIDEMIOLOGY

Overview

All cancers combined account for about 23% of deaths in the United States, placing cancer second only to heart disease as a cause of death. Cancer has also become the second leading cause of death worldwide after heart diseases, owing to increasing longevity, the global dispersion of tobacco use, and Western patterns of diet, physical inactivity, and reproduction. At current rates, nearly one in two men and more than one in three women in the United States will be diagnosed with cancer at some point in life. The National Institutes of Health estimates that the overall costs of cancer in 2008 equaled $228.1 billion.

Research has identified the causes of many types of cancer as well as basic mechanisms that drive carcinogenesis. Various control measures have reduced exposure to tobacco (Chapter 31) and occupational carcinogens (Chapter 18) in most industrialized countries. These advances in prevention, together with progress in early detection and treatment, have achieved a nearly 16% reduction in the death rate from all cancers combined in the United States from 1991 to 2006, and a 6% reduction in the incidence rate from 1999 to 2006.

Measures of Occurrence and Survival

Incidence and Death Rates

Cancer *incidence* and *death rates* are usually expressed per 100,000 people per year and are age-standardized to allow valid comparisons across populations of different sizes and age structures. Age-standardized rates must be standardized to the same age distribution in order for different time periods and geographic areas to be comparable. Conventionally, rates within the United States are standardized to the age distribution of the U.S. population (currently the year 2000 age standard), whereas international comparisons are based on the world population standard in 1960. Data on cancer incidence rates in the United States are collected by population-based tumor registries that now encompass 92% of the population. Temporal trends in cancer incidence have been monitored since 1973 in 10% of the population by the National Cancer Institute (NCI) Surveillance, Epidemiology, and End Results (SEER) program. Deaths from cancer have been tabulated nationally in U.S. vital statistics since 1930. Mortality rates are based on the underlying cause of death as coded from death certificates using systematic nosologic rules. Validation studies have documented that, despite the well-known limitations of death certificates, there is greater than 90% agreement between the clinical diagnosis and the underlying cause of death coded systematically from death certificates for the 17 cancer sites that represent more than two thirds of cancers in the United States.

Relative Survival

Survival in patients with cancer is usually expressed as *relative survival,* which compares the percentage of cancer patients alive after a designated period (often 5 years) with the corresponding percentage in a population without cancer but of similar age, race, and sex. A *relative survival* of 100% signifies that cancer patients have the same survival as people of the same age without cancer. *Relative survival* is different from *absolute survival* in that the latter reflects death from any condition, whether or not it relates to cancer. Trends in *relative survival* have been monitored by the NCI SEER program since 1975. Relative survival has improved substantially for many types of cancer (Table 183-1). Caution is advised, however, in interpreting trends in relative survival for cancer sites detected by screening because of the potential for lead-time bias (see Screening).

Cumulative Incidence

The terms *cumulative incidence* and *cumulative risk* describe the average probability of developing or dying from a specified condition (in this case all cancers or specific cancer sites) over a defined period. Annual incidence and death rates per 100,000 people per year (or alternatively per 1 million

TABLE 183-1 RELATIVE 5-YEAR SURVIVAL RATES* (%) FOR SELECTED CANCER SITES DURING THREE TIME PERIODS, UNITED STATES, SEER

people per year for childhood cancers) correspond to 1-year cumulative risks. The cumulative risk of developing or dying from cancer increases with age. Lifetime cumulative incidence is strongly influenced by life expectancy; improvements in longevity increase the cumulative risk of developing cancer, even if the annual incidence and death rates at every age remain the same.

Geographic Variation

Cancer occurs in all countries of the world, although the predominant types of cancer vary widely (E-Table 183-1). In general, cancers caused by chronic infections (e.g., stomach, liver, cervix) predominate in economically developing countries, whereas those related to Western patterns of tobacco use and diet (lung, breast, prostate, and colon) are most common in high-resource countries. Some of the geographic variation reflects differences in diagnostic capabilities and data quality, yet much of the difference is real, reflecting geographic variation in causal factors. The regional cancer registries that provide these data are maintained by the International Agency for Research on Cancer (IARC), which makes special efforts to improve the completeness of registration. The international variation in cancer occurrence has historically provided important evidence that much of the disease burden from cancer is caused by exposures rather than inherited genetic susceptibility and could, in principle, be prevented.

Lung cancer (Chapter 197) is the most common cancer worldwide in terms of both new cases and deaths. The incidence rate varies from more than 70 per 100,000 among men in Eastern Europe to less than 5 per 100,000 among men in West Africa. The geography of lung cancer principally reflects the progression of populations through the stages of the tobacco epidemic. Within a country, the uptake of smoking manufactured cigarettes typically begins among middle-aged men and then spreads progressively to younger men and women. The resulting increase in lung cancer begins 25 to 30 years later and continues until publicity about the adverse effects of smoking and tobacco control measures cause a downturn in smoking, which is later followed by a downturn in lung cancer.

Breast cancer (Chapter 204) is the most common incident cancer in women worldwide. Incidence rates have increased, even in developing countries, but continue to be about five times higher in North America, Europe, and other Western industrial countries than among women in rural Asia. Increased longevity and the widespread use of screening contribute to the high lifetime risk (12.7%) of breast cancer among women in the United States, as does the prevalence of risk factors such as delayed childrearing, excess body weight, physical inactivity, and hormone use.

Prostate cancer (Chapter 207) is the second most commonly diagnosed cancer in men globally, with nearly three fourths of all cases diagnosed in economically developed countries. Incidence rates are especially high in the United States because of widespread screening with prostate-specific antigen (PSA), which finds tumors that might otherwise be missed. In contrast, the much higher incidence and death rates among men of African descent in Africa, the Caribbean, and the United States represents a true disparity that is currently unexplained.

Cancers of the colon and rectum (Chapter 199) are more common in economically developed than in developing countries. The incidence rate in the United States is 20 to 30 times higher than in rural India and Southeast Asia. Risk factors thought to contribute to the geographic variation include obesity, physical inactivity, high consumption of red and processed meat, cigarette smoking, and heavy alcohol consumption.

The geographic distribution of several cancers caused by infectious agents or behavioral practices closely parallels the prevalence of the causal agent. For example, the high incidence of liver cancer (Chapter 202) in parts of Asia and sub-Saharan Africa matches the geographic patterns of *hepatitis B virus* (HBV) infection in childhood, just as mortality from stomach (Chapter 198) and cervical (Chapter 205) cancer correlates closely with the prevalence of infection with pathogenic strains of *Helicobacter pylori* and *human papillomavirus* (HPV), respectively. The exceptionally high incidence of oropharyngeal (Chapter 196) cancer throughout much of the Indian subcontinent and Southeast Asia is caused by the practice of chewing betel quid and areca nut, often mixed with tobacco. In contrast, it is not fully understood why squamous cell carcinoma of the esophagus (Chapter 198) was extraordinarily common until the late 20th century in countries surrounding the Caspian Sea. This was attributed to a combination of severe nutritional deficiency corresponding to a seasonal lack of vegetables and the practice of swallowing the charred residue from opium pipes. The incidence of this cancer has decreased rapidly over the past 20 years following improvement of the food supply. Other incompletely understood geographic variations involve why ovarian cancer (Chapter 205) is more common in certain European countries than in others, or how dietary consumption of salted fish may interact with Epstein-Barr virus (EBV) infections and genetic susceptibility to cause nasopharyngeal cancer (Chapter 196) in southern China and in Eskimos in Alaska and Greenland.

Geographic and demographic variations in cancer risk are seen for all cancers combined as well as for individual sites. An extreme example is that the cumulative incidence of being diagnosed with any type of cancer is almost ten times higher among African American men than men of similar age in parts of India. These large variations in overall cancer risk indicate that geographic variability does not simply reflect substitution of one form of cancer for another, but affects disease occurrence overall.

Temporal Variation

Temporal variations in the incidence or death rates from certain cancers further illustrate the importance of potentially modifiable "environmental" factors on the burden of disease. For example, the large changes in mortality from stomach and lung cancer among men and women in the United States (Fig. 183-1A and B) reflect changes in external exposure rather than inherited genetic susceptibility. Cancer of the stomach was one of the most common fatal cancers in the United States in 1930, as was cancer of the uterus (principally uterine cervix) in women. Mortality from these cancers has decreased dramatically over the past 75 years. The global decrease in stomach cancer (Chapter 198) probably reflects an unintended benefit of changes in food preservation and reduced prevalence of *H. pylori* infection. The advent of refrigeration increased the availability of fresh vegetables and fruit and decreased reliance on salted, smoked, and pickled foods, whereas improvements in sanitation and housing and widespread antibiotic use decreased the prevalence of chronic infection with *H. pylori.* Progress in reducing the incidence and death rate from cervical cancer (Chapter 205) is largely attributable to the introduction of Papanicolaou testing and early removal of premalignant and cancerous lesions. The close relationship between global trends in lung cancer (Chapter 197) and cigarette smoking was discussed previously.

Screening

Trends in cancer incidence rates are more difficult to interpret than trends in mortality, especially for sites that are detectable by screening. The introduction of a new screening test can create the appearance of a sudden increase in cancer incidence, especially when the test detects prevalent but undiagnosed tumors that would otherwise be missed. For example, a sudden increase in the incidence rate of prostate cancer (Chapter 207) in the United States in the late 1980s (Fig. 183-2A) coincided with the introduction of PSA screening. The upward trend reversed after 1992 because of saturation of

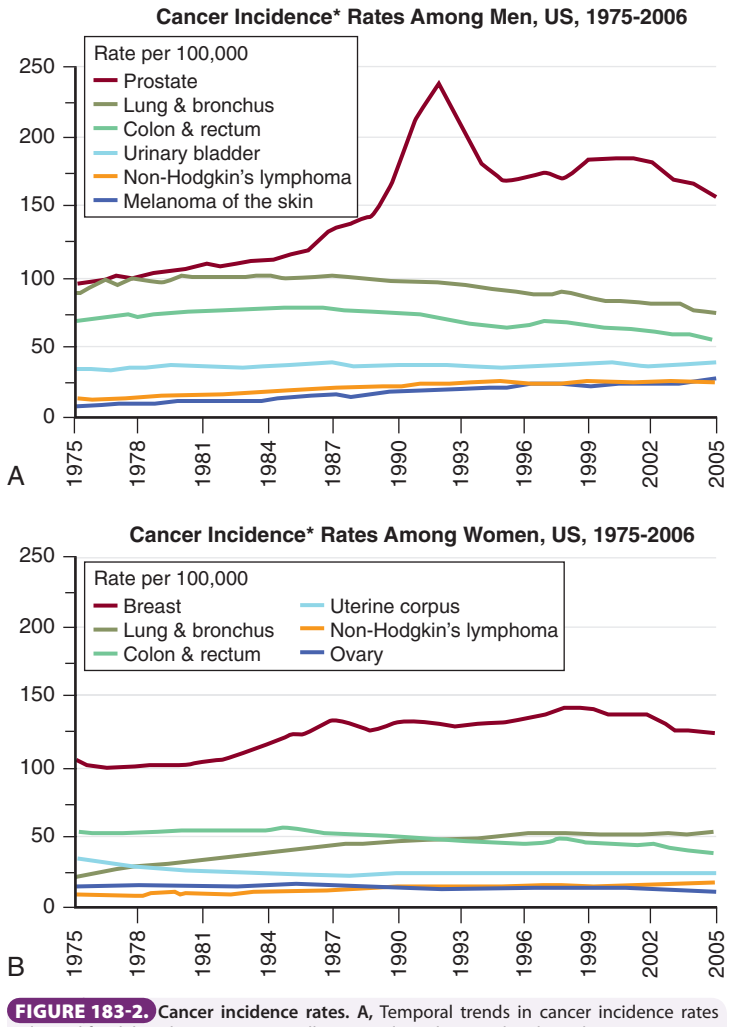

FIGURE 183-2. Cancer incidence rates. A, Temporal trends in cancer incidence rates adjusted for delayed reporting, Surveillance, Epidemiology, and End Results (SEER), 1975 to 2006, men. **B,** Temporal trends in cancer incidence rates adjusted for delayed reporting, SEER, 1975 to 2006, women. *Age-adjusted to the 2000 U.S. standard population and adjusted for delays in reporting. (Data from Surveillance, Epidemiology, and End Results Program, Delay-Adjusted Incidence Database: SEER Incidence Delay-Adjusted Rates, 9 Registries, 1975-2005, National Cancer Institute, 2008.)

screening among older men. The upward trend in reported incidence has since returned to the more gradual increase that prevailed before the introduction of PSA testing. Likewise, the introduction of mammography screening during the 1980s contributed to the increase in breast cancer incidence among women (see Fig. 183-2B), although the impact was considerably smaller than that of PSA screening on prostate cancer incidence (see Fig. 183-2A). The introduction of mammography had a much larger impact on the detection of ductal carcinoma in situ (DCIS), which is not included in the incidence rates, than invasive breast cancer.

The introduction of new screening tests also complicates the interpretation of temporal trends in *relative survival* among patients with cancer (see Table 183-1). Screening tests detect cancer earlier, before the tumor would otherwise have been diagnosed, thus creating an apparent lengthening of survival that exaggerates actual progress. This so-called lead-time bias can be difficult to separate completely from improvements in relative survival for sites that are commonly diagnosed by screening, such as breast and prostate cancer, even in analyses that stratify for stage at diagnosis. New screening tests can also alter the mix of cancers being diagnosed by increasing the detection of indolent tumors that may not be life-threatening. Advances in the molecular characterization of tumors may ultimately resolve this problem by providing more homogeneous groupings of tumors in which to measure relative survival.

Demographic Factors

Age

The incidence of most cancers increases exponentially with age from 10 to 84 years (Fig. 183-3). Age is a stronger predictor of cancer risk than any other factor. About three fourths (77%) of all cancers occur in the approximately 19% of the U.S. population 55 years or older. This age-related increase reflects the multistage nature of carcinogenesis and the time required for a single cell line to accumulate all the mutations and epigenetic events needed for malignant transformation (Chapter 185). The apparent decrease in the incidence of cancer after 85 years of age reflects incomplete diagnosis of cancer in elderly people as well as the fact that generations born before 1920 preceded the peak of cigarette smoking.

Age affects the types of cancer that occur as well as their frequency. In the United States, the five most common fatal cancers before age 20 are acute lymphocytic leukemia, cancer of the brain and other nervous system, bones and joints, endocrine system, and soft tissues. In women aged 20 to 59 years, breast cancer is the most common fatal cancer. At age 60 and older, the four most common cancers are lung and bronchus (Chapters 197), breast (Chapter 204), prostate (Chapter 207), and colon and rectum cancer (Chapter 199).

Sex

For most cancers that affect both sexes, the incidence rate is higher in men than women, the exceptions being cancers of the breast, thyroid, gallbladder, and anus. The incidence rate from all cancers combined is higher in men than women except in the age range of 30 to 54 years, when, because of breast cancer, women have higher incidence rates (see Fig. 183-3). The male excess for cancers of the oropharynx, esophagus, larynx, lung, pancreas, and kidney can be attributed to higher tobacco or alcohol use, or both. For other sites, such as brain, hematopoietic, and childhood cancers, however, the reasons for higher risk in men are unclear.

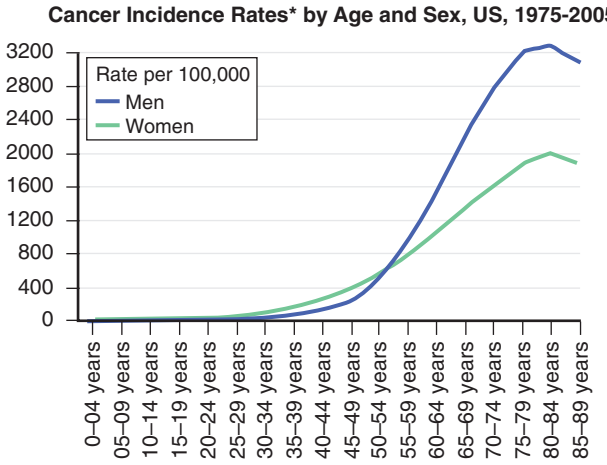

FIGURE 183-3. Age- and sex-specific incidence rates for all cancer combined in the nine Surveillance, Epidemiology and End Results (SEER) areas. *Age-adjusted to the 2000 U.S. standard population. (Data from U.S. Mortality Data, National Center for Health Statistics.)

Socioeconomic Status, Race, and Ethnicity

African Americans experience disproportionately high incidence and death rates from most cancers. Racial disparities in death rates are largest for cancers of the prostate, stomach, larynx (men), myeloma, and uterine cervix. Relatively few studies have attempted to separate the impact of biologic differences associated with race from factors related to poverty and its effects on education, risk factors, and access to high-quality care for prevention, early detection, and treatment. Accumulating data suggest that socioeconomic factors account for most of these disparities (Chapter 5). For example, black women have the highest death rate from breast cancer among all racial or ethnic groups in the United States. Although the incidence rate is higher in white than in black women, this paradox likely results from underdiagnosis of breast cancer in black women. Survival among women with breast cancer is lower in black than in white women in the general population, but it is similar in military hospitals where both races have equal access to care. Relative survival is lower in African Americans than in whites for many other cancers, including prostate, uterine cervix and corpus, colon, and rectum cancer.

Other ethnic groups in the United States also have distinctive cancer patterns. Relative to whites, age-adjusted incidence and mortality rates among Hispanics are higher for gallbladder, stomach, and cervical cancer; those among American Indians are higher for cancer of the gallbladder, stomach, and cervix; rates in Japanese Americans are higher for stomach and liver cancer; those in Chinese Americans are higher for nasopharynx, liver, and stomach cancer; Native Hawaiians have higher death rates from breast, esophagus, liver, pancreas, lung, and cervical cancer; and Filipino Americans have a lower risk of most cancers except for cancers of the stomach, liver, oral cavity, and esophagus. Many of these ethnic differences are known to reflect differences in the use of tobacco, dietary habits, infectious exposure, or medical care. Research is needed to identify practical interventions to reduce these disparities.

Causes of Cancer

Whereas infectious diseases are defined by exposure to a specific microorganism, chronic diseases such as cancer may have multiple causes, none of which need be necessary or sufficient for the disease to occur (Table 183-2). For instance, tobacco smoking is the major cause of lung cancer, but it is neither necessary nor sufficient for the disease to occur. Approximately 10 to 15% of lung cancers occur in people who have never smoked actively, and in only about 20% of long-term cigarette smokers does lung cancer develop.

Tobacco

Exposure to tobacco (Chapter 31) is the single largest cause of cancer in the United States. Tobacco smoke contains more than 4000 chemicals, at least 40 of which are known to be carcinogenic in humans or animals, or both. All forms of tobacco can cause cancer. Cigarette smoking causes cancer of the lip, oral cavity, nasal cavity, paranasal sinuses, pharynx (nasal, oral, and hypopharynx), larynx, lung, esophagus (squamous cell and adenocarcinoma), stomach, colorectum, pancreas, liver, kidney (adenocarcinoma and renal pelvis), urinary bladder, uterine cervix, and myeloid leukemia. Secondhand smoke, or environmental tobacco smoke, contains a similar mix of carcinogens as active smoking at varying concentrations. Each year in the United States, secondhand smoke causes an estimated 3000 deaths from lung cancer and 30,000 to 40,000 deaths from heart disease.

Diet, Obesity, Physical Inactivity

Other important modifiable determinants of cancer risk are dietary patterns, physical inactivity, and obesity. Approximately one third of cancer deaths in the United States are attributed to nutritional factors. Obesity, physical inactivity, and an excess of caloric intake over energy expenditure are known to increase the risk for several types of cancer. Obesity (Chapter 227) is causally related to cancer of the endometrium, kidney, breast (in postmenopausal but not premenopausal women), esophagus, colon (especially in men), and gallbladder (particularly in women). More limited evidence suggests that obesity may also increase the risk for cancer of the liver, pancreas, and stomach as well as some hematopoietic cancers. Excessive alcohol consumption (Chapter 32) is an established cause of cancer of the oropharynx, larynx, esophagus, and liver; even moderate drinking increases the risk for breast cancer. The importance of other specific components of diet to the risk for cancer in Western populations is more controversial. The strongest evidence pertains to increased risk for colon cancer in people who have inadequate intake of folic acid or excessive consumption of red or processed meat.

Infectious Agents

It is estimated that about 17% of cancer cases worldwide are attributable to infectious agents. This percentage is higher in economically developing (26%) than in developed (7.2%) countries. Viruses known to cause cancer in humans include *HPV* (Chapter 381), *hepatitis B virus (HBV)* (Chapter 151), *hepatitis C virus* (HCV) (Chapter 151), *EBV* (Chapter 385), *human immunodeficiency virus (HIV)* (Chapter 400), and *human herpesvirus-8* (Chapter 382). Viruses increase the risk for cancer through a variety of mechanisms, including direct effects on DNA, promotion of tumor development by means of chronic inflammation *(HPV, HBV, HCV),* or suppression of specific elements of the immune system (e.g., *HIV*) (Chapter 185).

H. pylori, which is the only bacterial infection known to cause cancer, is a gram-negative, spiral bacteria that colonizes the mucous layer of the stomach. Chronic inflammation caused by strains of *H. pylori* that express the CagA (a 128-kD cytotoxin-associated gene–A positive) protein promotes the development of gastric ulcers, gastric carcinoma, and mucosa-associated lymphoid tissue (MALT) lymphoma of the stomach (Chapter 198). Parasitic infections known to increase the risk for cancer include *Schistosoma haematobium* (Chapter 363) (bladder cancer) and liver flukes such as *Clonorchis sinensis* (Chapter 364) and *Opisthorchis viverrini* (Chapter 364) (biliary tract cancer, Chapter 202).

Ionizing Radiation

Ionizing radiation (Chapter 19) from x-rays, gamma radiation, and other sources is one of the most extensively studied human carcinogens. Leukemia and cancer of the thyroid and female breast are most strongly associated with radiation, although cancer of the lung, esophagus, stomach, colon, brain, and bladder and myeloma are also causally related. The risk for development of cancer from ionizing radiation depends not only on cumulative exposure but also on the intensity, rate, and nature of the exposure as well as on the age at which it occurs. Childhood exposure from medical treatments or fallout from atomic bombs or nuclear accidents principally increases the risk for leukemia and thyroid cancer. Girls exposed to radiation during adolescence and young adulthood are more susceptible to breast cancer from this exposure than are women exposed later in life. Radioactive isotopes such as iodine-131, radium-224, -226, and -236, and phosphorus-32 concentrate in the thyroid, bone, and bone marrow, respectively, and deliver high localized doses to radiosensitive tissues. Radon-222, a naturally occurring radioactive decay product of uranium-238, was first discovered to cause lung cancer in occupational studies of highly exposed uranium miners. Radon gas is also a common contaminant of household basements and unventilated underground spaces, albeit at much lower concentrations. Exposure to ultraviolet radiation from sunlight and tanning booths is the principal cause of melanoma as well as squamous and basal cell skin cancer. Nonionizing radiation, such as the electromagnetic frequency emissions from cell phones, has not been thought to cause cancer because the energy that is imparted to tissues is too weak to

TABLE 183-2 SELECTED KNOWN CAUSES OF CANCER AND THE ASSOCIATED CANCER SITES*

TOBACCO	
Active and passive smoking	Multiple sites: see text
Spit tobacco (snuff, chewing)	Oral cavity, pancreas
NUTRITION, OBESITY, PHYSICAL INACTIVITY, AND FOOD CONTAMINANTS

†Classified as carcinogenic by the IARC but not by the NTP.

damage DNA. Because of the widespread use of cell phones, however, this remains an active area of research.

Iatrogenic Exposures

Many medical diagnostic and therapeutic interventions have been found to increase the risk for cancer, either directly as chemical or physical carcinogens or indirectly through suppression of immune responses. Alkylating drugs and other cytotoxic agents used to treat cancer increase the risk for development of a secondary malignancy, as does radiation therapy. Hormone replacement therapy increases the risk for breast cancer in postmenopausal women. Tamoxifen increases the risk for endometrial cancer, even though this risk is outweighed by the reduction in breast cancer in high-risk women. The

practice of treating pregnant women with diethylstilbestrol was discontinued because of the increased incidence of clear cell vaginal cancer in the daughters of these women during adolescence. Immunosuppressive drugs used to prevent graft rejection in organ transplantation and other autoimmune conditions increase the risk for certain lymphomas (non-Hodgkin B-cell lymphomas), Kaposi sarcoma, malignant melanoma, and liver cancer. Repeated use of diagnostic procedures such as whole body computed tomography results in substantial radiation exposure, although the potential long-term consequences receive surprisingly little attention.

Occupational and Environmental Carcinogens

Occupationally exposed workers (Chapter 18) have unfortunately served as the sentinel for many of the recognized industrial carcinogens, especially in workplaces where prolonged, heavy exposure caused unusual clusters of rare cancers. For example, clusters of scrotal cancer in London chimney sweeps, osteosarcoma of the jaw in watch dial painters exposed to radium, mesothelioma in asbestos workers, and angiosarcoma of the liver in chemical workers exposed to vinyl chloride monomer attest to the carcinogenicity of coal tar, radium, asbestos, and vinyl chloride monomer. In other instances, increases in the risk for common cancers have been sufficiently large to be detected in epidemiologic studies of several thousand workers. Examples include arsenic, asbestos, beryllium, bis(chloromethyl) ether, cadmium, chromium (hexavalent), coal tar, coke oven emissions, nickel, polycyclic aromatic hydrocarbons, and radon.

What Constitutes "Proof" of Causation?

There has been vigorous philosophic and scientific debate over what constitutes "proof" of causation in scientific studies of chronic (i.e., noninfectious) diseases. When policy decisions relate to exposures judged to be harmful, epidemiologic evidence alone is often considered sufficient to justify protective intervention. It is unethical to propose randomized clinical trials to confirm that smoking causes lung cancer, that ionizing radiation causes leukemia, or that HPV causes cervical cancer. Moreover, in these examples, the observational evidence is so strong that the epidemiologic evidence itself is virtually incontrovertible. In other instances, especially when the exposure of interest is difficult to measure and the observed association is weaker, judgments about causality must be based on the weight of the evidence with consideration of all potentially relevant information from observational, clinical, experimental, and basic studies.

The inference that an association is causal is supported when a number of the following apply:

1. The association is strong (higher relative risk being more likely to indicate cause).
2. The risk increases or decreases with exposure in a dose-response gradient.
3. Consistent findings are seen in multiple studies with different investigators, study populations, and designs.
4. The exposure or cause precedes disease onset.
5. It is biologically plausible that the exposure could cause the disease.
6. The association is specific between the exposure and a single disease.
7. The epidemiologic findings fit coherently with information from other types of research and other epidemiologic studies.

Reviews and listings of substances known or suspected to cause cancer in humans are maintained by the National Toxicology Program (NTP) and by the IARC, a branch of the World Health Organization (see Table 183-2). The IARC evaluations classify exposures into one of four categories: (1) "sufficient evidence" of carcinogenicity in humans (in the working group's opinion, chance, bias, and confounding can be excluded with reasonable confidence); (2) "limited evidence" of carcinogenicity (a causal relationship between the agent and risk of cancer in humans is plausible, but chance, bias, and confounding cannot be ruled out with reasonable confidence); (3) "inadequate evidence" of carcinogenicity (available studies are of insufficient quality, consistency, or statistical power to permit a conclusion regarding the carcinogenicity of the agent, or no data on carcinogenicity in humans are available); and (4) "evidence suggesting lack of carcinogenic activity" (several adequate studies of use or exposure are mutually consistent in not showing an increased risk for specified cancer sites, conditions, and levels of exposure). The NTP uses only two categories, "known to be a human carcinogen" and "reasonably anticipated to be a human carcinogen."

FUTURE DIRECTIONS

An exciting frontier in cancer epidemiology involves efforts to integrate insights from molecular biology and genetics into large-scale population studies to examine how the interaction of inherited genetic susceptibility (nature) with exposure after conception (nurture) influences an individual's risk for the development of cancer. In some cases, information on inherited genetic polymorphisms is now being used clinically to tailor the selection and dose of certain drugs used for chemotherapy or treatment of other conditions. Until now it has been difficult to identify well-established examples of gene-environment interactions that affect cancer risk, mostly because the technology for rapidly genotyping tens of thousands of people has only recently become available and affordable. Advances in proteomics, metabolomics, and epigenetics may soon make it possible to identify early markers and intermediate factors that affect tumor development. These may provide therapeutic targets by which to influence the development or progression of cancer, just as cardiovascular research has identified lipid abnormalities and hypertension as modifiable intermediates of heart disease.

184 CANCER GENETICS

HENRY T. LYNCH AND C. RICHARD BOLAND

CANCER IS A GENETIC DISEASE

Cancer is caused by alterations in genes. Many genes are involved in the process, and there is a broad range of mechanisms by which the genes may be altered. The genetic alterations are tumor specific, but there are common features to the genes that cause cancer. Also, one must individually consider the differences between somatic mutations (found in the cancers, but not present throughout the rest of the body) and germline mutations (inherited, and present in every cell of the body).

Oncogenes are normal cellular genes that participate in the stimulation of growth pathways and become abnormally activated in cancer. There are several ways for activation to occur. Point mutations may make the protein product unresponsive to downregulating signals, as in the case of mutant *KRAS*. The transcription factor *MYC* is often activated by copy number amplification, or it may be put under the control of an inappropriate promoter, achieving the same result. In the case of the *BCR-ABL* mutation, which is ubiquitous in certain leukemias, a chromosomal translocation relocates a promoter that is active in myeloid cells to a position that drives the unregulated production of a proliferation-promoting tyrosine kinase.

Tumor suppressor genes normally suppress cellular growth or mediate cellular differentiation, and these are inactivated in cancers. Because humans are born with two copies of almost every gene (the X and Y chromosomes in males are the exceptions), it takes two lesions or "hits" to release the cell from the regulatory effects of these genes. Tumor suppressor genes provide the conceptual basis for many of the hereditary forms of predisposition to cancer. The affected person is born with a "germline" mutation in one allele, which is present in every cell of the body. The cancer occurs in a specific cell lineage after the other allele suffers an inactivating "somatic" mutation, which is the second hit. Examples of tumor suppressor genes include the *Rb* gene, *p53*, and *p16*, which are inactivated in some cancers.

DNA repair genes are important in cancer. There are multiple types of DNA repair, each specific to one or more types of DNA damage. When these genes are inactivated, a hypermutability ensues within that cell, and this leads to numerous somatic mutations in the target genes, which will include oncogenes or tumor suppressors, and then leads to cancer. Defective DNA repair states also provide an additional explanation for certain inherited diseases. DNA repair systems inactivated in cancer include the DNA mismatch repair (MMR) system (which is involved in Lynch syndrome [LS]), the base excision repair system (which leads to an autosomal recessive form of familial polyposis called *MYH*-associated polyposis), and nucleotide excision repair (which leads to the autosomal recessive disease xeroderma pigmentosa).

HOW DO CANCERS DEVELOP?

Multistep Carcinogenesis

Cancers develop through the sequential accumulation of multiple mutations that synergize to overcome the multiple control mechanisms regulating the growth of a cell. There are rare instances in which a single mutation is thought to mediate the transition into neoplastic growth. The *BRC-ABL* translocation provides proof of this concept because inhibition of the activated kinase with imatinib can completely inhibit the growth of neoplastic cells. Most tumors do not respond to a single drug, but have multiple genetic lesions, necessitating more complex therapeutic strategies.

Some solid tumors can be characterized based on the mutational pattern, providing some insight into the provenance of the cancer. For example, most colorectal cancers (CRCs) are aneuploid and have large numbers of chromosomal duplications, deletions, and rearrangements. These tumors have a relatively small number of somatic mutations (perhaps one per 10^6 base pairs). Other CRCs tend to be diploid (or near-diploid), but have a very large number of point mutations because of loss of the DNA MMR system; these tumors have microsatellite instability (MSI) and a different natural history and response to chemotherapy. A third group of CRCs have a disorder in which multiple genes are silenced by "epigenetic" promoter hypermethylation. These tumors have the "CpG island methylator phenotype," or CIMP, and have other unique clinical features, including occurrence at a later age and 90% occurrence in the proximal colon.

The genetic abnormalities in tumors are highly heterogeneous, and no two tumors are exactly alike, raising serious therapeutic challenges. However, different tumors in a specific organ may lose the same genes (or genes in serial signaling pathway), albeit by different mechanisms. Thus, one tumor may lose or gain genes by chromosomal deletion or duplication, whereas others may lose genes by point mutation and still others by epigenetic silencing, and there may be combinations of these types of alterations within individual tumor specimens.

HEREDITARY CANCER SYNDROMES

The tumor suppressor gene concept provides an explanation for how a person could be born with a predisposition to cancer, which occurs when one allele of a gene is mutated in every cell, greatly increasing the likelihood that some cell would eventually lose both copies of the gene—a situation that would be statistically unlikely without the germline mutation. In fact, germline mutations in the previously mentioned tumor suppressors *Rb*, *p53,* and *p16* give rise to familial retinoblastoma, Li-Fraumeni syndrome, and the familial atypical multiple mole melanoma–pancreatic cancer (FAMMM-PC) syndromes, respectively.

Germline mutations in the DNA repair genes create more complex clinical scenarios. In case of hereditary nonpolyposis colon cancer, also known as LS, the most common hereditary CRC syndrome, accounting for approximately 3% of CRC incidence, a germline mutation occurs in one allele of a DNA MMR gene (including *MSH2*, *MLH1*, *MSH6,* or *PMS2*), and the loss of the other allele creates a cell without any DNA MMR activity. The affected cell becomes hypermutable, and mutations accumulate in growth-regulating target genes; this causes the cancer. (There are rare instances in which biallelic mutations in DNA MMR genes create constitutional MMR deficiency and a pediatric cancer diathesis.) More recently, it has been discovered that a deletion in the *EPCAM* gene (previously called *TACSTD1*, upstream of *MSH2*, can silence *MSH2*, thereby causing LS without a mutation in the *MSH2* gene itself. Thus, LS is inherited in a classic dominant mendelian fashion, but the cancers occur only after the second hit occurs, meaning that the disease is recessive at the tissue level. Constitutional deficiency of base excision repair occurs when there are biallelic mutations in the *MUTHY* genes (called *MUTHY*-associated polyposis); these patients develop multiple colorectal adenomas and are highly prone to CRC. Similarly, constitutional deficiency of nucleotide excision repair causes xeroderma pigmentosa (Chapter 444), in which patients are unable to tolerate even minimal degrees of sunlight, because the enzyme complex required to repair ultraviolet light–induced DNA changes is defective. These two conditions are classic recessive diseases, and the monoallelic carrier state does not lead to a clinically substantial increase in risk for cancer.

DIAGNOSIS OF FAMILIAL CANCER SYNDROMES

The primary care physician is often the first to apply cancer genetics to clinical care when there is the suspicion of a familial cancer-prone syndrome. It would not be possible to predict which mutations cause what familial cancers based on knowledge of the gene function. The diagnoses depend on pattern recognition and linkage to the known mutations. The recognition of a familial pattern of disease may result in further investigation of potentially affected patients and families. The goal will be effective screening and management recommendations. Examples of the most common familial cancer syndromes include the following:

- Breast and ovarian cancers with *BRCA1/BRCA2* mutations (the hereditary breast and ovarian cancer, or HBOC, syndrome)
- CRC, endometrial, ovarian, stomach, pancreas, and other cancer types with DNA MMR mutations in LS
- Sarcomas, breast cancers, brain tumors, leukemia, lymphoma, and adrenal cortical cancers with *p53* mutations in the Li-Fraumeni syndrome
- Medullary thyroid carcinoma and pheochromocytoma with the *RET* proto-oncogene mutation in the multiple endocrine neoplasia syndromes MEN 2a and 2b
- Malignant melanoma and pancreatic cancer with *CDKN2A* (*p16*) mutation in familial multiple mole melanoma syndrome
- Diffuse gastric cancer and lobular breast cancer with *CDH1* mutation in the hereditary diffuse gastric cancer (HDGC) syndrome
- Multiple adenomatous colonic polyps and CRC with mutations of the *APC* gene in familial adenomatous polyposis (FAP), or biallelic mutations in the *MUTHY* gene in *MUTHY*-associated polyposis

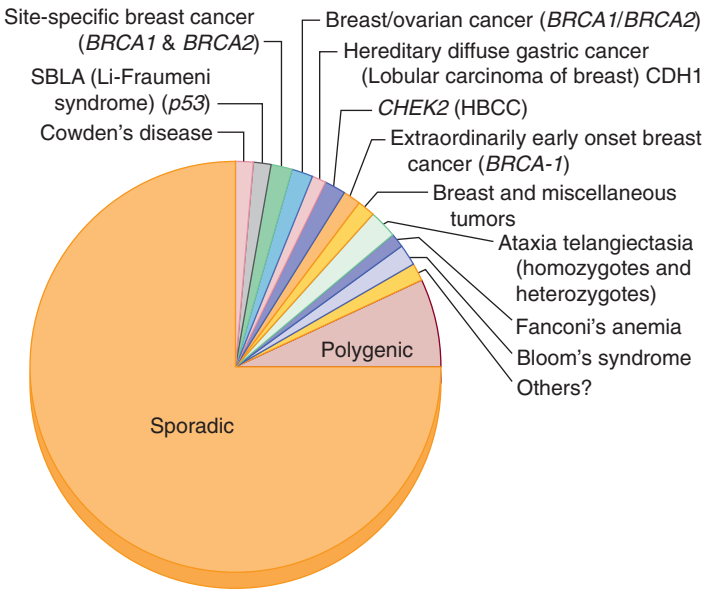

FIGURE 184-1. Schematic depicting heterogeneity in breast cancer. HBCC = hereditary breast and colorectal cancer; SBLA = *S*arcoma, *B*reast and brain tumors, *L*eukemia, laryngeal and lung cancer, and *A*drenal cortical carcinoma. (From Lynch HT, Fitzgibbons, RJ Jr, Lynch JF. Heterogeneity and natural history of hereditary breast cancer. *Surg Clin North Am*. 1990;70:753.)

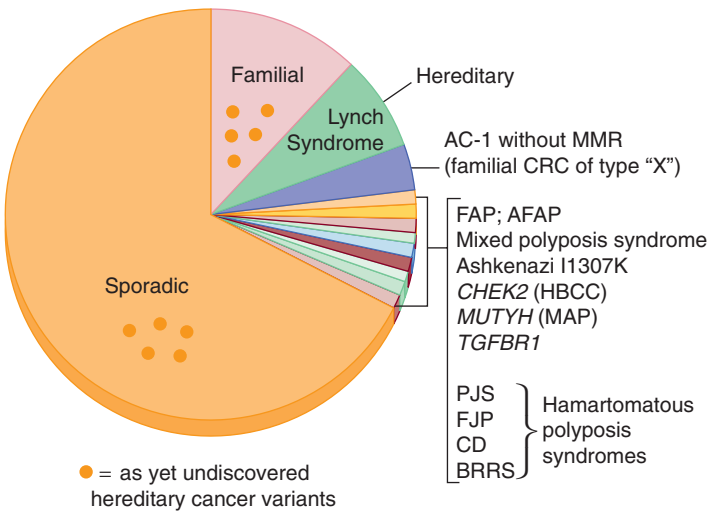

FIGURE 184-2. Circle graph depicting the marked genotypic and phenotypic heterogeneity in hereditary colorectal cancer syndromes. AC-1 = Amsterdam Criteria 1; AFAP = attenuated familial adenomatous polyposis; BRRS = Bannayan-Ruvalcaba-Riley syndrome; CD = Cowden's disease; FAP = familial adenomatous polyposis; FJP = familial juvenile polyposis; HBCC = hereditary breast and colorectal cancer; MAP = MUTYH-associated polyposis; MMR = mismatch repair; PJS = Peutz-Jeghers syndrome; TGFBR1 = transforming growth factor-β receptor type 1. (Revised from Lynch HT, Riley BD, Weissman SM, et al. Hereditary nonpolyposis colorectal carcinoma [HNPCC] and HNPCC-like families: problems in diagnosis, surveillance, and management. *Cancer*. 2004;100:53-64.)

The differential diagnosis is highly complex for common cancers, such as breast and CRC, as shown in Figures 184-1 and 184-2, respectively. Ideally, the family pedigree will cover a minimum of three generations. It must incorporate cancer of all anatomic sites with age of cancer onset and pathology documentation. Older individuals will often have passed through the cancer risk age and therefore will be more informative genetically. Pertinent noncancerous phenotypic features, such as perioral pigmentations in Peutz-Jeghers syndrome, multiple colonic adenomas in FAP, multiple atypical moles in the FAMMM syndrome, and the presence of sebaceous adenomas, sebaceous carcinomas, or multiple keratoacanthomas in the Muir-Torre syndrome variant of LS should also be included.

We are featuring LS as a hereditary cancer model owing to a major germline mutation in the MMR system. The following material is our attempt at a succinct summary of its cardinal features and emerging highly complex nosology.

Revised Classification of CRC

1. Sporadic microsatellite stable (MSS)
2. Sporadic with MSI
3. LS cancers with identified MMR mutations

- Autosomal dominant inheritance pattern seen for syndrome cancers in the family pedigree
- Earlier average age of CRC onset than in the general population
  - Average age of 45 years in LS versus 63 years in the general population
- Accelerated carcinogenesis (tiny adenomas can develop into carcinomas more quickly)
  - Within 2 to 3 years in LS versus 8 to 10 years in the general population
- Proximal (right-sided) colonic cancer predilection
  - About 70% of LS CRCs are proximal to the splenic flexure
- High risk of additional CRCs
  - About 25 to 30% of patients who have surgery for an LS-associated CRC will have a second primary CRC within 10 years if the surgery was less than a subtotal colectomy
- Increased risk for malignancy at certain extracolonic sites
  - Endometrium (40 to 60% lifetime risk for female mutation carriers)
  - Ovary (12 to 15% lifetime risk for female mutation carriers)
  - Stomach (higher risk in families indigenous to Asia, reason unknown at this time)
  - Small bowel
  - Hepatobiliary tract
  - Pancreas
  - Upper uroepithelial tract (transitional cell carcinoma of the ureter and renal pelvis)
  - Brain (in the Turcot's syndrome variant of the LS)
- Multiple sebaceous adenomas, sebaceous carcinomas, and keratoacanthomas in the Muir-Torre syndrome variant of LS
- Pathology of CRCs is more often poorly differentiated, with an excess of mucoid and signet cell features, a Crohn's disease–like reaction, and a significant excess of tumor-infiltrating lymphocytes within the tumor
- Increased survival from CRC
- The sine qua non for diagnosis is the identification of a germline mutation in an MMR gene (*MLH1*, *MSH2*, *MSH6*, or *PMS2*) that segregates in the family (i.e., members who carry the mutation show a much higher rate of syndrome-related cancers than those who do not carry the mutation)

4. Putative LS-like syndrome

- Deletion in *TACSTD1* gene silences MSH2
- Immunohistochemistry (IHC) shows absence of MSH2 protein, although no mutation identified in *MSH2* gene

5. MSS, Amsterdam-positive (MSS HNPCC or "type X")

- CRC predominantly left-sided
- Fewer CRCs and extracolonic cancers than in LS
- Later age of CRC onset than in LS, but higher than general population
- Molecular genetics (MSI, IHC, and MMR mutation) *absent*

Referral to a medical geneticist or a hereditary cancer center can be made at any time, depending on the physician's individual expertise as well as resources he or she has available. When referral is made, key medical, genetic, and genealogic findings must be made available to the center with the patient's written permission. In every potential hereditary cancer syndrome, it is essential to determine who needs to be tested. Unfortunately, even when a patient has a very strong family history of cancer and would be a candidate for DNA testing for a cancer-causing mutation, rates of referral for such testing are low. Many physicians are intimidated by the profusion of genes linked to cancer and the complexities involved in ordering and interpreting the tests. Therefore, many patients are not receiving critical information that is available at this time.

The ideal candidate for initial genetic testing will be an individual with an early-onset syndrome cancer who is in the direct line of hereditary descent, and will be the most likely candidate to carry the family's pathogenic mutation. If that mutation can be identified in a likely syndrome carrier, it is then possible for other at-risk members of the family to have "mutation-specific testing." Although the initial genetic diagnosis is limited by technical considerations, once the index mutation is identified in the proband, confirmatory testing is cheaper and is nearly 100% sensitive and specific when performed by the same reference laboratory.

USE OF GENETICS IN CANCER THERAPY

Genetic tests of somatic mutations can be used to assist in developing prognostic estimates and in predicting response to therapies, such as using trastuzumab in breast cancer patients who are *HER2* positive. It is known that the phenotype of breast cancer associated with a *BRCA1* mutation is different from that of sporadic breast cancer, whereas breast cancer associated with a *BRCA2* mutation is similar to sporadic tumors; it is not yet known, however, how these differences should affect treatment. Similarly, CRCs showing MSI do not respond favorably to adjuvant 5-fluorouracil therapy. Imatinib is effective in the treatment of some cancers, including chronic myelogenous leukemia and gastric stromal tumors, which share activating mutations in a tyrosine kinase. Finally, genetic profiling and studies looking for single nucleotide polymorphisms are being investigated as a way to identify incremental forms of cancer predisposition. Genome-wide association studies (Chapter 42) are providing a wealth of new information about risk and are likely to provide clues to developing personalized treatments of cancer.

BIOLOGY OF CANCER

JEFFREY A. MOSCOW AND KENNETH H. COWAN

GENETIC CANCER BIOLOGY

Cancer is an acquired genetic disease (Chapter 184). Spontaneous genetic changes overwhelm the mechanisms that maintain normal cellular homeostasis, disrupt the normal tight control of cell division and death, and result in the malignant phenotype.

The genetic damage that results in cancer can occur in several ways: translocations of genes can juxtapose two genes in ways that cause dysregulation of their function; mutations can activate cancer-causing genes or deactivate cancer-preventing genes; and epigenetic modifications of proteins that associate with DNA can alter the expression of critical genes (Chapter 184). Sometimes, the first step is the mutation of genes that normally prevent mutations in other genes—cells then quickly gain additional mutations that, through a morbid natural selection, ultimately produce the mutant clone that gives rise to a malignancy.

The very processes that generate malignant transformations also present obstacles to their treatment. The genetic plasticity that can manufacture cancer-causing mutations can also generate mutations that result in resistance to anticancer drugs.

Tumor formation after malignant transformation requires changes in cell biology that, in the processes of invasion and metastases, favor propagation of the malignant cells. Because individual cells, like organisms, are programmed to die, cancer cells must learn to evade the intricate systems of apoptosis that ensure cell death. Cancer cells must also enable the formation of new blood vessels to provide nutrition for the growing mass and develop strategies to escape the immune surveillance that suppresses tumor formation. These processes that give rise to malignant tumors can again raise barriers to successful therapies; for example, cells with impaired apoptosis may be resistant to anticancer drugs that kill cells through activation of apoptosis. However, the distinctive biology of malignancies can also provide opportunities for directed therapies.

Specific Mutations, Targeted Therapies

All cancer cells contain some genomic damage. In most cases, several abnormalities must occur, but sometimes even a single mutation appears sufficient to produce malignant transformation. The latter examples demonstrate clearly that cancer is a genetic disease of dysregulated growth, and they demonstrate that identification of a genetic cause can lead to a specific targeted therapy aimed at the product of the damaged gene.

In the case of acute promyelocytic leukemia (APL; Chapter 189), the characteristic t(15;17) translocation is the only identified genetic lesion. This genetic mishap splices the retinoic acid receptor *(RAR)* gene to another gene called *PML,* and the resulting hybrid RAR-PML protein does not function properly. The functional defect of the RAR-PML hybrid protein product can be overcome with pharmacologic doses of a vitamin A analogue, all-*trans*-retinoic acid (ATRA). The addition of ATRA to chemotherapy for APL doubles disease-free survival, from approximately 40% to approximately 80%. Similarly, the accidental genetic recombination that creates the BCR/ABL hybrid protein results in malignant transformation of myeloid cells (Chapter 190), and can be treated with specific inhibitors of the BCR/ABL kinase. Cancers driven by single mutations appear to be restricted to specific tissue types. Thus, genetic alterations that lead to malignant transformation are also dependent on the cellular context in which they occur.

Multistage Evolution of Malignancy

Most cancers do not have a single cause but rather are the products of a progression of genetic lesions that can be years in the making, as evidenced by their multiple and complex genetic alterations. The classical model of two stages of cancer development, initiation and promotion, has been replaced by a more dynamic and multistep model in which accumulated genetic damage leads to dysregulation of cell division and the disarming of the mechanisms of cell death.

Often the first step in the creation of a tumor is the development of genomic instability. During each cell division, some 3 billion nucleotide pairs must be faithfully copied to produce exact replicas in each daughter cell. The process of cancer can begin with alterations in any one of a number of factors that influence the accuracy of this process of genetic replication. Two major mechanisms create this acquired genetic damage: spontaneous mutations can disable the machinery that edits DNA replication and removes damaged genes, or, more frequently, cells are exposed to carcinogens that directly damage DNA, and the imprecise repair of damaged DNA results in an increase in spontaneous mutations.

Heritable conditions that impair the proteins that ensure genomic fidelity cause a predisposition to a variety of types of cancer. Examples of defects in genes that repair DNA damage, leading to increased hereditary cancer risk, are listed in Table 185-1.

Because cancer is a genetic disease, carcinogens are genomic toxins that damage DNA and create mutations. The DNA damage from cigarette smoke (Chapter 31) results from exposure to dangerous hydrocarbon products that bind DNA and disrupt faithful replication. Ultraviolet irradiation causes characteristic DNA damage in the skin that can lead to melanoma and other skin cancers (Chapter 210). Ionizing radiation (Chapter 19) from diagnostic and therapeutic radiation also cause genetic damage and cancer.

One key regulator of genomic integrity is the p53 protein, the product of a tumor suppressor gene that is commonly referred to as the "guardian of the

TABLE 185-1 GENOMIC INSTABILITY GENES ASSOCIATED WITH INCREASED HEREDITARY CANCER RISK

GENES	SYNDROME	HEREDITARY TUMOR TYPES
MUTYH	Attenuated polyposis	Colon
ATM	Ataxia-telangiectasia	Leukemias, lymphomas, brain
BLM	Bloom's	Leukemias, lymphomas, skin
BRCA1, BRCA2	Hereditary breast cancer	Breast, ovary
FANCA, FANCC, FANCD2, FANCE, FANCF, FANCG	Fanconi's anemia A, C, D2, E, F, and G	Leukemias
NBS1	Nijmegen breakage	Lymphomas, brain
MSH2, MLH1, MSH6, PMS2	Hereditary nonpolyposis colon cancer (Lynch syndrome)	Colon
XPA, XPC, ERCC2, ERCC3, ERCC4, ERCC5, DDB2	Xeroderma pigmentosum	Skin

TABLE 185-2 TUMOR SUPPRESSOR GENES ASSOCIATED WITH INCREASED HEREDITARY CANCER RISK

GENES	SYNDROME	HEREDITARY TUMOR TYPES
p53	Li-Fraumeni	Breast, sarcoma, adrenal, brain
APC	Familial adenomatous polyposis	Colon, thyroid, stomach, intestine
CDHI	Familial gastric carcinoma	Stomach
VHL	von Hippel-Lindau	Kidney
WT1	Familial Wilms' tumor	Wilms'
PTEN	Cowden's	Hamartoma, glioma, uterus
CDKN2A	Familial malignant melanoma	Melanoma, pancreas
CDK4	Familial malignant melanoma	Melanoma
RB1	Hereditary retinoblastoma	Eye
NF1	Neurofibromatosis	Neurofibroma, brain tumors
MEN1	Multiple endocrine neoplasia type 1	Parathyroid, pituitary, islet cell
NF2	Neurofibromatosis	Meningioma, acoustic neuromas

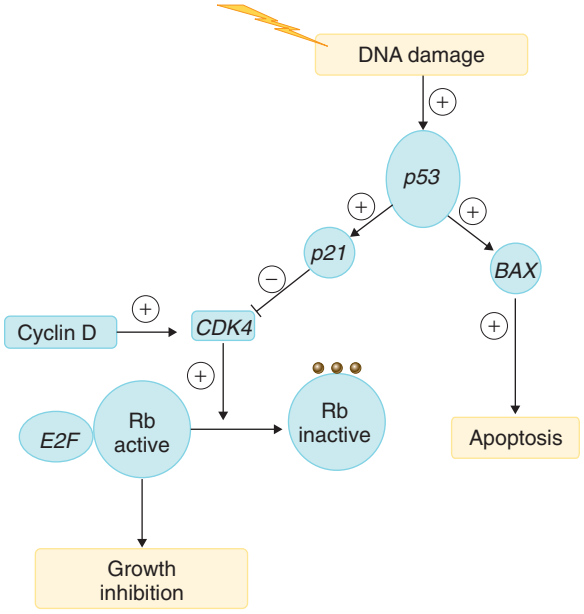

FIGURE 185-1. Response to p53 and DNA damage. After DNA damage, *p53* expression induces the cyclin kinase inhibitor p21, resulting in cell cycle arrest, and *BAX*, which induces apoptosis. Rb = retinoblastoma.

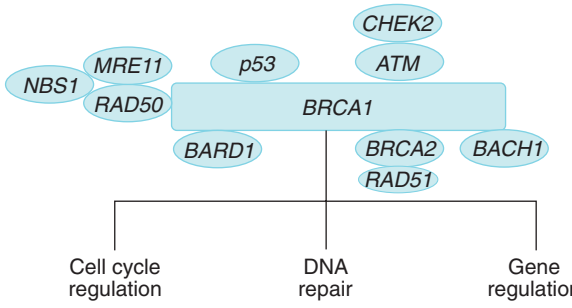

FIGURE 185-2. Protein interactions with *BRCA1* and *BRCA2*. *BRCA1* and *BRCA2* act as molecular scaffolds and promote assembly of protein complexes involved in cell cycle regulation in response to DNA damage as well as DNA repair. Signaling scaffolds, like *BRCA1*, bring together proteins belonging to interlinked pathways and orchestrate specific interactions among signaling proteins. Some of the more than 50 proteins that interact with *BRCA1* are shown.

genome." The p53 protein can sense DNA damage and direct the cell either to cell cycle arrest by increased expression of the cyclin kinase inhibitor p21 (Fig. 185-1), which provides the cell with the opportunity to repair genetic damage before cell division, or down the path of programmed cell death (apoptosis). Inactivating mutations in p53 are among the most common abnormalities observed in cancer, emphasizing the critical role of unrepaired genetic damage in the etiology of cancer. Individuals with inherited mutations of the *p53* gene have the Li-Fraumeni syndrome (Chapter 184), with increased susceptibility to specific types of cancer. The retinoblastoma *(RB)* gene is another tumor suppressor gene whose normal function is to regulate cell growth (see Fig. 185-1). Mutations in a number of other tumor suppressor genes are also associated with specific cancer syndromes (Table 185-2).

Similarly, the heritable breast cancer predisposition genes *BRCA1* and *BRCA2* encode proteins that associate with many intracellular proteins that are involved in DNA repair, including rad50, rad51, ATM, and p53 (Fig. 185-2). Cells defective in *BRCA1* or *BRCA2* display defects both in the response to DNA and in DNA repair. Mutations in the *BRCA1* and *BRCA2* (Chapter 204) are rare, so relatively few women inherit abnormal copies of these gene alleles from their parents, and only approximately 10% of breast cancers can be attributed to *BRCA1* and *BRCA2* mutations.

DNA damage, whether from heritable conditions, from somatic mutations in the DNA repair mechanisms themselves, or from carcinogen exposure, increases the rate of spontaneous mutations in cells and sets the stage for the natural selection of malignant clones. Although mutations of most of the approximately 25,000 genes in the genome do not result in malignancy, mutations or other disruptions of the right genes in the right cellular context can confer a selective proliferative or survival advantage, and set the stage for malignant progression.

Disease of the Messenger Proteins

In health, cells respond to external stimuli with complex and redundant protein networks that interact with external stimuli and transmit appropriate signals to the nucleus. The proteins involved in signal transduction include cell surface receptors, second messenger systems, and multiple transcription factors that directly regulate gene expression. Each of these elements of the signal transduction network is controlled by multiple proteins that tightly regulate the activation state of each element of the network. Disruption of any of the genes that encode the proteins involved in signal transduction—proteins that relay the external stimulus to the nucleus—occurs frequently in cancer.

Cell surface receptors for external stimuli involve families of receptor tyrosine kinases, proteins that become activated after binding to specific ligands. For example, the epidermal growth factor (ErbB) family receptor kinases are often amplified or found activated by mutations in breast, ovary, gastric, and lung cancers. Identification of such genetic abnormalities in cancer cells has

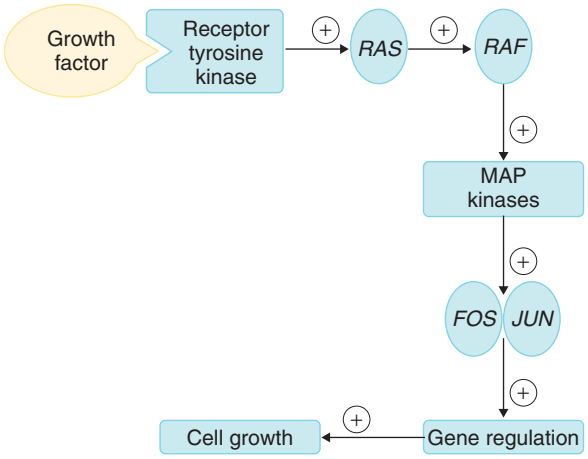

FIGURE 185-3. Growth factor–mediated signal transduction. Upon binding to specific receptor ligands, receptor tyrosine kinases activate downstream signal transduction cascades that result in changes in gene expression and enhanced cell growth. Alterations in various steps in the signal transduction cascade are frequently observed in cancer. MAP = mitogen-activated protein.

provided valuable targets for selective therapies. Thus, trastuzumab, a monoclonal antibody directed against the ErbB2/Her2neu protein, which is amplified and overexpressed in 25% of breast cancers, has been shown to improve disease-free survival and overall survival when given in combination with chemotherapy (Chapter 204). Erlotinib, an inhibitor of ErbB1 (epidermal growth factor [EGF]) receptor, may be effective in treatment of lung cancers that contain mutations in the ErbB1 (EGF) receptor (Chapter 197).

Unregulated growth can also result from mutations that affect downstream signal transduction networks (Fig. 185-3). Receptor tyrosine kinases transmit their signals through biochemical pathways and ultimately drive gene transcription. In some pathways, receptor tyrosine kinases activate Ras proteins, which act as second messengers that amplify and direct signals from receptor tyrosine kinases to other intracellular proteins, which then ultimately generate the cellular response to the stimulus. Ras mutations, which are frequently found in cancer, typically result in the Ras protein being stuck in the "on," or activated, position, which provides a constant, unregulated stimulus to downstream proteins, which in turn creates a cascading effect that stimulates cell growth. Although mutations in other genes are also commonly found in tumors that harbor Ras mutations, mutation of Ras alone has been shown to transform normal cells into malignant cells. Activating mutations of Ras family proteins can frequently be found in melanoma, myeloid leukemias, and cancers of the colon, pancreas, and lung. Genetic abnormalities are also frequently found in the other signaling pathways that transmit signals from receptor tyrosine kinases, including the PIP3/PDK1/Akt pathway, as well as in the nonreceptor tyrosine kinases signaling pathways, including the Jak/STAT and the c-Src pathways.

Disruption of the genes that encode the proteins that regulate gene transcription, which are the downstream targets of signal transduction cascades, can also create malignancy. For example, amplification of the Myc family of transcription factors is frequently observed in neuroblastoma and in cancers of the lung, bladder, breast, stomach, and colon. Certain acute leukemias (Chapter 189) arise when the normal gene recombination process that produces diverse immune responses goes awry and an immunoglobulin or T-cell receptor locus is accidentally spliced onto a gene encoding a transcription factor, resulting in loss of regulation of the transcription factor activity. Several pathognomonic oncogenic chromosomal translocations commonly found in sarcomas also involve genes for transcription factors; for example, the t(11;22) of Ewing's sarcoma (Chapter 209) creates the *EWSR1-FLI1* hybrid transcription factor, and the characteristic t(2;13) of alveolar rhabdomyosarcoma creates the hybrid *PAX3-FOXO1A* DNA binding protein.

Suppression of Tumor Suppressors

Normal cells contain proteins that prevent malignant transformation. Inactivation of the tumor suppressor genes that encode these proteins also leads to cancer. Because a loss of function is required for a malignant effect, both copies of the tumor suppressor gene must be affected. In almost all cases, patients have a physical loss of one copy of a gene and an acquired mutation of the other. The spontaneous deletion of genetic material, called loss of heterozygosity, is a frequently observed genetic abnormality in tumors.

Some familial cancer predisposition syndromes are based on the inheritance of one damaged copy of a tumor suppressor gene (Chapter 184). Hereditary retinoblastoma, which results from inheritance of a mutated *RB* gene, and the Li-Fraumeni syndrome (Chapter 184), which results from inheritance of a mutant *p53* gene, predispose affected individuals to cancers. Both the Rb and p53 proteins play critical roles in regulating the progression of proliferating cells through the cell cycle, and the loss of this checkpoint regulation can contribute to uncontrolled cell growth and cancer.

The importance of the p53 and Rb signaling pathways in tumor suppression is further revealed by the mechanism by which infection with the human papillomavirus (HPV; Chapter 381) in cervical epithelial cells leads to cervical cancer (Chapter 205). HPV proteins E6 and E7 inactivate p53 and Rb proteins, respectively, thereby creating a virally induced premalignant state in which the machinery that prevents damaged cells from proliferating has been turned off. For this reason, vaccination against certain HPV serotypes holds the promise of preventing most cases of cervical cancer.

DISTINCTIVE CANCER BIOLOGY

Cancer cells do not behave like normal cells. The alterations in the regulation of cell growth, differentiation, and death that give rise to cancer also produce common abnormal biologic characteristics, which are shared by tumors that arise from different cells of origin. These common features conspire to allow the transformed cell to grow into a tumor.

Telomerase

Normal cells are programmed to differentiate and ultimately to die, and this programming is regulated through enzymatic pathways that lead to terminal differentiation, senescence, or apoptosis. Cancer cells evade the mechanisms that are designed to steer cells toward terminal differentiation and senescence by altering the function of telomerase. As primitive cells divide and differentiate, the ends of chromosomes, called telomeres, progressively shorten and ultimately lead to a growth arrest that is termed replicative senescence. An enzyme called telomerase adds length back to the telomeres and reverses the process of replicative senescence. Telomerase is usually expressed at significant levels only in stem cells. However, telomerase is highly expressed in most malignant tissues, demonstrating a common alteration of cell biology that is necessary for creation and maintenance of the malignant phenotype.

Apoptosis

In addition to bypassing senescence, cancer cells disable the pathways that lead to apoptosis. Because apoptosis is literally a life-and-death decision for the cell, it must be tightly controlled by intricate pathways of regulatory proteins. Apoptosis can be triggered through either external or internal pathways that converge to activate a family of enzymes, called caspases, that systematically degrade cellular proteins and DNA in a characteristic pattern resulting in cell death. Cancer cells contain many common aberrations in the machinery that regulates apoptosis, including increased activity of antiapoptotic proteins, such as Bcl-2 and Mcl-1, or increased levels of inhibitors of apoptosis, such as the protein survivin, which inhibits caspase activity.

Cancer Epigenetics

Epigenetic changes in gene expression are also hallmarks of malignancy (Chapter 184). In normal cells, gene expression is controlled by epigenetic processes that limit the physical accessibility of genes to transcription factors. Gene expression can be silenced by processes that methylate specific DNA sequences on chromosomes, called CpG islands. In cancer, tumor suppressor genes are frequently found to be abnormally methylated, leading to a loss of their expression and function. The drugs 5-azacytidine and decitabine reverse methylation and have activity in the myelodysplastic syndrome (Chapter 188) and leukemia. Gene expression is also controlled by histone acetylases, which influence how tightly genomic DNA is spooled around large complex nuclear proteins called histones and alter the interaction of chromatin proteins with DNA. A novel group of drugs called histone deacetylase inhibitors are currently under development as anticancer agents.

Energy Metabolism

Cancer cells also demonstrate characteristic alterations in glucose metabolism, known as the Warburg effect. Malignant cells tend preferentially to shunt glucose into the glycolytic pathway, taking up excessive amounts of glucose and metabolizing glucose into lactate instead of channeling glucose

into the typical aerobic pathway that more efficiently captures energy and creates the end products of carbon dioxide and water. This disruption of normal cellular energy metabolism is thought to be due to dysregulation of a gene that is also involved in the regulation of apoptosis, Akt, and its downstream effectors. This abnormal metabolism of glucose in cancer cells is also the principle behind the use of positron emission tomographic scans to image tumors. Inherited inactivating mutations of the phosphatase and tensin homologue *(PTEN)*, which inactivates Akt, are also responsible for Cowden's syndrome, in which the susceptibility to breast and thyroid cancers is increased.

Ubiquitinylation and Proteasomes

Normal cells have tightly regulated mechanisms to degrade and recycle proteins by attaching one or more ubiquitin molecules to a protein. Ubiquitinylation can serve as a signal that a protein should be trafficked to and degraded by lysosomes or the proteasome. Ubiquitinylation plays an important role in the regulation of receptor tyrosine kinases, in cell cycle progression, and in repair of DNA damage. This regulatory mechanism is altered in many types of cancer. The first anticancer drug targeted at this abnormality in cancer cells is bortezomib, which inhibits proteasome activity and is effective in the treatment of multiple myeloma (Chapter 193).

Angiogenesis

Because tumors must find mechanisms to feed themselves as they grow, the malignant transformation must include the ability to stimulate new blood vessel formation, or angiogenesis. Malignant cells have in common the ability to stimulate the formation of endothelial cells and the breakdown of extracellular membranes, often by secreting vasculature endothelial growth factor (VEGF). The resulting tumor vasculature, although functional, does not have the vessel architecture or endothelial wall characteristics of a normal vascular bed. The realization that tumor cells have unique angiogenesis has led to the novel therapeutic approach of targeting tumor vessel formation, and not the malignant cell itself, such as with the monoclonal anti-VEGF antibody bevacizumab in metastatic colorectal cancer (Chapter 199).

Tumor Immune Evasion

Tumors also develop strategies to evade immune surveillance. The T cells and natural killer cells of the immune system play a role in protecting the host against malignancy, just as they also protect against infectious agents. Tumors can grow unimpeded after malignant cells have been selected with properties that disarm the host's immune response to tumors; these mechanisms include downregulation of costimulatory and major histocompatibility complex molecules, as well as secretion of cytokines that inhibit the immune system, such as transforming growth factor-β. The development of therapies designed to harness the immune system for cancer treatment, including tumor antigen vaccines, has been hindered by properties that allow tumors to escape immune destruction.

Drug Resistance

The same genetic plasticity that leads to cancer also gives cancer cells access to the human genome repertoire, with the capability to express and mutate any of its genes—sometimes resulting in resistance to anticancer therapy. Cancer cells can specifically alter the chemotherapy target to become resistant. In the case of imatinib mesylate, the targeted therapy for chronic myeloid leukemia (Chapter 190), cells can become resistant by mutating the binding site of the drug to the already mutant BCR/ABL protein. Cancer cellular resistance to older targeted drugs such as methotrexate, which targets the enzyme dihydrofolate reductase, can be mediated by multiple steps in the folate metabolic pathway. Cancer cells can also reach into their genomes and call on more general mechanisms of protection from stress. Normal cells can upregulate genes to protect against environmental toxins. In cancer, malignant cells use the same proteins to evade chemotherapy, such as adenosine triphosphate–dependent efflux drug pumps MDR1 (for multidrug resistance) and the MRP (for multidrug resistance–related protein) family of transmembrane proteins. Cancer cells also use other detoxification pathways, such as those involving glutathione, for protection against chemotherapy. For every anticancer drug developed, a cancer cell has found a way to circumvent it.

Cancer Stem Cells

Tissues are composed of a vast majority of cells that are irreversibly committed toward terminal differentiation. Hidden within tissues are also a very small minority of primitive, seemingly nondescript cells that are capable of repopulating the tissue with new cells and have the potential for self-renewal, that is, the ability to divide without differentiating; these are called stem cells. The view of cancer as a homogeneous mass of clonally derived malignant cells has been replaced by a view that, in some tumors, cancer cell division is organized more like a tissue in that most of the cells of a tumor do not have unlimited capacity for self-renewal but rather are the progeny of a minute population of cancer-initiating (or stem) cells. In hematopoietic malignancies and other tumors, flow cytometric techniques have demonstrated small, unique populations of cancer cells within tumors that have the ability to re-form the tumor, whereas the vast majority of cells in a malignancy do not have this potential.

This concept of cancer has enormous consequences for the study and treatment of cancer. Most important, all previous studies that have examined the overall expression of genes in a malignancy may not reveal critical and unique characteristics of the cancer-initiating cells from which the tumor has arisen. The pattern of treatment response followed by treatment relapse may be due not only to the acquisition of drug resistance but also to a failure of the therapy to treat the distinctive biology of the cancer stem cell. Isolation and characterization of cancer stem cells may reveal new cancer stem cell–specific targets that distinguish them from both their malignant progeny and normal stem cells. Treatments aimed at cancer stem cells hold the potential for markedly improving cancer therapy.

ENDOCRINE MANIFESTATIONS OF TUMORS: "ECTOPIC" HORMONE PRODUCTION

ROBERT F. GAGEL

It is now commonly accepted that genetic abnormalities, either activating or inactivating mutations, cause disordered cell growth leading to cellular transformation. A corollary of this fundamental tenet is that changes in a handful of important cellular genes can result in altered expression of other genes and thereby lead to the production of cellular proteins not normally expressed in the differentiated cell type. Among the more interesting and clinically relevant types of abnormal proteins are those associated with "ectopic" hormone syndromes, a small but clinically important group of disorders.

There are several patterns of "ectopic" hormone production. The most common is the production of small polypeptide hormones by tumors derived from a specific class of neuroendocrine cells. These neuroendocrine cells are widely dispersed throughout the lung, gastrointestinal tract, pancreas, thyroid gland, adrenal medulla, breast, prostate, and skin; they share several common cytologic and biochemical characteristics (amine precursor uptake and decarboxylation), are often derived from the neural crest, and normally produce both biogenic amines and small polypeptide hormones. The list of hormones produced by tumors derived from members of this group of neuroendocrine cells includes adrenocorticotropic hormone (corticotropin, ACTH), calcitonin, vasoactive intestinal peptide, growth hormone–releasing hormone, corticotropin-releasing hormone (CRH), somatostatin, and other small peptides. A second group of tumors, generally derived from squamous epithelium, produces parathyroid hormone–related protein (PTHrP) and vasopressin.

Current evidence suggests that aberrant hormone production is due to reversion to an earlier state of differentiation and an earlier developmental

TABLE 186-1 CLINICAL SYNDROMES OF ECTOPIC HORMONE PRODUCTION

Hepatoma
Pheochromocytoma
Benign conditions: cerebellar hemangioblastoma, uterine fibroid

pattern of transcription factor expression. In hypercalcemia caused by ectopic production of PTHrP, activation of the *ras*–mitogen-activated protein kinase signaling pathway, through mutation, appears to be responsible for PTHrP production by squamous epithelium. For example, normal fibroblasts can be stimulated to express PTHrP by combined expression of an activated *ras* gene and mutated tumor suppressor gene *p53*. In this example, a combinatorial effect of common genetic changes in human cancer results in abnormal expression of this hypercalcemic peptide.

The clinical syndromes associated with ectopic hormone production are important because they are often difficult diagnostic dilemmas, they are a major cause of morbidity and death in cancer patients, and their therapy can be challenging (Table 186-1). Management of these clinical syndromes is often difficult because of the necessity to treat both the cancer and the syndrome caused by excessive hormone production.

HUMORAL HYPERCALCEMIA OF MALIGNANCY

Hypercalcemia (Chapter 253) is one of the most common hormonal syndromes associated with cancer and is caused by several different pathophysiologic processes. To differentiate among these possibilities and initiate appropriate treatment, each patient must be approached in an organized manner.

PATHOBIOLOGY

Parathyroid Hormone–Related Protein

PTHrP is normally involved in chondrocytic and dermatologic differentiation. Eight of the first 16 amino acids of PTHrP are homologous with parathyroid hormone (PTH), and both peptides exert their various effects through interaction with the PTH receptor. Activation of this receptor in the osteoblast increases the expression of an osteoblast-specific cell surface protein called receptor activator of nuclear factor-kappa B ligand (RANKL). Interaction of RANKL with the RANK receptor on undifferentiated osteoclasts causes increased osteoclast differentiation and formation, bone resorption, and hypercalcemia. Ectopic production of PTHrP by a wide variety of tumors is one of the most common causes of hypercalcemia associated with malignancy; ectopic production of PTH itself is uncommon.

Increased Production of Calcitriol

Increased production of calcitriol occurs in a high percentage of patients with lymphoma (Chapters 191 and 192). There is compelling evidence for increased expression of 1α-hydroxylase by lymphomatous tissue. Other granulomatous conditions such as sarcoidosis (Chapter 95), berylliosis (Chapter 93), tuberculosis (Chapter 332), or fungal infection can also cause this clinical syndrome. Calcitriol-mediated hypercalcemia is caused by increased calcium absorption and is characterized by a suppression of serum immunoreactive PTH.

Bone Metastasis

Bone metastasis (Chapter 208) should always be considered in the differential diagnosis of hypercalcemia in a cancer patient. Bone metastases are frequently associated with local production of cytokines, PTHrP, or other substances that cause increased bone resorption. Indeed, the distinction between humoral hypercalcemia of malignancy and localized osteolysis has become blurred because of evidence that tumors such as breast cancer (Chapter 204) or myeloma (Chapter 193) cause localized osteolysis by the local production and secretion of PTHrP in addition to RANKL. In breast cancer there is considerable evidence of a local regulatory loop between transforming growth factor-β (TGF-β) and PTHrP production. TGF-β is a normal component of bone matrix. Local PTHrP production by breast cancer cells can stimulate osteoclastic bone resorption and the release of TGF-β. The release of TGF-β in turn stimulates breast cancer growth and greater PTHrP production, accelerating the osteolytic process. Other activators of bone resorption, including tumor necrosis factor, lymphotoxin, endothelin, interleukin (IL)-1, and IL-6, can be produced by other tumors that metastasize to (renal cell carcinoma) or reside in (myeloma) bone.

CLINICAL MANIFESTATIONS

The clinical syndrome associated with elevated levels of PTHrP is nearly identical to that observed with hyperparathyroidism and includes increased osteoclast-mediated bone resorption, as well as an increase in renal tubular calcium resorption and a decrease in renal phosphorus resorption. The only significant clinical difference between PTHrP- and PTH-mediated hypercalcemia is the finding of increased serum calcitriol (1,25-dihydroxycholecalciferol) levels in hyperparathyroidism and low or normal values in PTHrP-mediated hypercalcemia, presumably because of the inhibitory effects of cancer on 1α-hydroxylase, the enzyme that produces calcitriol. PTHrP production is most commonly associated with squamous cell carcinoma (Chapter 197), although production has been observed in other types of cancer as well, including breast (Chapter 204), neuroendocrine (Chapter 201), renal (Chapter 203), skin (Chapter 210), and prostate (Chapter 207) cancer. A notable trend over the past decade has been the reduction of hypercalcemia in patients with breast cancer. Routine bisphosphonate use and more effective therapies for breast cancer, particularly the widespread use of aromatase inhibitors, have led to decreased bone metastasis and hence a substantial reduction in hypercalcemia.

Clinical features that differentiate patients with increased production of calcitriol from those with PTHrP-mediated hypercalcemia include a suppressed intact serum PTH level (Fig. 186-1), an increased or normal serum phosphorus level, hypercalciuria, and no evidence of bone metastasis. An elevated serum calcitriol concentration is found in approximately half of patients with calcitriol-mediated hypercalcemia with a malignancy.

DIAGNOSIS

Measurement of intact PTH provides a useful starting point for diagnosis (see Fig. 186-1). An elevated PTH level in the context of hypercalcemia should prompt further evaluation for parathyroid disease (Chapter 253). However, in the majority of cancer patients with hypercalcemia, the intact PTH value is suppressed, indicating that the malignancy is causing the hypercalcemia. It should be kept in mind that hyperparathyroidism is not an uncommon disease, and a small percentage of patients with hypercalcemia and cancer may have both hyperparathyroidism and cancer-mediated hypercalcemia.

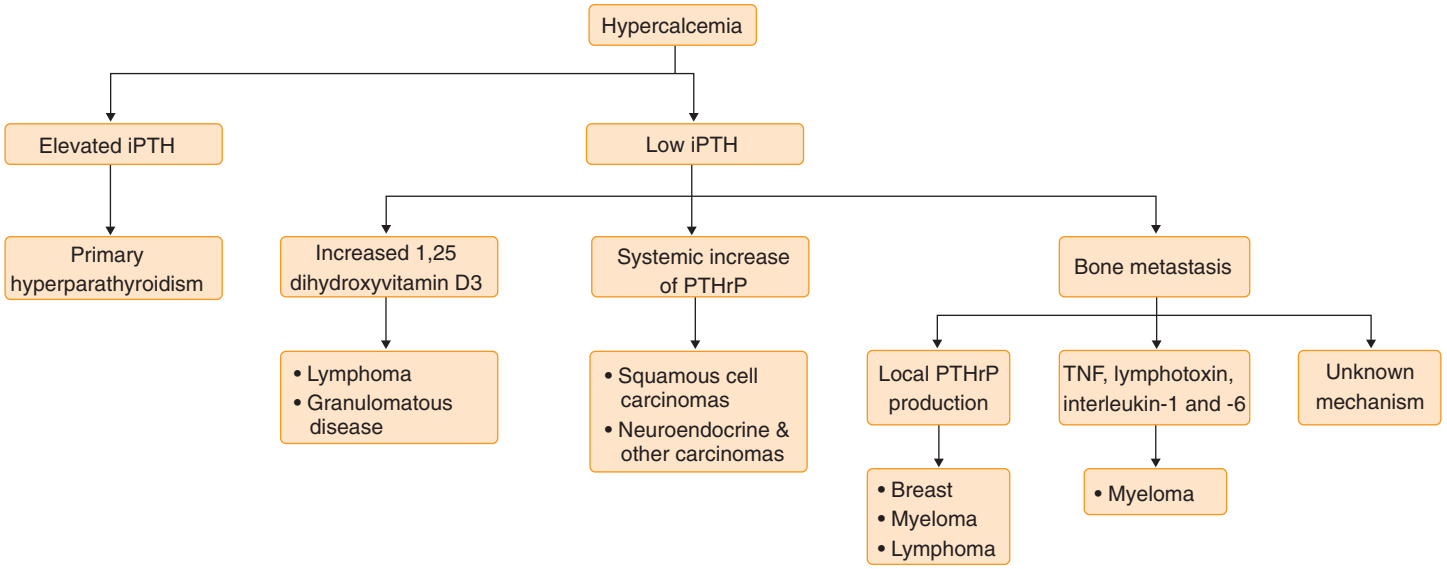

FIGURE 186-1. Strategy for evaluation of hypercalcemia in the context of malignancy based on measurement of intact parathyroid hormone (iPTH). PTHrP = parathyroid hormone–related protein; TNF = tumor necrosis factor.

TREATMENT

Rx

The initial management of hypercalcemia should focus on reversing dehydration and increasing urine calcium excretion by the infusion of normal saline solution at rates of 100 to 300 mL/hour, depending on the patient's cardiac status. A patient with a serum calcium concentration greater than 13 mg/dL (3.25 mM/L), altered mental status, or renal dysfunction should also be treated with a bisphosphonate (intravenous pamidronate 60 to 90 mg over 4 hours, or intravenous zoledronate 4 mg over a 15-minute period), glucocorticoids (prednisone or methylprednisolone 40 to 60 mg/day), gallium nitrate (200 mg/m^2/day, infused for 7 days), or salmon calcitonin (100 to 200 U intravenously or subcutaneously every 6 to 12 hours), alone or in combination. PTHrP-mediated or localized osteolysis is most responsive to bisphosphonates or gallium nitrate; vitamin D–mediated hypercalcemia is most responsive to glucocorticoid therapy (Chapter 253).

Use of high-dose intravenous bisphosphonates for extended periods has been associated with osteonecrosis of the jaw, a condition in which the mandibular or maxillary bone becomes devascularized, leading to loss of the overlying mucosa and exposed bone (Chapter 256). This condition developed in approximately 1 to 2% of patients with breast cancer and 2 to 3% with myeloma who received monthly intravenous pamidronate or zoledronate. Replacement of the devascularized and sclerotic bone occurs slowly—some patients have exposed bone for 3 to 5 years. Because many cases have been associated with dental procedures, such as removal of a tooth or tooth implantation, or with poorly fitting dentures, patients should have any dental issues addressed before the initiation of intravenous bisphosphonate therapy. The benefits of intravenous bisphosphonates in the context of bone metastasis or myeloma are substantial, and their continued use seems appropriate; however, trials are ongoing to determine whether the use of bone turnover markers to monitor suppression of bone resorption will permit use of less intensive bisphosphonate therapy.

Long-term management is focused on treatment of the underlying malignancy. Average survival in a patient with PTHrP-mediated hypercalcemia is less than 3 months, in part related to the underlying malignancy. Long-term therapy for PTHrP-mediated hypercalcemia, like that associated with parathyroid carcinoma, is difficult: patients tend to become less responsive to the effects of bisphosphonate or salmon calcitonin therapy over time and may experience renal toxicity when gallium nitrate therapy is used for extended periods.

Identification of the aforementioned RANKL/RANK receptor system has led to the development of a monoclonal antibody that binds to RANKL, thereby preventing activation of the RANK receptor. This agent, denosumab, is administered subcutaneously and recently approved for treatment of bone metastases; it is comparable to intravenous bisphosphonates in suppressing bone turnover and reducing the risk of skeletal events in patients with cancer-related bone metastases.

ECTOPIC ADRENOCORTICOTROPIC HORMONE SECRETION

PATHOBIOLOGY

Inappropriate secretion of ACTH is a rare but important cause of morbidity and mortality in cancer patients. It can be caused by two different mechanisms: expression of the proopiomelanocortin (POMC) gene by a tumor, or ectopic expression of CRH. In cell types that express the POMC gene, post-translational processing of this gene product can proceed down one of several mutually exclusive pathways and result in the expression of β-lipotropin, γ-lipotropin, and β-endorphin or the expression of big melanocyte-stimulating hormone and ACTH. Although POMC expression by malignant tumors is relatively common, expression of the enzymes necessary to cleave ACTH from the precursor is found less frequently outside the pituitary gland. ACTH production occurs in a broad spectrum of tumors, but it is most commonly associated with small cell carcinoma of the lung (Chapter 197) or classic neuroendocrine tumors such as pulmonary carcinoid (Chapter 240), medullary thyroid carcinoma (Chapter 233), islet cell adenoma or carcinoma (Chapter 238), pheochromocytoma (Chapter 235), and occasional neural tumors such as ganglioneuroma. Ectopic ACTH production causes adrenal cortical hyperplasia and excessive cortisol production (Chapter 234).

CLINICAL MANIFESTATIONS

Ectopic production of CRH causes a clinical syndrome characterized by pituitary corticotrope hyperplasia and laboratory results that mimic those of pituitary Cushing's disease (Chapter 231). Diagnosis requires a high index of suspicion combined with either measurement of CRH in blood or identification of a neoplasm outside the pituitary. Some neoplasms produce both ACTH and CRH. Tumors reported to produce CRH include medullary thyroid carcinoma, paraganglioma, prostate cancer, and islet cell neoplasms.

Hypercorticism associated with ectopic ACTH syndrome may manifest with classic features of Cushing's syndrome, such as easy bruisability, centripetal obesity, muscle wasting, hypertension, diabetes, and metabolic alkalosis. In other patients, particularly those with rapidly growing small cell carcinoma of the lung, the clinical picture may be dominated by profound hypokalemic metabolic alkalosis and hypertension, without the other clinical findings of Cushing's syndrome.

DIAGNOSIS

Evaluation of Cushing's syndrome (Chapter 234) is based on the plasma ACTH measurement in a patient with suggestive clinical and laboratory features (Fig. 186-2). The finding of a marked elevation in the plasma ACTH concentration (>100 pg/mL) should prompt a search for an ectopic source of ACTH. In a patient with a plasma ACTH value greater than 10 pg/mL but

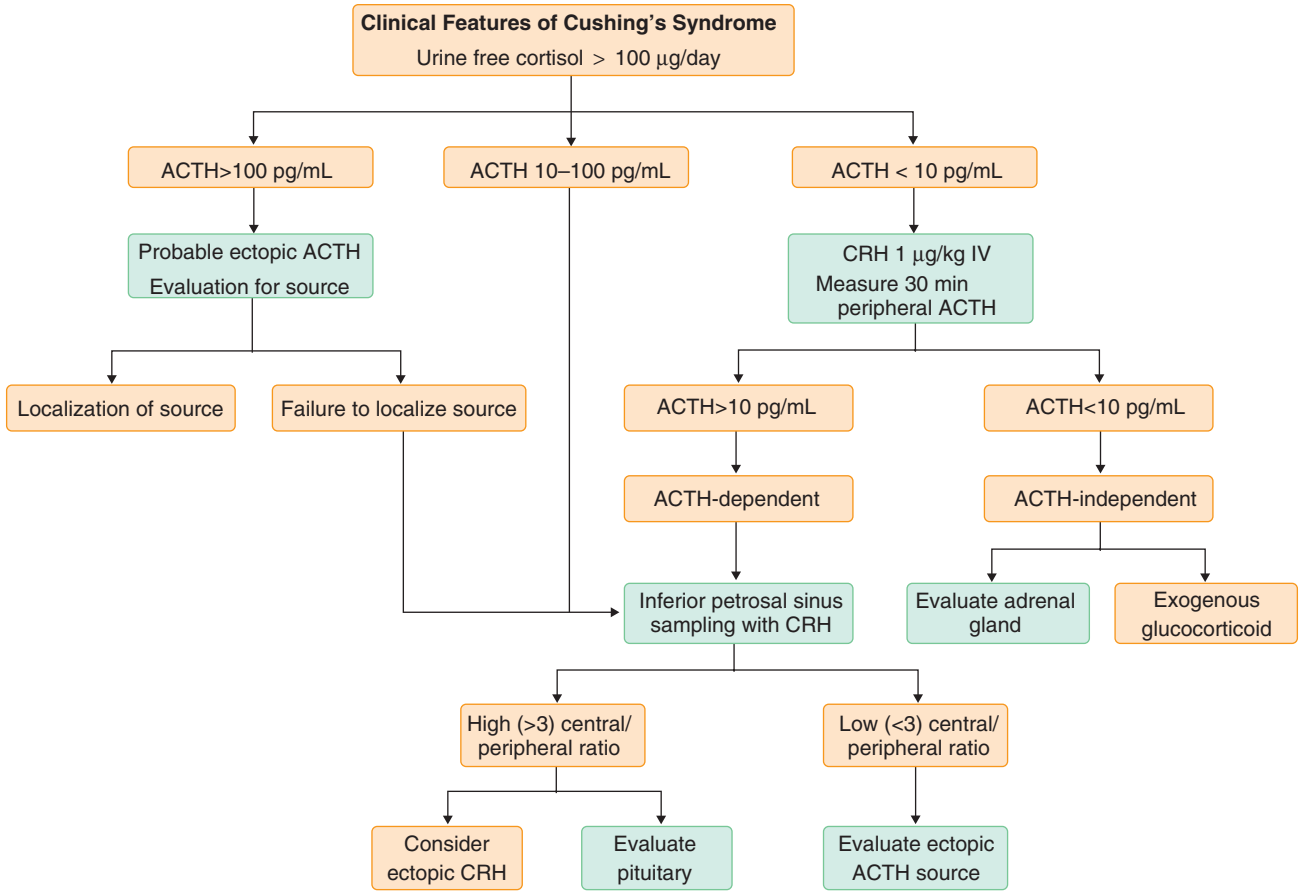

FIGURE 186-2. Evaluation strategy for a patient with Cushing's syndrome and suspected ectopic adrenocorticotropic hormone (ACTH) production. In patients with a plasma ACTH concentration greater than 100 pg/mL, an ectopic ACTH source should be considered, although some patients with pituitary Cushing's disease may have values in this range. In patients with a plasma ACTH concentration between 10 and 100 pg/mL, inferior petrosal sinus sampling for ACTH should be performed after peripheral corticotropin-releasing hormone (CRH) injection (Chapter 234) to separate a pituitary (high central-peripheral ACTH ratio) from an ectopic (low central-peripheral ACTH ratio) ACTH source. In patients with a low basal peripheral ACTH value (<10 pg/mL), a low-dose CRH test (1 µg/kg) should be performed, followed by inferior petrosal sinus sampling in individuals whose plasma ACTH concentration rises to greater than 10 pg/mL.

less than 100 pg/mL, a more detailed evaluation is appropriate. Differentiation between a pituitary and an ectopic source may require stimulation of ACTH secretion by CRH combined with measurement of ACTH in blood from the pituitary venous drainage (inferior petrosal sinus sampling). Lack of an increase in the inferior petrosal sinus ACTH concentration (less than three times the peripheral ACTH concentration) after peripheral CRH stimulation should prompt a search for an ectopic source. In patients with an increased (more than three times the peripheral level) inferior petrosal sinus ACTH level after CRH, a pituitary source is likely. Ectopic CRH can yield confusing results and may not be diagnosed unless the clinician considers the possibility and measures plasma CRH or looks for an ectopic source.

Other approaches have also been applied to the diagnosis of ectopic ACTH syndrome. For example, ACTH production from an ectopic source is not generally suppressed by high-dose dexamethasone. In a patient with an ACTH concentration greater than 10 pg/mL, administration of a single 8-mg oral dose of dexamethasone at 11:00 PM, followed by measurement of the serum cortisol level at 8:00 AM, can differentiate between a pituitary and an ectopic source. The serum cortisol level in pituitary Cushing's disease (caused by a pituitary tumor) is generally suppressed 50% after dexamethasone, whereas levels in ectopic ACTH are usually not suppressed. However, false-positive or false-negative results occur with each of these testing procedures, making the differential diagnosis of Cushing's syndrome one of the most challenging in medicine.

TREATMENT

Rx

Hypercortisolism associated with ectopic ACTH can be managed by removal of the ACTH- or CRH-producing tumor or by inhibition of cortisol synthesis with metyrapone (1 to 4 g/day orally), aminoglutethimide (250 mg orally four times/day with upward titration), or ketoconazole (200 to 400 mg orally twice a day). Parenteral etomidate, used for sedation and induction of anesthesia, rapidly inhibits cortisol synthesis at subhypnotic concentrations. It is titrated from 0.3 to 4 mg/kg/hour to normalize serum cortisol measurements and has been used to rapidly reverse hypercorticism in a small number of patients. Replacement glucocorticoid therapy is needed to prevent adrenal insufficiency in patients receiving inhibitors of cortisol synthesis (Chapter 234). If surgical removal of an ACTH- or CRH-producing tumor is not possible and inhibition of cortisol synthesis is inadequate, bilateral adrenalectomy (with replacement glucocorticoid and mineralocorticoid therapy) may be required. In patients with a rapidly progressive small cell carcinoma of the lung and ectopic ACTH syndrome, the oncologic imperative to initiate immediate cytotoxic therapy must be counterbalanced by the desire to normalize cell-mediated immunity by normalizing cortisol secretion, hypokalemia, and metabolic alkalosis. Cytotoxic chemotherapy should generally be delayed, if possible, until the serum cortisol level is normalized because neutropenic patients with hypercortisolism have a high rate of infection that often causes death. If cancer treatment is initiated, prophylactic therapy for pulmonary *Pneumocystis carinii* (Chapter 349) and fungal infections should be considered.

HUMAN CHORIONIC GONADOTROPIN PRODUCTION

PATHOBIOLOGY

Two different genes encode the α- and β-subunits of human chorionic gonadotropin (HCG). The β-subunit is common to all the pituitary glycoprotein hormones (luteinizing hormone, follicle-stimulating hormone, thyroid-stimulating hormone [TSH], and HCG), whereas each of these hormones has a unique β-subunit gene. Inappropriate production of the α-subunit occurs in a variety of pituitary and nonpituitary tumors and does not cause any discernible clinical syndrome. The β-subunit confers biologic specificity. Production of intact HCG occurs commonly in trophoblastic

tumors (choriocarcinoma, testicular embryonal carcinoma, and seminoma; Chapter 206) and less commonly in other tumors such as those of the lung and pancreas.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical syndromes associated with the production of HCG include precocious puberty, gynecomastia, and hyperthyroidism. Hyperthyroidism results from the low-affinity interaction of HCG with the TSH receptor when β-HCG is present in high concentrations. β-HCG concentrations that are several orders of magnitude higher than normal interact with the TSH receptor and increase the production of thyroid hormone, thereby suppressing endogenous TSH production below normal.

TREATMENT Rx

Therapy for precocious puberty and gynecomastia is directed toward removal or treatment of the underlying tumor. Hyperthyroidism is treated by inhibiting thyroid hormone synthesis, usually with thionamide therapy, followed by therapy for the underlying tumor. Treatment of hyperthyroidism by surgical removal of the thyroid gland or ablation with radioactive iodine is rarely required because the hyperthyroidism resolves rapidly after treatment of the underlying tumor.

HYPOGLYCEMIA ASSOCIATED WITH CANCER

PATHOBIOLOGY

Tumor-associated hypoglycemia is a rare but important cause of morbidity in cancer patients. Three different clinical syndromes cause most cancer-related hypoglycemia. The first is production of insulin by an islet tumor. Although primary insulinomas are rare, dedifferentiation and bulky hepatic metastasis of an islet cell carcinoma may be associated with excessive insulin production (Chapter 238). A second cause of hypoglycemia, insufficient hepatic gluconeogenesis to maintain the plasma glucose concentration in the fasting state, is caused by nearly complete replacement of the liver by metastatic tumor. A third cause of hypoglycemia is increased concentrations of insulin-like growth factor type II (IGF-II), which activates the insulin receptor associated with large abdominal or retroperitoneal tumors such as fibrosarcoma, hemangiopericytoma, or hepatoma. This increased activity appears to be due to the failure to form a normal IGF binding protein 3 (IGFBP-3) and the acid-labile subunit (ALS) complex that normally binds IGF-II; the result is an increase in free IGF-II concentrations. It is usually possible to differentiate among the three causes by measuring serum insulin, C-peptide, proinsulin, IGF-I, IGF-II, and ALS levels during a controlled fast that causes hypoglycemia (Chapter 238).

CLINICAL MANIFESTATIONS, DIAGNOSIS, AND TREATMENT Rx

In all three types of hypoglycemia, the patient is at greatest risk for symptoms during periods of fasting, most commonly while sleeping. Therapy should focus on surgical excision, when possible, or antineoplastic therapy directed at the tumor. Initial therapy for hypoglycemia is focused on frequent meals, and patients occasionally remain symptom free if awakened for one or more snacks during sleeping hours. If the tumor progresses or the patient's caloric intake is inadequate, additional measures may be required. If hepatic replacement by tumor is evident, a continuous infusion of 20% dextrose through a central line may be required, especially during sleep. In patients with insulin-producing or large retroperitoneal tumors, glucagon infusion (0.5 to 2 mg/hour) stimulates hepatic gluconeogenesis and prevents hypoglycemia; however, in rare patients a rash associated with glucagonoma may develop. An increase in glucose concentration after a single injection of glucagon (1 mg) should be documented before initiating therapy. In patients with large retroperitoneal tumors, treatment with growth hormone (3 to 6 μg/kg subcutaneously) or glucocorticoids (20 to 40 mg/day) may reverse the hypoglycemia, possibly by facilitating IGFBP-3/ALS complex formation, thereby reducing free serum IGF-II levels. This condition has also been treated with growth hormone doses as high as 2600 μg/day; long-term treatment with this dose may cause acromegaly. Somatostatin analogues (octreotide or lanreotide) are not generally effective for normalizing the plasma glucose level in patients with islet cell tumors; diazoxide (3 to 8 mg/kg/day in two or three divided doses) may be effective, but problems with fluid retention frequently preclude its long-term use.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

PATHOBIOLOGY

Ectopic production of vasopressin by head and neck tumors (3%), small cell carcinoma of the lung (15%), and other lung carcinomas (1%) causes the clinical syndrome of inappropriate antidiuretic hormone (SIADH), which is characterized by hyponatremia, hypo-osmolality, excessive urine sodium excretion, an inappropriately high urine osmolality for the low serum osmolality, and normal function of the kidneys and adrenal and thyroid glands. Other malignant neoplasms (primary brain tumors; hematologic neoplasms; skin tumors; gastrointestinal, gynecologic, breast, and prostate cancers; and sarcomas) are rare causes of this clinical syndrome.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

In most cases the hyponatremia is asymptomatic, although altered mental status and seizures may develop when the serum sodium concentration falls below 120 mEq/L. Hyponatremic women of reproductive age may experience profound cerebral degeneration.

TREATMENT Rx

Fluid restriction may be effective for short-term management, but it is difficult to maintain over long periods. Hypertonic fluids can be given with great caution to symptomatic patients (Chapter 118); the serum sodium concentration should be monitored to prevent an increase of more than 12 mEq/day. Treatment with 150 to 300 mg/day demeclocycline can block the effects of vasopressin on the kidney and is an effective long-term therapy in patients with cancer. Oral tolvaptan and intravenous conivaptan are vasopressin receptor type 2 antagonists that are effective treatments for hyponatremia.

RARE ECTOPIC HORMONE SYNDROMES

Tumor-Induced Osteomalacia

A clinical syndrome characterized by profound hypophosphatemia, muscle weakness, and osteomalacia (Chapter 252) can be produced by mesenchymal tumors (osteoblastoma, giant cell osteosarcoma, hemangiocytoma, and, rarely, prostate and lung carcinoma). Fibroblast growth factor 23 (FGF-23), mutated in autosomal dominant hypophosphatemic rickets (Chapter 252), is overexpressed in neoplasms causing this disorder. Therapy is directed toward correction of hypophosphatemia with either oral or intravenous supplementation and vitamin D treatment. Surgical removal of the tumor is curative. Identification of FGF-23 overexpression as a cause may lead to the development of specific antagonists.

Hematologic Syndromes

The kidney is the primary site of erythropoietin production; therefore, the relatively common erythropoietin production by benign or malignant renal tumors is not an "ectopic" hormone syndrome. Production of erythropoietin by cerebellar hemangioblastomas (Chapter 195), uterine fibroids, pheochromocytomas (Chapter 235), and ovarian (Chapter 205) and hepatic (Chapter 202) tumors is generally considered "ectopic." Patients with excessive erythropoietin production may or may not have polycythemia (Chapter 169). Other ectopic syndromes, less well defined, include production of thrombopoietin or colony-stimulating factor by some tumors. These conditions are treated by removal of the tumor or by appropriate chemotherapy.

Hypertension

Renal (Wilms' tumor, renal cell carcinoma, hemangiopericytoma), lung (small cell carcinoma of the lung, adenocarcinoma), hepatic, pancreatic, and ovarian carcinomas may produce renin. The clinical findings in these patients can include hypertension, hypokalemia, and evidence of increased aldosterone production. Therapy with aldosterone antagonists or angiotensin-converting enzyme inhibitors may be effective.

Growth Hormone and Prolactin Production

Rare examples of growth hormone production have been identified in lung and gastric adenocarcinoma. Ectopic production of growth hormone–releasing hormone has been documented for islet cell tumors (Chapter 238), bronchogenic carcinoids (Chapter 240), and small cell carcinoma of the lung (Chapter 197). Increased prolactin production is a rare phenomenon

associated with lymphomas and cancer of the lung, colon, kidney, and oral cavity. Hyperprolactinemia produces galactorrhea and amenorrhea in women and hypogonadism and gynecomastia in men. Treatment with dopamine agonists (bromocriptine, quinagolide, or cabergoline), which is effective in pituitary prolactinoma (Chapter 231), should be tried, but it is most commonly ineffective.

PARANEOPLASTIC SYNDROMES AND OTHER NON-NEOPLASTIC EFFECTS OF CANCER

HOPE S. RUGO

DEFINITION

The direct clinical manifestations of cancer are usually due to local effects of tumor growth, either in the primary site or at a distant site, or are nonspecific such as anorexia, malaise, weight loss, night sweats, and fever. The term *paraneoplasia,* which means "alongside cancer," has been commonly used to denote remote effects of cancer that cannot be attributed either to direct invasion or to distant metastases.

EPIDEMIOLOGY

These syndromes may be the first sign of a malignancy and affect up to 15% of patients with cancer. However, if patients with cachexia are excluded, the incidence probably drops to only a few percent.

Paraneoplastic syndromes are important clinically for a number of reasons. First, they may be the initial presenting sign or symptom of an underlying malignancy. Up to two thirds of paraneoplastic syndromes arise before an associated malignancy is diagnosed. In some cases, the paraneoplastic syndrome may be associated with relatively small tumors; recognition of these associations may lead to earlier diagnosis and possibly more effective therapy. Second, one of the hallmarks in defining a paraneoplastic syndrome is that the course of the syndrome generally parallels the course of the tumor. Therefore, effective treatment of the underlying malignancy is often accompanied by improvement or resolution of the syndrome. Conversely, recurrence of the cancer may be heralded by return of systemic symptoms. One exception is the neurologic paraneoplastic syndromes, in which damage to structures within the nervous system may not be reversible. Third, the clinical manifestations of the paraneoplastic syndrome (or the toxic effects of electrolyte disturbances) may constitute a more urgent hazard to life or have a greater impact on quality of life than the underlying cancer.

PATHOBIOLOGY

Paraneoplastic syndromes may be caused by a variety of mechanisms; the endocrine (Chapter 186) and neurologic syndromes are the best understood. Possible etiologies include (1) secretion of proteins that are not associated with the normal tissue equivalent of the cancer (e.g., ectopic endocrine syndromes, local destruction of tissues by tumor-secreted cytokines), (2) antibodies that are directed against aberrantly expressed antigens on the tumor cell that cross-react with antigens that are normally expressed on other tissues (e.g., neurologic syndromes), and (3) effects related to unknown mechanisms, such as unidentified tumor products or circulating immune complexes stimulated by the tumor (e.g., osteoarthropathy associated with bronchogenic carcinoma; Chapter 197). Clinical findings may resemble those of primary metabolic, hematologic, dermatologic, or neuromuscular disorders or be specific to a cancer-related syndrome. Even such nonspecific symptoms as fever and weight loss are truly paraneoplastic and are due to the production of specific factors (e.g., tumor necrosis factor) by tumor cells or by normal cells in response to the tumor (see later).

DIAGNOSIS

In a patient who presents with symptoms or signs of a paraneoplastic syndrome, the screening evaluation (Table 187-1) should focus on the most common associated malignancies. If the initial evaluation is unrevealing, a repeated evaluation should be considered after several months. If the relationship between the syndrome and malignancy is less clear or less frequently observed, the evaluation should be focused on the patient's individual risks and symptoms.

The most common cancer associated with paraneoplastic syndromes is small cell cancer of the lung (Chapter 197), probably because of its neuroectodermal origin. Other neoplasms commonly associated with paraneoplastic syndrome include carcinomas of the breast (Chapter 204), ovary (Chapter 205), other adenocarcinomas, lymphoproliferative diseases (especially Hodgkin's disease; Chapter 192), and thymoma (Chapter 99).

NEUROLOGIC PARANEOPLASTIC SYNDROMES

PATHOBIOLOGY

Increasing evidence suggests that the underlying mechanisms of most neurologic syndromes associated with cancer are autoimmune in origin (Table 187-2). Tumors express antigens that are normally isolated to the nervous system and are found on neurons, referred to as onconeuronal antigens. Antineuronal antibodies that are produced against the new tumor cell antigen circulate in serum and spinal fluid and, at least in some patients, cause damage at the primary site of normal antigen expression. Pathologically, perivascular and interstitial lymphocytic infiltrates are found in the affected area of the brain. Indirect immunofluorescence of serum detects antibodies reactive with neurons. Disorders mediated by antibodies against neuronal cell surface or synaptic proteins may occur with or without tumor association; both may respond to immunotherapy.

It is unclear what susceptibility factors lead to development of a neurologic paraneoplastic syndrome. In addition to direct antibody-mediated damage, there is evidence that cell-mediated autoimmune mechanisms may

TABLE 187-1 EVALUATION AND DIAGNOSIS OF PARANEOPLASTIC SYNDROMES

Characterize abnormality; obtain laboratory studies and biopsy as necessary.
Carefully elicit any additional symptoms and signs.
Eliminate common causes.
If there is no obvious etiology, consider a paraneoplastic syndrome.
If findings are consistent with a known syndrome, screen for underlying malignancy.
If signs and symptoms are consistent with a known paraneoplastic syndrome, undertake a search for an unknown primary cancer or recurrence or progression of a known primary tumor.
Screening should include a careful physical examination with breast, gynecologic, and prostate evaluations; basic hematology, chemistry, and urine studies; chest radiograph; and mammogram.
Computed tomography (CT) of the abdomen and pelvis or positron emission tomography CT scan is indicated if there are any suspicious symptoms, signs, or laboratory abnormalities. Antibody testing for paraneoplastic neurologic syndromes and/or skin biopsy should be performed as indicated.
Consider treatment of cancer and/or appropriate palliative treatment, including immunosuppressive therapy for paraneoplastic symptoms when possible.

TABLE 187-2 PARANEOPLASTIC NEUROLOGIC SYNDROMES, ASSOCIATED ANTIBODIES, AND MALIGNANCIES

NEUROLOGIC SYNDROME	CLINICAL PRESENTATION	ANTIBODY	ASSOCIATED MALIGNANCY
Lambert-Eaton myasthenic syndrome	See text	Anti-VGCC Anti-SOX1	SCLC (>80%)
Paraneoplastic encephalomyelitis/ subacute sensory neuropathy	See text	Anti-Hu Anti-SOX1 Anti-amphiphysin Anti-Ma Anti-Trk (sensory)	SCLC (75-80%), neuroblastoma SCLC, breast Various carcinomas Lymphoma
	Acute psychosis	Anti-NMDA	Ovarian teratoma
Paraneoplastic cerebellar degeneration	See text	Anti-Yo Anti-SOX1 Anti-Ri Anti-Hu Anti-Tr, Anti-GluR Anti-Ma	Breast, ovarian, and other gynecologic malignancies Breast (50%) SCLC Hodgkin's lymphoma Various carcinomas
Limbic encephalopathy	Subacute amnestic syndrome, affective disorder, seizures DDX: herpes encephalit*is* Improvement common with treatment of underlying tumor; immunosuppression is of unclear benefit	Anti-Hu, Antiamphiphysin, Anti-SOX1, Anti-VGKC, Anti-AMPA Anti-Ta	SCLC Testicular, breast
Opsoclonus/myoclonus	Saccadic eye movements with ataxia and myoclonus Most occur in children with neuroblastomas Pathology reveals diffuse dropout of Purkinje cells Treatment of underlying tumor may improve symptoms; ACTH, steroids, and IVIG may also benefit	Anti-Ri Anti-Hu Antiamphiphysin Anti-Ta	Breast (70%), ovarian SCLC, neuroblastoma (50%) SCLC Testicular
Stiff-person syndrome	Progressive muscle stiffness and rigidity, with intermittent and painful muscle spasms. EMG: continuous firing of motor unit potentials Treat with muscle relaxants; may improve with cancer therapy	Antiamphiphysin Anti-GAD	Breast, SCLC Breast
Neuromyotonia	Diffuse muscle stiffness and cramps; may be associated with myasthenia gravis Responds to treatment of tumor and immunosuppression	Anti-VGCC	Thymoma
VISUAL SYNDROMES			
CAR	Gradual to acute and progressive visual loss	Antiretinal, antirecoverin	SCLC
MAR	Reports of response to immunosuppressive therapy and plasmapheresis	Antibipolar cell	Melanoma
Bilateral diffuse melanocytic proliferation (BDUMP)		?	Gynecologic malignancy Various adenocarcinomas
SYNDROMES WITH NO ASSOCIATED ANTIBODY IDENTIFIED			
Demyelinating neuropathies (including CDP, mononeuritis multiplex)	Sensory more common than motor or both May improve with treatment of paraprotein, plasmapheresis	IgM paraprotein may cross-react with MAG, cryoglobulins	Plasma cell and lymphoproliferative neoplasms, osteosclerotic myeloma, POEMS, amyloid, SCLC, other carcinomas
Necrotizing myelopathy	Symptoms associated with specific levels of spinal cord dysfunction Rapid deterioration and death		Variety of carcinomas and lymphomas
Motor neuron disease	Similar to ALS with progressive weakness; may improve with plasmapheresis and treatment of paraproteinemia		Plasma cell and lymphoproliferative neoplasms
Polymyositis/dermatomyositis	Unclear relationship to cancer, higher risk with dermatomyositis May improve with treatment of cancer, otherwise treat as idiopathic		Variety of carcinomas

ACTH = adrenocorticotropic hormone; AGNA = antiglial nuclear antibody; ALS = amyotrophic lateral sclerosis; AMPA = α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid; amphiphysin = synaptic vesicle–associated protein; CAR = carcinoma-associated retinopathy; CDP = chronic demyelinating polyneuropathy; DDX = differential diagnosis; EMG = electromyogram; GAD = glutamic acid decarboxylase; GluR = glutamate receptor; IgM = immunoglobulin M; IVIG = intravenous immunoglobulin; MAG = myelin-associated glycoprotein; MAR = melanoma-associated retinopathy; NMDA = *N*-methyl-D-aspartate; POEMS = polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, and skin changes associated with osteosclerotic myeloma; SCLC = small cell lung cancer; VGCC = voltage-gated calcium channel, VGKC = voltage-gated potassium channel.

contribute. The finding of $CD8^+$ T lymphocytes infiltrating neurologic tissue in postmortem studies of patients with neurologic paraneoplastic syndromes, combined with data that patients with antibodies (with or without neurologic paraneoplastic syndromes) may have longer survival rates than otherwise similar patients without circulating antibodies, suggests that $CD8^+$ T lymphocytes play a beneficial role in tumor-directed immune responses. This immune response may be mediated by aberrant expression of native antigens.

CLINICAL MANIFESTATIONS

Neurologic paraneoplastic syndromes may involve the brain, cranial nerves, spinal cord, dorsal root ganglia, peripheral nerves, neuromuscular junction, muscle, or multiple levels of the nervous system. Perhaps because of cross-reactivity of antibodies, it is not uncommon for patients to develop more than one paraneoplastic syndrome, making the diagnosis of a particular syndrome more difficult. Classic paraneoplastic disorders include those whose clinical manifestations are unique and are frequently associated with cancer;

TABLE 187-3 GENETIC SYNDROMES WITH CUTANEOUS MANIFESTATIONS ASSOCIATED WITH AN INCREASED RISK OF SYSTEMIC CANCERS

GENETIC SYNDROME	SKIN LESION	GENETIC MUTATION	ASSOCIATED CANCERS	RISK
Torre's (Muir-Torre)	Multiple sebaceous gland tumors, basal cell cancers	Mutations in DNA mismatch repair genes leading to microsatellite instability (*MSH2*, 2p22-p21)	GI and GU cancers	High
Gardner's	Multiple epidermal and sebaceous cysts of face and scalp, desmoid tumors of skin, osteomas of face and head, GI polyps	Adenomatous polyposis coli tumor suppressor gene (5q21-q22)	GI cancers	High
Cowden's	Multiple hamartomas of skin, mucous membranes (trichilemmomas), lipomas	*PTEN/MMAC1* tumor suppressor gene	Breast, thyroid cancers	High
MEN 2B	Multiple papular mucosal neuromas on lips, oropharynx, conjunctiva	Receptor tyrosine kinase (*RET*) protooncogene	Medullary carcinoma of thyroid, pheochromocytoma	High
Ataxia-telangiectasia	Telangiectasias over face, conjunctiva	*ATM* gene (11q22-23)	Lymphomas	Medium
Neurofibromatosis type 1	Cafe au lait spots, axillary freckles, neurofibromas	*NF1* gene (17q11.2)	Neurofibrosarcoma, pheochromocytoma, acoustic neuromas	Low
Peutz-Jeghers	Pigmented macules on the lips, oral mucosa, hands, feet; hamartomatous GI polyps	*STK11/LKB1* gene (19p13.3)	GI, pancreas, ovary, testes	Low
Basal cell carcinoma nevus (Gorlin's)	Multiple basal cell cancers	*PTCH1* gene (9q22) resulting in activation of hedgehog signaling	Basal cell cancers, medulloblastoma, fibrosarcoma	Low
Bloom's	Telangiectatic redness of skin in photo-exposed areas, stunted growth	DNA helicase gene (*RECQL3*)	Lymphomas, leukemias	Medium

GI = gastrointestinal; GU = genitourinary; MEN = multiple endocrine neoplasia.

nonclassic syndromes frequently occur without cancer and may be difficult to identify. The differential diagnosis of neurologic paraneoplastic syndromes includes idiopathic presentations of the same syndrome, side effects of chemotherapy (Chapter 182) and radiation therapy (Chapter 19; Table 187-2), infections (usually associated with lymphoproliferative diseases), vascular disease (including infarction and hemorrhage), and metabolic and nutritional abnormalities (including hormonal paraneoplastic syndromes). Therapy includes treatment of the underlying tumor as well as immunosuppressive therapy with or without plasmapheresis. Unfortunately, this approach usually results in only modest, if any, improvement of the neurologic deficit.

DIAGNOSIS

A patient presenting with neurologic complaints regardless of a prior diagnosis of malignancy should undergo a standard evaluation for diseases such as a primary central nervous system (CNS) malignancy, a metastatic malignancy, bleeding, vascular events, and infection. Generally, this evaluation includes a careful history regarding onset, associated symptoms, and other general medical conditions, as well as a careful physical and neurologic examination. Studies should include initial contrast-enhanced magnetic resonance imaging (MRI) and examination of the cerebrospinal fluid (CSF) for protein and cells if the MRI is normal or showed leptomeningeal enhancement. If the evaluation does not reveal evidence of primary CNS disease, a body positron emission tomography (PET) or computed tomography (CT) scan along with standard laboratory testing may be useful to screen for undetected malignancies.

If a neurologic paraneoplastic syndrome is suspected, serum and CSF should be tested for antineuronal antibodies targeted to either intracellular or cell surface proteins (see Table 187-2). However, a high degree of specificity of an antibody for a particular syndrome does not prove that the antibody is pathogenic. Finding a circulating antibody is useful but not diagnostic of any particular syndrome; patients can have circulating antibodies without the associated clinical syndrome, and most lung cancers as well as many breast and gynecologic malignancies express neuronal antigens, although the antibody titer is usually much lower than that seen with a neurologic paraneoplastic syndrome. High serum antibody levels and the presence of antibody in the CSF are more specific findings. Diagnosis of a neurologic paraneoplastic syndrome should instigate a reasonable search for the commonly associated malignancy (see Table 187-1). PET and CT scans have been shown to improve the detection of cancers when other screening tests are negative, particularly when patients are found to have antineuronal antibodies.

Lambert-Eaton Myasthenic Syndrome—Anti-VGCC and Anti-SOX1 Antibodies

DEFINITION AND EPIDEMIOLOGY

The Lambert-Eaton myasthenic syndrome (LEMS) is one of the first recognized and most common neurologic paraneoplastic syndromes, and it is one of the only syndromes with direct evidence to support the role of autoantibodies in producing clinical disease. This disorder affects 1 to 2% of patients with small cell cancer of the lung (SCLC), and up to two thirds of the cases are associated with an underlying malignancy.

PATHOBIOLOGY

LEMS is associated with a defect in the release of neurotransmitters (acetylcholine) from the presynaptic neurons at the neuromuscular junction and other sites. Acetylcholine release is mediated by P-type voltage-gated calcium channels (VGCCs); antibodies to VGCC are found in the serum of more than 85% of patients with Lambert-Eaton myasthenic syndrome. Paraneoplastic LEMS and idiopathic LEMS are clinically and immunologically similar, but a recently discovered antibody significantly associates with the presence of SCLC. Antiglial nuclear antibody (AGNA) binds to the SOX1 antigen, found in nuclei of specialized glia cells in the cerebellum. Anti-SOX1 antibodies have been identified in the sera of more than 60% of patients with paraneoplastic LEMS and appear to be a relatively specific marker of an associated underlying malignancy. SOX antibodies, as well as antibodies to the Zic protein, have been found in patients with a number of other paraneoplastic neurologic syndromes associated with SCLC as well as in the serum of patients with SCLC without neurologic symptoms.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinically, patients present with proximal lower limb weakness, with improvement in strength after several seconds of sustained voluntary contraction (Chapter 430). Autonomic symptoms, including dry mouth, ptosis, and impotence, are also common. Patients may also have associated CNS dysfunction, such as encephalomyelitis, cerebellar dysfunction, and peripheral neuropathy resulting from cross-reactivity or the presence of combinations of antibodies. The diagnosis is made by an electromyogram, which shows *increased* muscle action potential with repeated nerve stimulation greater

than 10 Hz (the opposite of myasthenia gravis; Chapter 430). As noted previously, the finding of SOX1 antibodies significantly associates with the presence of SCLC.

TREATMENT Rx

Treatment consists of a combination of plasmapheresis, intravenous immunoglobulin (IVIG) to bind circulating antibodies, and immunosuppression (to remove antibodies and suppress their production), as well as treatment of the underlying malignancy. Successful removal of the primary malignancy may result in resolution of symptoms. Pharmacologic facilitation of neuromuscular transmission with pyridostigmine, 3,4-diaminopyridine, and guanidine may be useful.■

Paraneoplastic Encephalomyelitis and Subacute Sensory Neuropathy—Anti-Hu Antibodies

This heterogeneous group of disorders can affect the cerebral hemispheres, limbic system, cerebellum, brain stem, spinal cord, dorsal root, and autonomic ganglia.

PATHOBIOLOGY

About 75 to 80% of paraneoplastic encephalomyelitis and subacute sensory neuropathy (Chapter 428) is associated with SCLC (Chapter 197), with a variety of other neoplasms representing the remainder. Most patients have circulating antineuronal anti-Hu autoantibodies; a small number have either no antibodies or antibodies to other proteins. One report found evidence of impairment of the Trk-neurotrophin receptor by the serum of a patient with subacute sensory neuropathy, suggesting production of anti-Trk autoantibodies. Although neuronal loss is accompanied by perivascular and leptomeningeal infiltration of lymphocytes, the pathogenesis of this syndrome is unknown.

CLINICAL MANIFESTATIONS

The most common manifestations are related to subacute sensory neuropathy, including patchy or asymmetrical numbness, burning or aching paresthesias, and sensory ataxia with loss of proprioception and vibration sense. Patients may also present primarily with subacute cerebellar degeneration or brain stem encephalitis, and nearly all patients have evidence of multifocal involvement of the CNS and dorsal root ganglia.

DIAGNOSIS

The diagnosis is made on clinical grounds and is aided by finding circulating antibody in serum. MRIs are usually normal, and the CSF can show elevated protein levels with a lymphocytosis. The usual course is deterioration over weeks to months, with stabilization at a level of severe neurologic disability.

TREATMENT Rx

Treatment has been largely unsuccessful, but a small number of patients have improved with immunosuppressive therapy, including prednisone and IVIG.

Paraneoplastic Cerebellar Degeneration—Anti-Yo Antibodies

Paraneoplastic cerebellar degeneration is usually the initial manifestation of cancer. About 90% of patients have breast cancer, ovarian or other gynecologic tumors, SCLC, or Hodgkin's disease.

PATHOBIOLOGY

Patients with paraneoplastic cerebellar degeneration and carcinomas of the breast or ovary or other gynecologic cancers have been found to have high titers of an anti–Purkinje cell antibody, anti-Yo, in the serum and CSF, but other antibodies that react against Purkinje cell antigens can also be found (see Table 187-2). Autopsy reveals nearly complete loss of cerebellar Purkinje cells, with occasional inflammatory infiltrates.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Symptoms are often abrupt in onset and include dysarthria, ataxia, and oculomotor dysfunction. Syndromes such as paraneoplastic encephalomyelitis or LEMS may be superimposed. The diagnosis is based on clinical signs and may be aided by the presence of circulating antibody; however, anti-Yo antibodies are also found in patients who have a variety of cerebellar disorders but no evidence of cancer even on follow-up. CSF may reveal a pleocytosis and an elevated protein level or may be normal. MRI may show diffuse cerebellar atrophy but is often normal.

TREATMENT Rx

Treatment of the underlying malignancy occasionally results in significant improvement of cerebellar function. Rarely, responses have been seen to immunosuppressive therapy.

DERMATOLOGIC PARANEOPLASTIC SYNDROMES

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Recognition of cutaneous manifestations of malignancy can be critical for the early diagnosis and successful treatment of malignancy, but some syndromes are seen only with advanced, incurable disease. Cutaneous manifestations include direct involvement of the skin with tumor as well as the remote effects of cancer.

Benign skin changes may be the only sign of genetic syndromes that predispose to an increased risk for malignancy over a lifetime (see Table 187-3). Recognition of these syndromes is critical for screening, early diagnosis, and genetic counseling of affected family members.

Associations between cutaneous syndromes and underlying malignancies may be difficult to confirm. Generally, and unlike the situation in neurologic paraneoplastic syndromes, the skin condition and cancer should follow a parallel course, and the two diagnoses should be made at about the same time (Table 187-4). Some skin lesions are almost always associated with malignancy. Others, however, are nonspecific and are most commonly seen with nonmalignant conditions, making it difficult or impossible to connect the skin disease with the underlying malignancy. In addition, biopsies of the skin lesion are usually nonspecific, showing features identical to those when the same lesion is seen with a nonmalignant condition. The formation of tumor-related autoantibodies has been rarely associated with dermatologic paraneoplastic syndromes, although inflammatory cell infiltration may be seen.

The finding of a new skin lesion that is almost always associated with an underlying malignancy (e.g., Bazex's syndrome, erythema gyratum repens) should prompt a directed evaluation for that tumor. In contrast, diagnosis of a common problem that is only occasionally associated with cancer (e.g., pruritus, dermatomyositis) should prompt a careful physical examination and routine cancer screening as well as continued awareness of this possible association over time. The etiology of most dermatologic paraneoplastic syndromes is not well understood. The diagnosis of a paraneoplastic dermatologic syndrome is based on characteristic clinical and pathologic findings, including deposition of immunoglobulin G (IgG) and C3 at the basement membrane of affected skin in a variety of syndromes and the finding of an underlying malignancy.

Selected Specific Syndromes

ACANTHOSIS NIGRICANS

One of the most well-known paraneoplastic syndromes is acanthosis nigricans, whose pathogenesis is unclear. The tumor may produce factors that activate insulin-like growth factors or the insulin receptor in skin. Many tumors are known to produce transforming growth factor-α (TGF-α), which might activate epidermal growth factor receptors in skin, causing hyperpigmentation and thickening.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The skin lesions (Fig. 187-1) arise as velvety, verrucous hyperpigmentation of the neck, axilla, groin, and mucosal membranes, including the lips,

TABLE 187-4 EXAMPLES OF CUTANEOUS AND RHEUMATOLOGIC LESIONS ASSOCIATED WITH MALIGNANT DISEASE

SYNDROME	CLINICAL PRESENTATION	ASSOCIATED MALIGNANCY	ASSOCIATION/RISK
CUTANEOUS			
Acanthosis nigricans	Velvety, verrucous, brown hyperpigmentation involving body folds and mucosal membranes	Gastric cancer (also endocrinopathies)	High
Acquired hypertrichosis lanuginosa (malignant down)	Long, fine, nonpigmented lanugo hairs on face, trunk, limbs, axillae	Carcinomas of the lung, colon, breast, uterus, bladder, and lymphoma (also seen with AIDS, anorexia, thyrotoxicosis, porphyria, medications)	Moderate to high
Acquired tylosis	Hyperkeratosis of palms	Lung cancer, esophageal cancer	Likely low
Bazex's syndrome	Acral hyperkeratotic papulosquamous lesions, onychodystrophy	Squamous cell carcinomas of the oropharynx, larynx, bronchi, esophagus	High
Extramammary Paget's	Nonhealing superficial dermatitis	Genitourinary and rectal cancers	Moderate to high
Sign of Leser-Trélat	Diffuse eruption of seborrheic keratoses	Gastrointestinal cancers (also seen with aging)	Likely moderate
Tripe palms	Thickened, velvety palms	Lung and gastric cancers (almost always seen with acanthosis nigricans)	High
Necrolytic migratory erythema	Circinate erosive erythematous rash, stomatitis	Glucagonoma	Likely moderate
Erythema gyratum repens	Concentric rings on trunk and proximal extremities; may have pruritus	Carcinomas of the lung, esophagus, and breast	High
Erythroderma	Diffuse erythema	Lymphoma	Low to moderate
Paraneoplastic pemphigus	Painful erythematous lesions with blistering; mucous membrane ulcerations	Lymphoma	High
Sweet's syndrome	Red nodules or plaques, fever, dermal neutrophilic infiltrates	Acute myelogenous leukemia (also seen with infection)	Moderate
Pruritus	Excoriations, pruritus occurs on extremities, upper trunk, extensor surfaces	Lymphoma and myeloproliferative neoplasms (especially polycythemia vera)	Low
CUTANEOUS WITH ARTHRITIS OR MYOPATHY			
Amyloidosis	Waxy papules and nodules, occasionally with associated symmetrical arthritis; renal insufficiency	Multiple myeloma	Moderate
Palmar fasciitis-polyarthritis	Thickening of the palmar fascia; inflammatory distal symmetrical arthritis	Ovarian cancer	Low
Panniculitis-arthritis	Erythematous subcutaneous tender nodules; inflammatory monoarticular or polyarticular arthritis	Cancer of the pancreas (also pancreatitis)	Low
Eosinophilic fasciitis	Edema, thickening of the dermis and fascia associated with joint contractures	Breast cancer, myeloproliferative neoplasm, lymphoproliferative disease	Low
Dermatomyositis/polymyositis	Heliotrope rash (erythema in periorbital area); Gottron's papules (erythematous papules over phalangeal joints); proximal myopathy	Various tumors, primarily adenocarcinomas	Low to moderate, more with dermatomyositis
ARTICULAR			
Digital clubbing	Loss of nail bed angle	Lung cancer (also seen with benign cardiopulmonary disorders)	Low
Hypertrophic pulmonary osteoarthropathy	Periostosis of long bones; pain and swelling in distal joints	Lung cancer	High
Carcinoma polyarthropathy	Sudden onset of seronegative arthritis at a late age	Cancers of the breast and lung	Low to moderate
Gout	Classic acute painful gouty arthritis	Acute leukemias, lymphomas associated with rapid tumor cell turnover and tumor lysis	Low
VASCULAR			
Leukocytoclastic vasculitis	Palpable purpura, urticaria, maculopapular rash with or without arthritis	Myeloproliferative and lymphoproliferative neoplasms, myelodysplasia; rarely with adenocarcinoma and melanoma	Low to moderate
Polyarteritis nodosa	Cutaneous and/or mesenteric vasculitis; fever, myalgia; arthritis; mononeuritis multiplex	Hairy cell leukemia	Low
Raynaud's syndrome	Classic Raynaud's with progression to digital necrosis or gangrene common	Lymphoma, leukemia, myeloma, and cancers of the lung, ovary, small bowel, breast, pancreas, kidney	Low to moderate in patients older than 50 years
Erythromelalgia	Painful, erythematous digits, relieved by aspirin	Myeloproliferative neoplasms (especially essential thrombocythemia)	Moderate to high

periocular area, and anus. Although acanthosis nigricans clearly occurs as a benign entity associated with obesity and endocrinopathy, its appearance in older adults, especially when it includes mucosal lesions, has been highly associated with malignancies of the gastrointestinal tract as well as other adenocarcinomas. The lesions often regress with successful treatment of the underlying tumor.

PARANEOPLASTIC PEMPHIGUS

This syndrome is manifested by ulcerative and blistering mucocutaneous lesions with acantholysis; it is primarily associated with lymphoma (Chapters 191 and 192), other lymphoproliferative diseases, and thymic cancers. Patients have high titers of autoantibodies to tumor antigens that cross-react with antigens at the epidermal cell junction, including the plakin family of

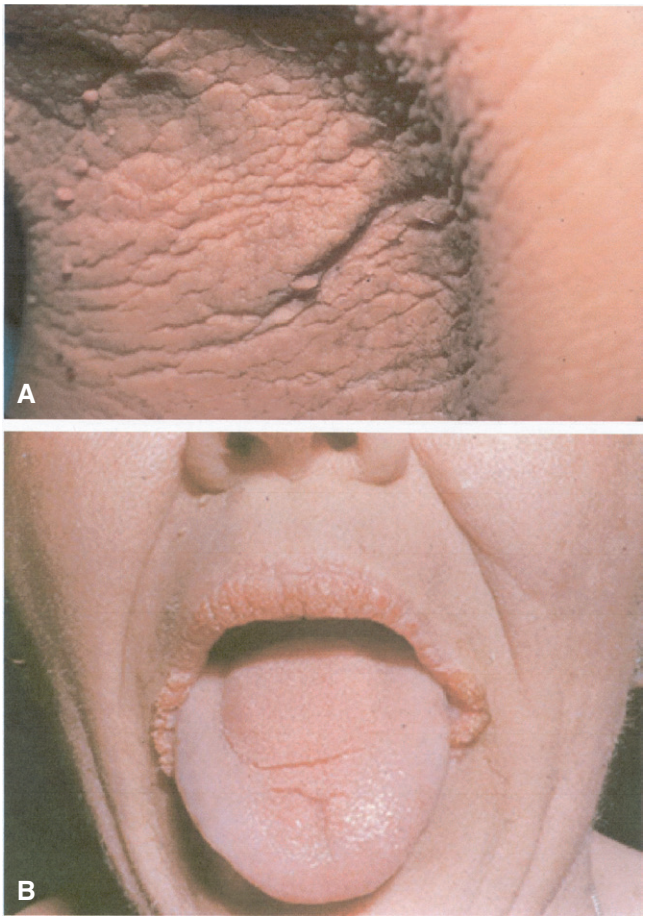

FIGURE 187-1. Acanthosis nigricans. A, Paraneoplastic acanthosis nigricans with a velvety hyperpigmented rash in the axilla in a patient with gastric cancer. **B,** Acanthosis nigricans of the oral mucosa. This pattern of involvement is almost always associated with cancer. (Courtesy of Dr. Timothy Berger.)

desmosomal proteins and desmogleins; indirect immunofluorescent staining shows IgG and C3 deposition on the surface of keratinocytes and on the basement membrane zone. Antibody titers may correlate with the severity of the skin disease and its response to therapy.

DIAGNOSIS

The diagnosis of paraneoplastic pemphigus should include finding specific major criteria including a polymorphic cutaneous eruption, concurrent internal neoplasia, and a specific immunoprecipitation pattern on testing of serum. Minor criteria include histologic evidence of acantholysis, intercellular and basement membrane staining with antibodies to IgG and C3 on direct immunofluorescence, and staining of rat urothelium with antibodies to desmoplakin on indirect immunofluorescence. The development of paraneoplastic pemphigus in patients with lymphoma (Chapters 191 and 192), chronic lymphocytic leukemia (Chapter 190), Castleman's disease (Chapter 191), and, less commonly, other malignancies is associated with a very poor prognosis and is often associated with pulmonary involvement.

BAZEX'S SYNDROME

Bazex's syndrome is a papulosquamous eruption that is also termed acrokeratosis paraneoplasia owing to the characteristic location of the hyperkeratotic lesions on the palms and soles. It is seen in association with squamous cell carcinoma of the head and neck (Chapter 196) as well as other malignancies involving the oropharynx or larynx. Bazex's syndrome has been postulated to be caused by antibodies that are directed against the tumor but that cross-react with keratinocyte or basement membrane antigens, similar to those in paraneoplastic pemphigus, or a T-cell-mediated immune response to epidermal tumor–like antigens.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The findings are similar in appearance to psoriatic plaques but are seen in unexpected locations including the ears, nails, nodes, fingers, palms, and soles. These lesions can predate the diagnosis of malignancy by as long as 1 year, and they may progress in parallel with the underlying tumor. The main differential diagnosis involves exclusion of benign acral variants of psoriasis.

RHEUMATOLOGIC PARANEOPLASTIC SYNDROMES

DEFINITION AND EPIDEMIOLOGY

A wide variety of rheumatologic paraneoplastic syndromes have been associated with underlying malignancies, but almost all of these syndromes are identical to their benign counterparts (see Table 187-4). The rheumatologic paraneoplastic syndromes can be classified as cutaneous with arthritis, articular, or vasculitic. Paraneoplastic rheumatologic syndromes may either coincide with the diagnosis of malignancy or precede it by several years, although the longer the interval between diagnoses, the less likely the association with cancer. Patients with a variety of rheumatologic diseases are known to have an increased risk of subsequent malignancy. For example, Sjögren's syndrome (Chapter 276) is associated with a slightly increased risk of lymphoproliferative disease, although the cause of this relationship remains unclear.

CLINICAL MANIFESTATIONS

In contrast to the nonparaneoplastic rheumatologic syndromes, rheumatologic paraneoplastic syndromes are associated with rapid onset, late age at onset (>50 years), negative serologies, and effusions characterized by the absence of inflammatory markers. Considerable overlap exists among the rheumatologic, dermatologic, and neurologic paraneoplastic syndromes.

DIAGNOSIS

In general, when a rheumatologic paraneoplastic syndrome is suspected, screening should include a physical examination, laboratory tests, and standard radiographic tests, such as a mammogram.

POEMS Syndrome

Osteosclerotic myeloma (Chapter 193) associated with the POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal protein, and skin changes suggestive of *s*cleroderma) is a rare condition that has features of neurologic, rheumatologic, and dermatologic paraneoplastic syndromes owing to the effects of a circulating paraprotein. It is likely that other factors also play a role in the pathogenesis of POEMS syndrome, including production of high levels of vascular endothelial growth factor and inflammatory cytokines.

Hypertrophic Osteoarthropathy

One of the more common and specific rheumatologic paraneoplastic syndromes is hypertrophic osteoarthropathy, which arises as an oligoarthritis or polyarthritis of the distal joints with clubbing, tender periostitis of the distal long bones, and noninflammatory synovial effusions. Hypertrophic osteoarthropathy may affect up to 10% of patients with adenocarcinoma of the lung. It is also seen with a variety of other pulmonary malignancies, including lung metastases from other primary sites. The etiology is unknown. Laboratory studies often reveal an elevation in the erythrocyte sedimentation rate; bone radiographs show linear ossification of the distal long bones separated by a radiolucent zone from the underlying cortex (Fig. 187-2). Treatment is symptomatic with anti-inflammatory agents; successful treatment of the underlying tumor may also improve the signs and symptoms of this syndrome.

Tumor-Induced Osteomalacia

Tumor-induced osteomalacia, a rare paraneoplastic syndrome associated with benign mesenchymal tumors and characterized by inappropriately low levels of serum 1,25-dihydroxyvitamin D and renal phosphate wasting thought to be due to tumor expression of fibroblast growth factor 23, is discussed in detail in Chapter 186.

Dermatomyositis and Polymyositis

Dermatomyositis or polymyositis has been reported to be associated with an underlying malignancy in less than 10% to as high as 60% of cases (Chapter 277). Dermatomyositis is more strongly and frequently associated with malignancy than is polymyositis. Studies of patients with dermatomyositis report a two- to four-fold increased risk of underlying malignancy, including cancer of the lung, ovaries, breast, gastrointestinal tract, and testes. The true incidence of malignancy in patients diagnosed with

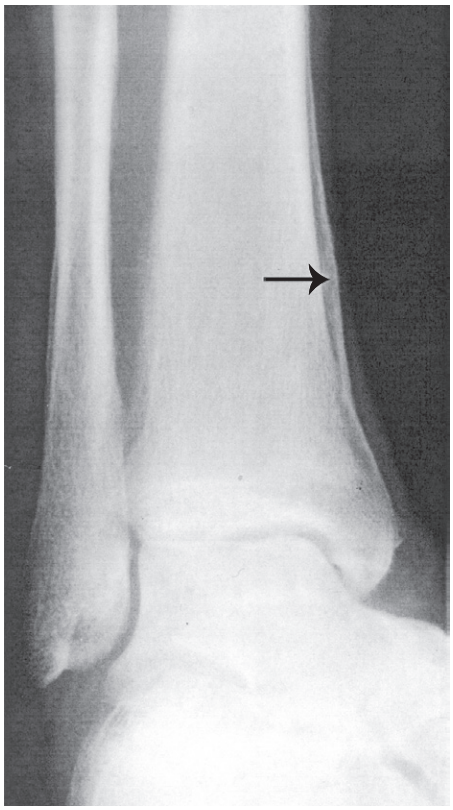

FIGURE 187-2. Hypertrophic pulmonary osteoarthropathy characterized by periosteal elevation of the tibia (*arrow*). (Courtesy of Dr. Lynne S. Steinbach.)

dermatomyositis is probably in the range 10 to 15%. Although the etiology is unknown, autoantibodies to muscle have been described. These autoantibodies are not well characterized and do not appear to be directed to known tumor antigens. The diagnosis of malignancy should be made within 1 year preceding or following the diagnosis of suspected paraneoplastic dermatomyositis; a longer duration of dermatomyositis without the development of cancer substantially decreases the risk of an associated malignancy.

Hematologic Paraneoplastic Syndromes

Routine blood testing may identify a hematologic paraneoplastic syndrome as well as the underlying malignancy. Hematologic paraneoplastic syndromes may involve all three cell lines.

RED CELLS

One of the most prevalent and commonly recognized paraneoplastic syndromes, seen with many cancers, is normochromic, normocytic anemia associated with a low reticulocyte count (Chapter 161). This hypoproductive anemia, generally termed *anemia of chronic disease,* or *anemia of chronic inflammation,* must be differentiated from anemia as a result of side effects of treatment or direct tumor infiltration of the bone marrow. It is associated with inappropriately low serum erythropoietin levels as well as the inability to reuse iron. Cytokines, including interleukin-1 (IL-1), tumor necrosis factor (TNF), and TGF-β, released by the tumor or local inflammatory cells mediate this disorder. Hypoproductive anemia may be effectively treated in patients with advanced malignancies with subcutaneous injections of erythropoietin or darbepoetin, although this treatment may possibly be associated with increased risk of thromboembolism (at high hemoglobin levels) and cancer progression (Chapter 161). Because of the potential risk of tumor stimulation, erythropoietic growth factors are not recommended for use in patients with early-stage or curable cancer. Pure red cell aplasia (Chapter 168) is a rare syndrome associated with cancer of the thymus gland (thymoma; Chapter 99) and is thought to be due to an autoimmune mechanism. Bone marrow examination shows absent red cell precursors.

Paraneoplastic anemia can also be caused by hemolysis (Chapter 163) related to warm- or cold-reacting antibodies in the setting of B-cell malignancies, especially chronic lymphocytic leukemia (Chapter 190) and lymphoma (Chapters 191 and 192). Treatment is directed toward the underlying lymphoproliferative disease but may also include IVIG, steroids, and possibly splenectomy for warm antibody hemolysis; cold-reacting hemolysis may require plasmapheresis. Microangiopathic hemolytic anemia (Chapter 163) with thrombocytopenia may occur with mucinous adenocarcinomas or after specific types of chemotherapy. Erythrocytosis is an uncommon paraneoplastic syndrome that is associated with tumors that produce erythropoietin, including renal cell cancer, hepatocellular carcinoma, and posterior fossa tumors (e.g., cerebellar hemangioblastoma) (Chapters 169 and 195).

WHITE CELLS

Leukocytosis (Chapter 170) is common in advanced cancer. Although infection and myeloproliferative disease must be excluded, the leukocytosis is generally caused by cytokines that are probably produced by the tumor itself, including granulocyte colony-stimulating factor and granulocyte-macrophage colony-stimulating factor. Although paraneoplastic leukocytosis requires no specific treatment, it may represent a poor prognostic sign. Eosinophilia (Chapter 173) can be seen with lymphoproliferative diseases.

PLATELETS

Paraneoplastic thrombocytosis, which is a relatively common laboratory finding, is caused by tumors that produce stimulatory cytokines (IL-6, thrombopoietin); platelet counts usually do not exceed 1 million. This type of secondary or reactive thrombocytosis, in contrast to the myeloproliferative neoplasm essential thrombocythemia (Chapter 169), is generally not associated with complications and does not require specific treatment. However, the underlying neoplasm may cause hypercoagulability by other mechanisms (see later). Iron deficiency, especially caused by gastrointestinal blood loss, should be excluded. Thrombocytopenia is uncommon except when it is associated with microangiopathic hemolytic anemia, disseminated intravascular coagulopathy (DIC), or marrow infiltration.

THROMBOSIS

EPIDEMIOLOGY

The best known and one of the first described hematologic paraneoplastic syndromes is Trousseau's syndrome, or the association of venous or arterial thrombosis with malignancy (Fig. 187-3). Although thrombosis frequently complicates progressive cancer, it may also be the first sign of cancer and predate diagnosis by a year or more. In approximately 10% of patients, deep vein thrombosis may herald an underlying malignancy, particularly in patients who present with an initial episode without other obvious risk factors, in the setting of recurrent thrombosis despite adequate doses of warfarin (warfarin resistance), or when the thrombosis occurs in unusual sites (e.g., subclavian vein, Budd-Chiari syndrome, portal vein thrombosis).

PATHOBIOLOGY

Paraneoplastic thrombosis is most commonly associated with adenocarcinomas, particularly of the stomach, breast, pancreas, and ovary. The etiology of thrombosis in patients with cancer is complex; tumor cells can activate coagulation through a number of mechanisms, including production of procoagulant mediators (e.g., sialic residues of tumor-secreted mucin), release of proangiogenic or inflammatory cytokines, direct interaction with host vasculature (endothelial damage) and blood cells through adhesion molecules, and tumor-mediated endothelial damage . Thrombosis may be associated with low-grade DIC (Chapter 178) and abnormal platelet activation. Risk factors for thrombosis in patients with known malignancy (Chapter 179) include the procoagulant effects of chemotherapy, indwelling catheters, immobility, surgery, older age, infection, obesity, prior thrombosis, and advanced stage of disease.

DIAGNOSIS

The evaluation of patients with a malignancy-associated thrombosis should include laboratory testing for DIC as well as a careful assessment of bleeding risk at sites of tumor, such as metastases to the nervous system, involvement of the gastrointestinal tract, or varices from portal hypertension in patients with liver involvement. It is important to exclude inherited clotting disorders, especially in younger patients who present with deep vein thrombosis without known underlying cause (Chapter 179) and in patients who develop a clot while taking tamoxifen.

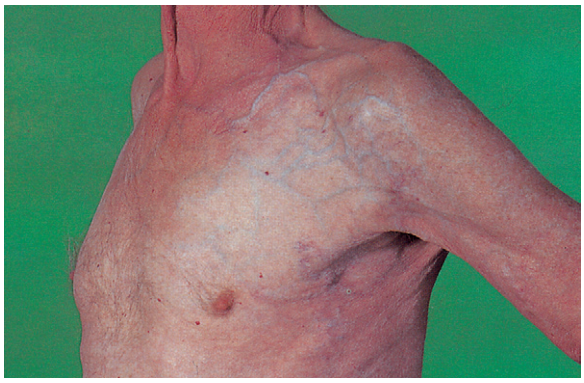

FIGURE 187-3. Thrombophlebitis in superficial or deep veins is relatively common in many forms of malignant disease, but it is particularly associated with carcinoma of the pancreas and sometimes is the presenting feature. In this patient, thrombosis in the veins of the upper arm is associated with an extensive collateral circulation in the superficial veins around the shoulder. Recurrent episodes of thrombophlebitis may precede the diagnosis of carcinoma by many months, and their occurrence in an otherwise apparently fit patient should lead to a search for underlying malignancy, especially in the pancreas. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

TREATMENT Rx

Treatment for thrombosis without evidence of DIC should include initial standard anticoagulation with heparin. Long-term treatment with low-molecular-weight heparin has been demonstrated to be superior to warfarin for preventing recurrent thromboembolism without increasing the risk of bleeding. Prophylactic low-dose or dose-adjusted subtherapeutic warfarin does not prevent or reduce catheter-related thromboses in patients with cancer. Venous interruption (Chapters 81 and 98) is associated with significant complications and should be reserved for patients without other treatment options; temporary devices may be placed when anticoagulation must be delayed for surgery or other reasons. Successful treatment of the underlying malignancy is the most effective way to reduce the risk of thrombosis.

HEMORRHAGIC PARANEOPLASTIC SYNDROMES

DIC caused by activation of the hemostatic system with consumption of coagulation factors and platelets can result in both thrombosis and hemorrhage (Chapter 178). Acute DIC can be seen with a variety of malignancies. Essentially all patients with acute promyelocytic leukemia (Chapter 189) either present with acute DIC and associated hemorrhage or develop it during treatment. Procoagulant material released from the leukemia cells activates the fibrinolytic pathway; treatment with all-*trans*-retinoic acid and low-dose heparin has significantly reduced the complications of hemorrhage with this leukemia.

Other causes of malignancy-associated bleeding disorders include paraproteins that interfere with fibrin polymerization, amyloid deposits associated with monoclonal gammopathies such as multiple myeloma (Chapters 194), and, rarely, acquired von Willebrand's disease associated with lymphoproliferative and myeloproliferative disorders (Chapter 176). Increased fibrinolysis may be seen in patients with advanced prostate cancer (Chapter 207).

RENAL PARANEOPLASTIC SYNDROMES

Renal involvement in the setting of malignancy may be due to direct tumor infiltration of the renal parenchyma or, less commonly, to a paraneoplastic syndrome. Paraneoplastic syndromes involving the kidney may be caused by tumor-related hormone production, may directly involve the glomerulus or the microvasculature, may be related to proteins produced by the tumor (e.g., amyloid, paraproteins), or may be caused by electrolyte disorders (hyponatremia, hyperuricemia). Hyponatremia due to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) is commonly associated with both limited and advanced-stage SCLC; some series have suggested a worse outcome in these patients (Chapter 186).

Glomerulonephritis

The renal paraneoplastic syndrome most clearly linked to malignancy is membranous glomerulonephritis, which is characterized by nephrotic range proteinuria, edema, hypoalbuminemia, microscopic hematuria, hypertension, and increased risk of thrombosis (Chapter 123). Associated cancers include adenocarcinomas of the lung (Chapter 197), breast (Chapter 204), and stomach (Chapter 198), as well as others. The pathology is related to thickening of the glomerular basement membrane from subepithelial deposition of tumor antigen that has reacted with circulating immunoglobulins (IgG) and complement. Other glomerular lesions include minimal change nephropathy complicating lymphoproliferative disorders, in particular Hodgkin's disease (Chapter 192); rapidly progressive glomerulonephritis associated with lymphoplasmacytic diseases; and other glomerulopathies (including nephrotic syndrome and minimal change disease) associated with a variety of malignant diseases.

It may be very difficult to differentiate a renal paraneoplastic syndrome from a benign disorder of the kidney; a biopsy demonstrating immune complex deposition, as well as a parallel course with an underlying malignancy, can help make the diagnosis.

Microvascular Disease

Renal microvascular involvement is uncommon and may be due to vasculitis or microangiopathy. Vasculitis may be caused by cryoglobulinemia in patients with hepatitis C–related hepatocellular carcinoma (Chapter 202) or rarely in patients with IgA monoclonal gammopathy in association with cancer of the lung. Thrombotic microangiopathy (hemolytic-uremic syndrome) or thrombotic thrombocytopenic microangiopathy (Chapter 175) is most commonly a complication of chemotherapy, including mitomycin C, cisplatin, and other drugs, but it may also be seen in association with a variety of advanced-stage adenocarcinomas as well as with promyelocytic leukemia. The etiology is unknown; the underlying malignancy should be treated, if possible, and plasma exchange may be helpful.

HEPATOPATHY

Paraneoplastic hepatopathy is an uncommon disorder characterized by hepatic dysfunction with elevated liver enzymes and abnormal synthetic function with fever and weight loss. This syndrome has been associated with nonmetastatic renal cell cancer (Chapter 203) and is probably due to either autoimmune effects or direct toxicity from tumor-related products. This unusual syndrome resolves with resection of the tumor.

FEVER AND CACHEXIA

Fever (Chapters 289), night sweats, and cachexia are nonspecific symptoms that, when seen in the absence of infection or a known disorder, suggest the diagnosis of an underlying malignancy. Cytokines clearly play a pathogenetic role in inducing both fever and cachexia. TNF-α (previously known as cachectin), interleukins (including IL-1 and IL-6), and interferon-γ are produced directly by the tumor or by tumor-associated host inflammatory cells, such as macrophages, which then results in a catabolic state. Cytokines may produce fever directly by acting at the hypothalamic thermoregulatory center (Chapters 289). In addition to the burden of tumor and the production of cytokines, cachexia may be caused or worsened by the side effects of cancer treatment, by intestinal blockage or malabsorption caused by tumor infiltration, and by depression.

Fever is generally cyclic and may be associated with drenching night sweats. Symptoms resolve with treatment of the underlying tumor, and return of fever usually heralds relapse. When treatment of the tumor is not possible or is ineffective, nonsteroidal anti-inflammatory agents or steroids given around the clock significantly improve quality of life. Although fever is most commonly seen in association with lymphoproliferative disease (Chapters 191 and 192), renal cell carcinoma (Chapter 203), and leukemias (Chapters 189 and 190), it may also occur with other cancers.

Cachexia, or the cancer wasting syndrome, is probably the single most common paraneoplastic syndrome, eventually affecting up to 80% of patients with cancer. This syndrome is characterized by anorexia, muscle wasting, loss of subcutaneous fat, and fatigue. It appears to be caused by a combination of protein wasting, malabsorption, immune dysregulation, and increased glucose turnover in the setting of tumor-induced increases in energy expenditure. Successful treatment of the underlying tumor reverses the process; most patients have advanced disease, for which treatment results in modest success at best. Megestrol acetate given in high concentrations in liquid form (400 to 800 mg/day) can significantly improve appetite and result in weight gain, as can dronabinol (Marinol; 2.5 to 5 mg three times a day). Corticosteroids may also help. Although agents that block TNF production are theoretically attractive to treat cancer-related cachexia, there is also concern that such agents may block cytokines that inhibit tumor growth. In addition, preclinical

data suggest that antibodies to parathyroid hormone–related protein may block the production of inflammatory cytokines in cancer; whether this effect is of clinical value remains a research question.

MYELODYSPLASTIC SYNDROME

ALAN F. LIST AND RAMI S. KOMROKJI

DEFINITION

Myelodysplastic syndrome (MDS) comprises a heterogeneous group of hematopoietic stem cell malignancies resulting in variable degrees of cytopenias with a tendency to progress to acute myeloid leukemia (AML). Pathologically, the disease is characterized by abnormal morphology and cytologic dysplasia.

EPIDEMIOLOGY

For many years, the incidence of MDS was not well characterized and was underestimated. In 2001, MDS became reportable to the Surveillance, Epidemiology, and End Results (SEER) cancer registry database; from these data, it is estimated that approximately 10,000 MDS cases are diagnosed annually in the United States. The overall incidence of MDS approaches 4 per 100,000, with a male predominance and a clear increase in incidence with age. In populations older than 60 years, the incidence of MDS approaches that for other hematologic malignancies like multiple myeloma and chronic lymphocytic leukemia (CLL), reaching approximately 50 per 100,000. Nonetheless, the complexities in diagnosis, nonspecific symptomatology, and underreporting make accurate estimates of incidence difficult.

Most cases of MDS are sporadic. There are few hereditary syndromes associated with MDS per se, but two ill-defined pediatric conditions, juvenile myelomonocytic leukemia (JMML) and the monosomy 7 syndrome, mimic MDS and show a familial tendency. Heterozygous germline mutations of the runt-related transcription factor 1 *(RUNX1)* gene are associated with an autosomal dominant familial predisposition to platelet abnormalities and MDS, with a median incidence of either MDS or AML among carriers of 35%. In the elderly population, other than senescence, the exact causes of MDS are not well recognized. Risk factors include benzene exposure, chemical or solvent exposure, tobacco smoke, and family history.

Therapy-related MDS (t-MDS) refers to a subset of MDS that is associated with prior exposure to mutagenic antineoplastic drugs or radiation. The increasing success in treatment of solid tumors is accompanied by a challenge whereby the incidence of t-MDS in survivors is on the rise. The risk of t-MDS varies from less than 1% (adjuvant breast cancer chemotherapy studies) to 15% (heavily treated lymphoma patients), depending on the age of the individual, class of antineoplastics, and duration of cytotoxic therapy.

PATHOBIOLOGY

The pathobiology of MDS is complex and remains under intense investigation. As opposed to other hematologic disorders like chronic myeloid leukemia (CML), there is unlikely to be a sentinel genetic event [i.e., t(9:22)]. The observed morphologic dysplasia is a common pathologic phenotype for the different underlying biology in various subsets of MDS patients. Ineffective erythropoiesis, genetic abnormalities, allelic haploinsufficiency, immune derangements, and microenvironment changes are examples of underlying disease biology.

Accelerated apoptosis is the hallmark of early MDS, which explains the paradoxical findings of normal or hypercellular bone marrow in most patients, accompanied by peripheral cytopenias. The malignant clone has an inherent susceptibility to premature apoptotic cell death. Other factors are recognized that amplify apoptotic sensitivity in MDS and include hematopoietic suppression from stromal production of inhibitory cytokines (e.g., tumor necrosis factor-α) and direct T-cell suppression akin to aplastic anemia. As the disease progresses, additional antiapoptotic signals are acquired, resulting sometimes in clonal evolution and transformation to higher-risk disease and, in some cases, to acute myeloid leukemia.

Cytogenetic Abnormalities

Cytogenetic abnormalities are observed in approximately 50% of MDS patients. The loss of genetic material is highly conserved among MDS and has led to a haploinsufficiency model of tumorigenesis. It is hypothesized that loss of even a single allele in the affected chromosomal regions may decrease the level and activity of critical gene products, presumably tumor suppressor genes. This may lead to dysplastic features, cytopenias, and the propensity to transform to AML. The most common cytogenetic abnormalities in MDS are deletions of the long arm of chromosomes 5, 7, and 20. Chromosome 5q deletion is present in approximately 15% of de novo MDS and 50% of t-MDS; abnormalities of 5q or 7, or both, are present in 70% of t-MDS. A potential validation of the haploinsufficiency model is illustrated in the analysis of a hematologic phenotype resulting from inactivation of genes encoded within the chromosome 5q common deleted region (CDR). Early growth response factor 1 *(EGR1)*, a member of the Wilms' tumor 1 (WT1) family of transcription factors, is one such gene located on 5q. It is a direct transcriptional activator of TP53, an important tumor suppressor, and is downstream of many signaling pathways. Ribosomal protein S14 *(RPS14)* is another candidate gene located more distally on 5q, and within the CDR linked to the 5q− syndrome (discussed later). This gene product is required in the 40s subunit of the ribosome and has tumor suppressor properties as well as direct action on erythropoiesis. Haploinsufficiency of the *RPS14* gene alone recapitulates the hematologic features of the 5q− syndrome, resulting in impaired erythroid differentiation and proliferation.

There are some chromosomal abnormalities that are associated with specific MDS subtypes. For example, the *MLL (HRX)* gene localized to chromosome 11q23 has been implicated in the pathogenesis of de novo AML and in t-MDS/AML. It is a translocation t(11;16)(q23;p13), which results in a fusion protein between *MLL* and the promoter of CBP (cyclic adenosine monophosphate response element binding protein [CREB] binding protein). The t(3;21)(q22;q22) translocation is also associated with t-MDS and results in fusion of *RUNX1* (formerly *AML1*) with one of several fusion partners on chromosome 3, including *EAP, EVI1,* and *MDS. RUNX1*'s product has been implicated in regulating the expression of important granulocyte elements such as myeloperoxidase and neutrophil elastase. Another translocation, t(5;12)(q33;p13), results in an activating mutation of *PDGFR*-β and is associated with chronic myelomonocytic leukemia (CMML). This is important because the *PDGFR* mutation renders the disease vulnerable to imatinib is some cases.

Epigenetics

Although loss of genetic material is common in MDS, 50% of patients with MDS have a normal karyotype. Therefore, undetectable translocations, point mutations, or epigenetic changes controlling gene expression may be responsible for the hypothesized loss of function. Because of the activity of hypomethylating agents in MDS, the role of epigenetic changes has emerged as a key contributor. DNA methyl transferase (DNMT) is responsible for methylating, and thus inactivating, gene promoters within CpG islands. Aberrant

methylation of presumed tumor suppressor genes such as *p15* has been observed in MDS with adverse prognostic connotations, thereby providing an alternate mechanism by which tumor suppressors are inactivated in the pathogenesis of MDS.

Point Mutations

Point mutations represent another mechanism by which tumor suppressor function can be altered. Several activating mutations have been observed in a minority of MDS cases. Activating mutations in the *RAS* gene family occur in 5 to 15% of patients with MDS and are associated with progression to AML. Activating *FLT3* mutations have also been reported and are associated with progression to AML. Recent investigation has described multiple, novel, loss-of-function mutations in a presumed tumor suppressor protein known as TET2. It is hypothesized that these mutations may have a role in MDS progression and AML prognosis, and may be present in up to 15% of MDS cases. Also, previously cryptic mutations have been elucidated using single nucleotide polymorphism technology on c-Cbl, a known regulator of tyrosine kinase. The *c-Cbl* mutation has been seen most in CMML and, in vivo, confers a proliferative advantage.

CLINICAL MANIFESTATIONS

The hallmark clinical manifestation in MDS is persistent or progressive cytopenias. The cytopenia is usually insidious and, in retrospect, may have been present for months before diagnosis. Neutropenia has been reported in 24 to 39% of patients, anemia in 45 to 93%, and thrombocytopenia in 28 to 45%. Symptoms from MDS reflect the magnitude and lineage of cytopenias and their interactions with comorbidities. For example, a patient with coronary artery disease may present with mild anemia associated with an increase in the frequency and duration of angina. A patient on chronic anticoagulation may present with petechiae, bruising, or frank hemorrhage secondary to thrombocytopenia or platelet dysfunction. Or, a diabetic patient may present with signs and symptoms of poor wound healing and infection secondary to neutropenia or neutrophil dysfunction (i.e., impaired chemotaxis and microbial killing in those neutrophils that are produced despite adequate absolute number).

The clinical course of MDS can be subdivided in two broad categories. Approximately 70% of patients with MDS have a clinical course primarily involving progressive cytopenia. The rate of progression of these cytopenias is highly variable, as is their effect on morbidity and mortality. Approximately half of the theses patients die of causes unrelated to MDS, whereas the other half succumb to complications of marrow failure.

The remaining 30% of patients evolve into AML. The clinical course of these patients is grimmer because the transformed AML is notoriously refractory to conventional chemotherapy. If a complete remission is achieved, bone marrow transplantation remains the mainstay of therapy and the only chance for a durable remission.

DIAGNOSIS

The diagnosis of MDS requires the presence of dysplastic hematopoiesis along with the exclusion of disorders that may be a secondary cause of dysplasia. Dysplasia can first be recognized by inspection of the peripheral smear. Neutrophils may show degranulation in the cytoplasm and hyposegmentation of the nucleus (the pseudo-Pelger-Huët anomaly) (Fig. 188-1). The erythrocytes may be mildly macrocytic, a hallmark of MDS, or in cases of refractory anemia with ring sideroblasts, microcytic. The mean corpuscular volume (MCV) ranges between 100 and 110 mm^3, and the erythrocytes are usually hypochromic. Other changes can be seen in the erythrocyte morphology that reflects a hypercellular marrow or even splenomegaly seen in CMML, an MDS variant with myeloproliferative features. Some of these changes include tear drops (dacryocytes), red cell fragments, rouleaux formation, and helmet cells.

Bone marrow aspirate and biopsy are indispensable in the diagnosis of MDS. Dysplastic features may be seen in one or all three hematopoietic lineages. Dysgranulopoiesis, for example, can result in abnormal cytoplasmic granules and pleomorphic nuclear forms. Hyposegmentation of the nucleus and Auer rods (see Fig. 160-25 in Chapter 160) may be seen, with a greater proportion of immature forms including myeloblasts. Dyserythropoiesis is characterized by pleomorphic nuclear forms, ringed sideroblasts, megaloblastic changes, and nuclear-cytoplasmic dyssynchrony. Lastly, dysplasia affecting megakaryocytes can include bizarre nuclear figures, decreased ploidy, separated nuclei (so-called nuclear dispersion), and small micromegakaryocytes. The marrow cellularity is usually increased as a result of ineffective hematopoiesis. Myeloblasts may also be increased, and indeed the percent increase is important in the classification and prognosis of MDS.

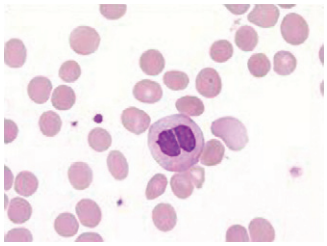

FIGURE 188-1. Pseudo-Pelger-Huët phenomenon. Abnormal, acquired, hyposegmented (usually bilobed) nucleus in neutrophil of a patient with MDS, resembling the familial Pelger-Huët anomaly (see Fig. 160-20 in Chapter 160).

TABLE 188-1 DIFFERENTIAL DIAGNOSIS OF MYELODYSPLASTIC SYNDROME

CONGENITAL DISORDERS
Hereditary sideroblastic anemia Fanconi's anemia Diamond-Blackfan syndrome Kostmann's syndrome Shwachman's syndrome Down syndrome
VITAMIN DEFICIENCY
B_{12}, folate, or iron deficiency
DRUG TOXICITY
Marrow suppression from oral or parenteral medications Toxins Chemotherapy and/or radiation therapy Alcohol
ANEMIA OF CHRONIC DISEASE
Renal failure Chronic infection, including tuberculosis Rheumatologic disorders
VIRAL MARROW SUPPRESSION
Including Epstein-Barr virus, parvovirus B19, human immunodeficiency virus, and others
MARROW INFILTRATION
Acute and chronic leukemias Metastatic solid tumor infiltration
PAROXYSMAL NOCTURNAL HEMOGLOBINURIA
HYPERSPLENISM

Characteristic clonal cytogenetic abnormalities are another helpful clue in the diagnosis of MDS, although normal cytogenetics do not exclude the diagnosis. Most cytogenetic abnormalities in MDS are characterized by loss of genetic material through deletions. Nonrandom chromosomal abnormalities associated with MDS include isolated chromosome 5q deletion (5q–), which occurs in approximately 15% of de novo MDS and 50% of secondary MDS; monosomy 7; trisomy 8; 21q–; 17q–; and 20q–.

Differential Diagnosis

Although MDS should be considered in older adults with an insidious presentation of cytopenia, more common causes should be excluded (Table 188-1). Because this disease predominantly affects elderly people, polypharmacy and vitamin deficiencies (iron, folate, and B_{12} deficiency) should be strongly considered as a cause of cytopenia and corrected before proceeding in the diagnosis of MDS. Infectious causes should be considered to include parvovirus B19, human immunodeficiency virus (HIV), and viral hepatitis. Splenic sequestration should also be considered in the presence of splenomegaly on physical examination, potentially arising from portal hypertension from cirrhosis, myelofibrosis, and infiltrating splenic diseases such as lymphoma. Alcoholism can cause cytopenia secondary to direct myelosuppression, vitamin deficiency, and with intrinsic liver disease, sequestration by the spleen. Autoimmune disorders and hypogonadism in men rarely cause cytopenia. Lastly, a careful history should focus on a personal history of congenital disorders that may causes cytopenias. Once a thorough history and physical examination, review of peripheral smear, and exclusion of the above causes is complete, a bone marrow (BM) biopsy with cytogenetic analysis is

warranted. The BM biopsy may then reveal hypercellularity with cytologic dysplasia (MDS), BM aplasia (aplastic anemia), or marrow infiltration with neoplastic cells (metastatic disease, leukemia).

Classification

In 1976, the French-American-British (FAB) classification was first reported and later revised in 1982 to include five MDS subtypes: refractory anemia (RA); refractory anemia with ring sideroblasts (RARS); refractory anemia with excess blasts (RAEB); CMML; and refractory anemia with excess blasts in transformation (RAEB-t). The FAB classification has since been revised by the World Health Organization (WHO) (Table 188-2) and expanded to more accurately classify patients into more homogeneous subgroups. The most important changes include lowering the threshold for AML diagnosis to 20% blasts instead of 30% and thereby omitting FAB RAEB-t subtype; recognizing CMML as a related but stand-alone MDS subtype included in the new category of myelodysplastic myeloproliferative neoplasms (MDS/MPN), and inclusion of the 5q– syndrome, a subtype of MDS that is characterized by this isolated cytogenetic abnormality, clinical distinctness, and unique response to lenalidomide.

TABLE 188-2 WORLD HEALTH ORGANIZATION CLASSIFICATION OF MYELODYSPLASTIC SYNDROME

CATEGORY	PERIPHERAL BLOOD	BONE MARROW
1a. RA without dysplasia	Blasts <1%; monocytes <1000/mm^3	Blasts <5%; ringed sideroblasts <15%
1b. RA with dysplasia	Same + dysgranulocytes and/or giant platelets	Same + dysgranulocytes and/or dysmegakaryocytes
2a. RARS without dysplasia	Blasts <1%; monocytes <1000/mm^3	Blasts <5%; ≥15% ringed sideroblasts
2b. RARS with dysplasia	Same + dysgranulocytes and/or giant platelets	Same + dysgranulocytes and/or dysmegakaryocytes
3a. RAEB-I	Blasts 1-4%; monocytes <1000/mm^3	Blasts 5-10%
3b. RAEB-II	Blasts 5-19%; monocytes <1000/mm^3	Blasts 11-19%

RA = refractory anemia; RAEB = refractory anemia with excess blasts; RARS = refractory anemia with ringed sideroblasts.

TABLE 188-3 INTERNATIONAL PROGNOSTIC SCORING SYSTEM (IPSS)

	Points				
PROGNOSTIC VARIABLE	0	0.5	1.0	1.5	2.0
Bone marrow blasts	<5%	6-10%	—	11-20%	21-30%
Karyotype*	Good	Intermediate	Poor	—	—
Cytopenias	0-1	2-3	—	—	—

*Good = normal, -Y, -5q, -20q; intermediate =other abnormal; poor = complex (>3) or monosomy 7. IPSS groups: (1) low = 0 points; (2) intermediate-1 = 0.5-1.0 points; (3) intermediate-2 = 1.5-2.0 points; (4) high = >2.5 points.

TREATMENT

The International Prognostic Scoring System (IPSS) is currently the most widely used risk stratification tool to tailor treatment options (Table 188-3). In patients in the low and intermediate-1 risk groups, the goals of treatment are improve quality of life and improve cytopenias. In higher-risk MDS patients, (intermediate-2 or high-risk IPSS), the goal of treatment is to alter the natural history of the disease by approaches such as allogeneic stem cell transplantation or hypomethylating agents in order to extend survival and suppress leukemia potential.

Hematopoietic Growth Factors

About 15 to 30% of patients have an erythropoietic response to treatment with a recombinant erythropoietic stimulating agent (ESA), favoring those with low (<200 U/mL) serum endogenous erythropoietin (EPO) levels and low transfusion burden (<2 units/month). Addition of granulocyte-colony stimulating factor (G-CSF) can increase the erythroid response rate in some patients. Responders to ESA may derive a survival benefit with improvement in erythropoiesis.

Epigenetic Therapy

Aberrant hypermethylation of tumor suppressor genes has been implicated in the pathogenesis of MDS. Hypomethylating agents like 5-azacytidine (5-aza) and decitabine aim to reverse this aberrant hypermethylation and restore transcription of tumor suppressor genes. Several trials have explored the use of 5-aza in MDS. A randomized phase III trial compared 5-aza with best supportive care (BSC) in patients with all FAB subtypes and yielded improvements in cytopenias, transfusion dependency, quality of life, and time to AML progression.[1] A more recent phase III trial, Aza-001, compared 5-aza with conventional therapy that included low-dose and intensive chemotherapy in patients with higher risk (intermediate-2, high-risk) MDS. This trial demonstrated a significant improvement in median overall survival (24 months versus 15 months).[2] 5-aza likewise improved overall survival compared with conventional care regimens in the MDS subgroup of elderly patients with low BM blast count AML.[3] Romiplostim, which activates the thrombopoietin receptor, may provide incremental benefit during 5-aza therapy.[4] Decitabine has also been found in a phase III clinical trial to improve time to AML transformation and death compared with BSC; however, no survival advantage was observed compared with BSC.[5,6]

Immunomodulatory Drugs

Lenalidomide, a more potent and less toxic analogue of thalidomide, is approved for the treatment of transfusion-dependent anemia in patients with lower-risk MDS with a chromosomal 5q deletion. In the registration phase II study, 76% experienced a transfusion response, and 67% became transfusion independent that was sustained for a median duration greater than 2 years. Unlike treatment with ESAs, lenalidomide suppresses the del(5q) MDS clone to yield cytogenetic improvement in more 70% of patients. Neutropenia and thrombocytopenia are commonly seen, especially in the initial months of treatment, but are also predictive for hematologic and cytogenetic response. Activity also exists in those without a chromosome 5q deletion, albeit less robust. A multicenter trial in lower-risk patients without del(5q) reported 43% overall transfusion response, with 26% achieving transfusion independence.[7] The mechanism of action of lenalidomide is karyotype specific with clonal suppression in patients with deletion of 5q and erythropoiesis stimulation in non-5q-deletion patients.

Immunosuppressive Therapy

Based on clinical similarities between a subset of hypocellular MDS and aplastic anemia, antithymocyte globulin plus cyclosporine has been used with success in select patients with MDS. A phase III randomized trial has recently demonstrated that immunosuppressive therapy with antithymocyte globulin (15 mg/kg for 5 days) in combination with oral cyclosporine) for 180 days (average daily dose 290 mg) was associated with hematologic response in a subset of patients with MDS, compared with best supportive care, without apparent impact on transformation-free or overall survival.[8]

Hematopoietic Stem Cell Transplantation

Despite novel therapies, allogeneic hematopoietic stem cell transplantation (HSCT) remains the only curative option for MDS (Chapter 181). The overall 5-year survival rate approaches 40%. Based on decision analysis and limited data from randomized trials , the best timing for allogeneic HSCT is on a diagnosis of higher-risk MDS[9]; deferring HSCT until disease progression optimizes survival potential in patients with lower-risk disease with a compatible donor.

Conventional Chemotherapy

Response rates to conventional acute leukemia chemotherapy regimens for MDS patients are low, and mortality and morbidity can be substantial owing to comorbidities and age. Conventional chemotherapies are generally reserved for the setting of hypomethylating agent failure with disease progression.

Signal Transduction Inhibitors

Multiple signal transduction pathways have been implicated in the pathogenesis of MDS. In the rare MDS patient with *PDGFR*-activating mutations, imatinib is an effective agent. Several other agents are currently in clinical trials targeting different pathways implicated in the pathobiology of MDS.

Iron Chelation

An important consideration in lower-risk patients who are transfusion dependent is iron overload. Iron overload as measured by incremental rise in serum ferritin is an independent prognostic factor in lower-risk MDS, with increased cardiac comorbidity and decrease in survival. In practice, iron chelation therapy is considered in transfusion-dependent lower-risk MDS patients with persistent elevation in ferritin greater than 1000 ng/mL and in patients who have received more than 15 to 20 units of red blood cells. Newer oral iron-chelating agents (e.g., deferasirox) are more appealing and offer a higher expectation for patient compliance.

PROGNOSIS

Unfortunately, most MDS patients will ultimately succumb to complications from the disease or transformation to AML. The IPSS can be applied at the time of diagnosis to estimate the natural history of the disease and therefore guide treatment selection. The cumulative score is based on BM myeloblast percentage, karyotype, and number of cytopenias to risk-stratify patients into four distinct groups: low, intermediate-1, intermediate-2, and high-risk MDS (see Table 188-3). Newer risk models have been proposed to further enhance our ability to predict outcome but more importantly to tailor our therapy according to risk and disease behavior.

FUTURE DIRECTIONS

As our understanding of underlying disease biology improves, one can expect to individualize therapy based on biologic response signatures and enhanced risk stratification.

THE ACUTE LEUKEMIAS

FREDERICK R. APPELBAUM

DEFINITION

Normal hematopoiesis (Chapter 159) requires tightly regulated proliferation and differentiation of pluripotent hematopoietic stem cells that become mature peripheral blood cells. Acute leukemia is the result of a malignant event or events occurring in an early hematopoietic precursor. Instead of proliferating and differentiating normally, the affected cell gives rise to progeny that fail to differentiate but continue to proliferate in an uncontrolled fashion. As a result, immature myeloid cells in acute myeloid leukemia (AML) or lymphoid cells in acute lymphoblastic leukemia (ALL)—often called blasts—rapidly accumulate and progressively replace the bone marrow, diminishing the production of normal red cells, white cells, and platelets. This loss of normal marrow function in turn gives rise to the common clinical complications of leukemia: anemia, infection, and bleeding. With time, the leukemic blasts pour out into the blood stream and eventually occupy the lymph nodes, spleen, and other vital organs. If untreated, acute leukemia is rapidly fatal; most patients die within several months after diagnosis. With appropriate therapy, however, the natural history of acute leukemia can be markedly altered, and many patients can be cured.

EPIDEMIOLOGY

Incidence

About 39,000 new cases of leukemia were diagnosed in the United States in 2009, at a rate of about 8.5 cases per 100,000 persons; this rate has remained relatively consistent for the past 3 decades. The leukemias account for about 3% of all cancers in the United States. The impact of leukemia is heightened because of the young age of some patients. For example, with a maximum incidence between ages 2 and 10 years, ALL is the most common cancer and the second leading cause of death in children younger than 15 years. In contrast, the incidence of AML gradually increases with age, without an early peak. The median age at diagnosis of AML is about 60 years.

Determinants

In most cases, acute leukemia develops for no known reason, but sometimes a possible cause can be identified.

Radiation

Ionizing radiation (Chapter 19) is leukemogenic. The incidence of ALL, AML, and chronic myeloid leukemia (CML) is increased in patients given radiation therapy for ankylosing spondylitis and among survivors of the atomic bomb blasts at Hiroshima and Nagasaki. The magnitude of the risk depends on the dose of radiation, its distribution in time, and the age of the individual. Greater risk results from higher doses of radiation delivered over shorter periods to younger patients. In areas of high natural background radiation (often from radon), chromosomal aberrations are reportedly more frequent, but an increase in acute leukemia has not been consistently found. Concern has been raised about the possible leukemogenic effects of extremely low-frequency nonionizing electromagnetic fields emitted by electrical installations. If such an effect exists at all, its magnitude is small.

Oncogenic Viruses

The search for a viral cause of leukemia has been pursued intensely, but only two clear associations have been found. Human T-cell lymphotropic virus type I (HTLV-I), an enveloped, single-stranded RNA virus, is considered the causative agent of adult T-cell leukemia (Chapter 386). This distinct form of leukemia is found within geographic clusters in southwestern Japan, the Caribbean basin, and Africa. Because HTLV-I seropositivity was found with increasing frequency among heavily transfused patients and intravenous drug users, screening of blood products for antibodies to HTLV-I is now routine practice in blood banks in the United States. Epstein-Barr virus (Chapter 385), the DNA virus that causes infectious mononucleosis, is associated with Burkitt's lymphoma (Chapter 191) and its leukemic counterpart, mature B-cell ALL.

Chemicals and Drugs

Heavy occupational exposure to benzene and benzene-containing compounds such as kerosene and carbon tetrachloride may lead to marrow damage, which can take the form of aplastic anemia, myelodysplasia, or AML. A link between leukemia and tobacco use has recently been reported.

With the increasing use of chemotherapy to treat other malignancies, the incidence of AML secondary to prior chemotherapy has increased and may represent 6 to 10% of all cases. Prior exposure to alkylating agents such as melphalan and the nitrosoureas is associated with an increased risk of secondary AML, which often manifests initially as a myelodysplastic syndrome (Chapter 188), frequently with abnormalities of chromosomes 5, 7, and 8 but with no distinct morphologic features. These secondary AMLs typically

develop 4 to 6 years after exposure to alkylating agents, and their incidence may be increased with greater intensity and duration of drug exposure. Secondary AML associated with epipodophyllotoxin (teniposide or etoposide) exposure tends to have a shorter latency period (1 to 2 years), lacks a myelodysplastic phase, has a monocytic morphology, and involves abnormalities of the long arm of chromosome 11 (band q23) or chromosome 21 (band q22). Because patients frequently receive combination chemotherapy, it is often difficult to identify a single causative agent.

PATHOBIOLOGY

Genetics

If leukemia develops before 10 years of age in a patient with an identical twin, the unaffected twin has a 20% chance of developing leukemia. Several syndromes with somatic cell chromosome aneuploidy, including trisomy 21 (Down), trisomy 13 (Patau), and XXY (Klinefelter), are associated with an increased incidence of AML. Other inherited mutations, for example, a mutation at 21q22, have been associated with a high incidence of AML in rare families. Several autosomal recessive disorders associated with chromosomal instability are prone to terminate in acute leukemia, including Bloom's syndrome, Fanconi's anemia (Chapter 168), and ataxia-telangiectasia (Chapter 258).

Clonality and Cell of Origin

The acute leukemias are clonal disorders, and all leukemic cells in a given patient are descended from a common progenitor. The clonal nature of acute leukemia suggests that there are leukemic stem cells capable of both self-renewal and proliferation. Recent studies suggest that the leukemic stem cells in AML are rare among the leukemic mass, with a frequency of 0.2 to 10 per 10^6, and are within the primitive $CD34^{++}$ $CD38^{-}$ fraction. Less is known about the ALL stem cell.

Classification

The World Health Organization (WHO) classification of acute leukemias is based on clinical, morphologic, immunophenotypic, cytogenetic, and molecular features (Table 189-1).

Morphology

Leukemic cells in AML are typically 12 to 20 nm in diameter, with discrete nuclear chromatin, multiple nucleoli, and cytoplasm that usually contains azurophilic granules. Auer rods, which are slender, fusiform cytoplasmic inclusions that stain red with Wright-Giemsa stain, are virtually pathognomonic of AML. The French-American-British (FAB) morphologic system divides AML into eight subtypes: M0, M1, M2, and M3 reflect increasing degrees of differentiation of myeloid leukemic cells; M4 and M5 leukemias have features of the monocytic lineage; M6 has features of the erythroid cell lineage; and M7 is acute megakaryocytic leukemia. The WHO system also recognizes acute basophilic leukemia and acute leukemia with predominant myelofibrosis.

The leukemic cells in ALL tend to be smaller than AML blasts and relatively devoid of granules. ALL can be divided by FAB criteria into L1, L2, and L3 subgroups. L1 blasts are uniform in size, with homogeneous nuclear chromatin, indistinct nucleoli, and scanty cytoplasm with few, if any, granules. L2 blasts are larger and more variable in size and may have nucleoli. L3 blasts are distinct, with prominent nucleoli and deeply basophilic cytoplasm with vacuoles.

Immunophenotyping

Immunophenotyping by multiparameter flow cytometry is used to determine lineage involvement of newly diagnosed acute leukemias and to detect aberrant immunophenotypes, allowing the measurement of minimal residual disease after therapy. Antibodies that react with antigens found on normal immature myeloid cells, including CD13, CD14, CD33, and CD34, also react with blast cells from most patients with AML. Exceptions are the M6 and M7 variants, which have antigens restricted to the red cell and the platelet lineage, respectively. Myeloid leukemia blasts also express human leukocyte antigen (HLA)-DR antigens but usually lack T-cell, B-cell, and other lymphoid antigens. In 10 to 20% of patients, however, otherwise typical AML blasts also express antigens usually restricted to B- or T-cell lineage. Expression of lymphoid antigens by AML cells does not change either the natural history or the therapeutic response of these leukemias.

Approximately 75% of cases of ALL express B-lineage antigens and can be subdivided into four categories. The most immature group, pro-B ALL, expresses CD19 but not other B-lineage antigens and represents about 10% of cases of ALL. Approximately 50 to 60% of cases of ALL express the common ALL antigen (CALLA, or CD10), a glycoprotein that is also found occasionally on normal early lymphocytes and other nonhematopoietic tissues. CALLA-positive ALL is thought to represent an early pre-B-cell differentiation state. Approximately 10% of cases of ALL have intracytoplasmic immunoglobulin and are termed pre-B-cell ALL. B-cell ALL is signified by the presence of immunoglobulin on the cell surface and accounts for less than 5% of cases of ALL. In general, the best therapeutic outcomes among B-cell ALL types are with early pre-B-cell (CALLA positive) ALL. Among the 25% of cases of ALL that express T-lineage antigens, less than half are so-called pre-T-cell types that express CD3 with either CD4 and CD8 or neither CD4 nor CD8; the majority of cases, termed T-cell ALL, express CD3 and either CD4 or CD8. The prognosis for T-cell ALL is superior to that for pre-T-cell ALL. In about 25% of patients with ALL, the leukemic cells also express myeloid antigens. Historically, the presence of such antigens defined a group of patients with a somewhat worse prognosis; however, with current, more aggressive regimens, the impact of myeloid antigen expression has disappeared.

Acute leukemias of ambiguous lineage are rare cases with no evidence of lineage differentiation (i.e., acute undifferentiated leukemia [AUL]) or those with blasts that express markers of more than one lineage (i.e., mixed phenotype acute leukemia [MPAL]). MPAL can contain either distinct blast populations of different lineages (bilineal) or a single population expressing features of both lineages (biphenotypic). In general, the prognosis

TABLE 189-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF ACUTE LEUKEMIAS

CLASSIFICATION SUBTYPES (2008)
Acute Myeloid Leukemia (AML) and Related Neoplasms
AML with recurrent genetic abnormalities
AML with t(8;21)(q22;q22); *RUNX1-RUNX1T1*
AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); *CBFB-MYH11*

ALL = acute lymphoblastic leukemia.

of patients with AUL or MPAL is poor when treated with standard chemotherapy.

Cytogenetics and Molecular Biology

In most cases of acute leukemia, an abnormality in chromosome number or structure is found. These abnormalities are clonal, involving all the malignant cells in a given patient; they are acquired and are not found in the normal cells of the patient; and they are referred to as "nonrandom," because specific abnormalities are found in multiple cases and are associated with distinct morphologic or clinical subtypes of the disease. These abnormalities may be simply the gain or loss of whole chromosomes, but more often they include chromosomal translocations, deletions, or inversions. When patients with acute leukemia and a chromosomal abnormality receive treatment and enter into complete remission, the chromosomal abnormality disappears; when relapse occurs, the abnormality reappears. In many cases, these abnormalities have provided clues into the pathobiology of acute leukemia.

The most common cytogenetic abnormalities seen in AML can be categorized according to their underlying biology and prognostic significance. The translocation t(8;21) and the inversion inv(16) result in abnormalities of a transcription factor made up of core binding factor-α (CBF-α) and CBF-β. The t(8;21) results in the fusion of CBF-α on chromosome 21 with the *MTG8* gene on chromosome 8, whereas inv(16) results in the fusion of CBF-β on the q arm of chromosome 16 with the *MYH11* gene on the p arm. Both of these "core binding factor" AMLs are characterized by a high complete response rate and relatively favorable long-term survival. An additional translocation with a favorable prognosis, t(15;17), involves two genes, *PML* and *RAR-α* (a gene encoding the α-retinoic acid receptor), and is invariably associated with acute promyelocytic leukemia (APL), the M3 subtype of AML. Translocations involving the *MLL* gene, located at chromosome band 11q23, carry an intermediate prognosis. *MLL* is perhaps the most promiscuous oncogene partner in oncology, with more than 30 fusion partners identified. Trisomy 8 is among the most common nonrandom cytogenetic abnormalities seen in AML; it accounts for 9% of cases and carries an intermediate prognosis. Trisomies of chromosome 21, chromosome 11, and other chromosomes are sometimes seen as well. Deletions of part or all of chromosome 5 or 7 each account for 6 to 8% of cases of AML. These abnormalities are seen with greater frequency in older patients and in patients with AML secondary to myelodysplasia or prior exposure to alkylating agents, and they are associated with an unfavorable prognosis.

In addition to the abnormalities detectable by routine cytogenetic analysis, other mutations exist in the malignant cells in a substantial proportion of AML cases. Many of these involve signal transduction pathways. Activating mutations in the FLT3 receptor have been found in 20 to 40% of cases of AML. These mutations may be internal tandem repeats (15 to 30%) or point mutations (5 to 10%) and are associated with a poorer overall response to therapy. Mutations in FMS, which, like FLT3, is a receptor tyrosine kinase, are seen in 10 to 20% of cases of AML, and mutations in HRAS, KRAS2, and NRAS1, which are cellular proteins involved with signal transduction, are seen in 15 to 20% of AML cases. Mutations in the nucleophosmin gene (*NPM1*) have been identified in 20 to 30% of AML cases and appear to be associated with a favorable clinical outcome. *CEBPA*, a gene encoding a leucine zipper transcription factor involved in myeloid differentiation, is mutated in 4 to 15% of cases of AML and may be associated with a more favorable outcome. All these mutations are of interest not only for their prognostic importance but also because they may serve as targets for new therapies.

The most common cytogenetic abnormality seen in adults with ALL is the Philadelphia (Ph) chromosome, or t(9;22). This translocation results in fusion of the *BCR* gene on chromosome 22 to the *ABL* tyrosine kinase gene on chromosome 9. This results in the constitutive activation of *ABL*, but the precise mechanism by which this activity leads to leukemia is unclear. The *BCR-ABL* fusion is associated with both ALL and CML (Chapter 190), with a difference in the breakpoint of *BCR* distinguishing the two. A slightly smaller 190-kD fusion protein is usually found in ALL, whereas a larger 210-kD protein is characteristic of CML. The frequency of t(9;22) in ALL increases with age: it is found in approximately 5% of childhood cases, 25% of adults, and 50% of adults older than age 50. Before the development of specific tyrosine kinase inhibitors, ALL with t(9;22) had a poor prognosis; newer regimens combining tyrosine kinase inhibitors with chemotherapy are providing improved outcomes. The most common translocation seen in childhood ALL is t(12;21), which involves the genes *TEL* and *AML1*. Like the AML-associated t(8;21) and inv(16), t(12;21) is thought to result in abnormal DNA transcription by interfering with the normal function of CBF. Although t(12;21) is difficult to diagnose by routine cytogenetics, by molecular studies it has been shown to account for 25% of childhood ALL and 4% of adult ALL and has a favorable prognosis. Partial deletions in 9p, seen in 5 to 7% of adult ALL, are also associated with a favorable outcome. Other abnormalities sometimes seen in B-cell ALL include t(8;14) and t(8;22), which result in translocation of the *MYC* gene on chromosome 8 and immunoglobulin enhancer response genes on chromosomes 14 or 22; they are associated with a poor therapeutic outcome. T-cell ALLs are frequently associated with abnormalities of chromosome 7 or 14 at the sites of T-cell receptor enhancer genes on these chromosomes. The leukemia cells in about 20% of patients with ALL have a propensity to gain chromosomes, sometimes reaching an average of 50 to 60 chromosomes per cell. Patients with such hyperdiploid leukemias tend to respond well to chemotherapy.

CLINICAL MANIFESTATIONS

The signs and symptoms of acute leukemia are usually rapid in onset, developing over a few weeks to a few months at most; they result from decreased normal marrow function and invasion of normal organs by leukemic blasts. Anemia is present at diagnosis in most patients and causes fatigue, pallor, headache, and, in predisposed patients, angina or heart failure. Thrombocytopenia is usually present, and approximately one third of patients have clinically evident bleeding at diagnosis, usually in the form of petechiae, ecchymoses, bleeding gums, epistaxis, or hemorrhage. Most patients with acute leukemia are significantly granulocytopenic at diagnosis. As a result, approximately one third of patients with AML and slightly fewer patients with ALL have significant or life-threatening infections when initially seen, most of which are bacterial in origin.

In addition to suppressing normal marrow function, leukemic cells can infiltrate normal organs. In general, ALL tends to infiltrate normal organs more often than AML does. Enlargement of lymph nodes, liver, and spleen is common at diagnosis. Bone pain, thought to result from leukemic infiltration of the periosteum or expansion of the medullary cavity, is a common complaint, particularly in children with ALL. Leukemic cells sometimes infiltrate the skin and result in a raised, nonpruritic rash, a condition termed *leukemia cutis*. Leukemic cells may infiltrate the leptomeninges and cause leukemic meningitis, typically manifested by headache and nausea. As the disease progresses, central nervous system (CNS) palsies and seizures may develop. Although less than 5% of patients with ALL have CNS involvement at diagnosis, the CNS is a frequent site of relapse; therefore, CNS prophylaxis is an essential component of ALL therapy. Because the incidence of CNS disease is low in AML, there is no proven benefit to CNS surveillance or prophylaxis. Testicular involvement is seen in ALL, and the testicles are a frequent site of relapse. In AML, collections of leukemic blast cells, often referred to as *chloromas* or *myeloblastomas*, can occur in virtually any soft tissue and appear as rubbery, fast-growing masses.

Certain clinical manifestations are unique to specific subtypes of leukemia. Patients with APL of the M3 type commonly have subclinical or clinically evident disseminated intravascular coagulation (DIC; Chapter 178) caused by tissue thromboplastins released by the leukemic cells. Acute monocytic or myelomonocytic leukemias are the forms of AML most likely to have extramedullary involvement. M6 leukemia often has a long prodromal phase. Patients with T-cell ALL frequently have mediastinal masses.

DIAGNOSIS

Abnormalities in peripheral blood counts are usually the initial laboratory evidence of acute leukemia. Anemia is present in most patients. Most are also at least mildly thrombocytopenic, and up to one fourth have severe thrombocytopenia (platelets <20,000/μL). Although most patients are granulocytopenic at diagnosis, the total peripheral white cell count is more variable; approximately 25% of patients have very high white cell counts (>50,000/μL), approximately 50% have white cell counts between 5000 and 50,000/μL, and about 25% have low white cell counts (<5000/μL). In most cases, blasts are present in the peripheral blood, although in some patients the percentage of blasts is quite low or absent.

The diagnosis of acute leukemia is typically established by marrow aspiration and biopsy, usually from the posterior iliac crest. Marrow aspirates and biopsy specimens are usually hypercellular and contain 20 to 100% blast cells, which largely replace the normal marrow (Figs. 189-1 and 189-2). Occasionally, in addition to the blast cell infiltrate, other findings are present, such as marrow fibrosis (especially with M7 AML) or bone marrow necrosis. Marrow

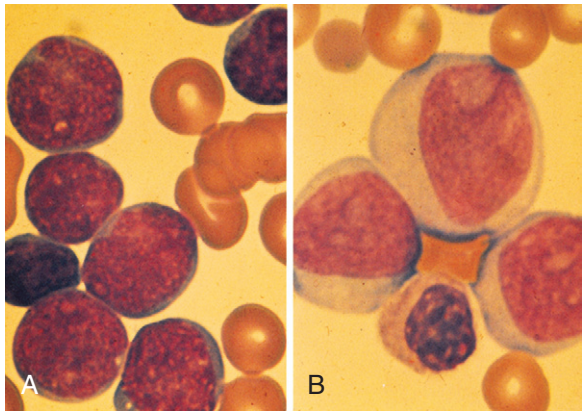

FIGURE 189-1. Acute leukemia. A, Acute lymphoblastic leukemia (ALL). **B,** Acute myeloid leukemia (AML). Lymphoblasts in ALL are smaller, with a higher ratio of nuclear to cytoplasmic material and less distinct nucleoli than in the myeloblasts in AML. The nucleoli in the myeloblasts are clear and "punched out."

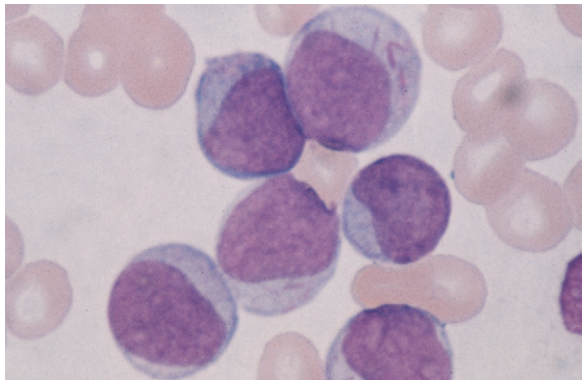

FIGURE 189-2. Acute myeloid leukemia. The myeloblasts in the smear show Auer rods as cytoplasmic inclusions.

samples should also be evaluated by immunophenotyping and cytogenetics. If AML is suspected, samples should be evaluated for the presence of mutations in *FLT3*, *NPM1*, and *CEBPA*. A diagnostic lumbar puncture is generally recommended in suspected cases of ALL, but not in asymptomatic cases of AML.

The prothrombin and partial thromboplastin times are sometimes elevated. In APL, reduced fibrinogen and evidence of DIC are often seen. Other laboratory abnormalities frequently present are hyperuricemia, especially in ALL, and increased serum lactate dehydrogenase. In cases of high cell turnover and cell death (e.g., L3 ALL), evidence of tumor lysis syndrome may be noted at diagnosis, including hypocalcemia, hyperkalemia, hyperphosphatemia, hyperuricemia, and renal insufficiency. This syndrome, which is more commonly seen shortly after therapy is begun, can be rapidly fatal if untreated.

Differential Diagnosis

The diagnosis of acute leukemia is usually straightforward but can occasionally be difficult. Both leukemia and aplastic anemia (Chapter 168) can manifest with peripheral pancytopenia, but the finding of a hypoplastic marrow without blasts usually distinguishes aplastic anemia. An occasional patient has hypocellular marrow and a clonal cytogenetic abnormality, which establishes the diagnosis of myelodysplasia or hypocellular leukemia. A number of processes other than leukemia can lead to the appearance of immature cells in the peripheral blood. Although other small round cell neoplasms can infiltrate the marrow and mimic leukemia, immunologic markers are effective in differentiating the two. Leukemoid reactions to infections such as tuberculosis can result in the outpouring of large numbers of young myeloid cells, but the proportion of blasts in marrow or peripheral blood almost never reaches 20% in a leukemoid reaction (Chapter 170). Infectious mononucleosis (Chapter 385) and other viral illnesses can sometimes resemble ALL, particularly if large numbers of atypical lymphocytes are present in the peripheral blood and the disease is accompanied by immune thrombocytopenia or hemolytic anemia.

TREATMENT Rx

With the development of effective programs of combination chemotherapy and advances in hematopoietic cell transplantation, many patients with acute leukemia can be cured. These therapeutic measures are complex and are best carried out at centers with appropriate support services and experience in treating leukemia. Because leukemia is a rapidly progressive disease, specific antileukemic therapy should be started as soon after diagnosis as possible, usually within 48 hours. The goal of initial chemotherapy is to induce a complete remission (CR) with restoration of normal marrow function. In general, induction chemotherapy is intensive and is accompanied by significant toxicities. Therefore, patients should be stabilized to the extent possible before specific antileukemic therapy is begun.

Preparing the Patient for Therapy

Severe bleeding usually results from thrombocytopenia, which can be reversed with platelet transfusions (Chapter 180). Once thrombocytopenic bleeding is stopped, continued prophylactic transfusions of platelets may be warranted to maintain the platelet count higher than 10,000 to 20,000/μL. Occasionally, patients also have evidence of DIC, usually associated with the diagnosis of M3 AML. If M3 AML is suspected as the cause, all-*trans*-retinoic acid (ATRA) should be started without waiting for molecular confirmation of the diagnosis; the drug can be discontinued if the diagnosis is not M3 AML. If active bleeding is due to DIC (Chapter 178), low doses of heparin (50 U/kg) given intravenously every 6 hours can be of benefit. Platelets and fresh-frozen plasma (or cryoprecipitate) should be transfused to maintain the platelet count higher than 50,000/μL and the fibrinogen level greater than 100 mg/dL until the DIC abates. Whether heparin should be given prophylactically to patients with laboratory evidence of DIC but no active bleeding is an often debated but unsettled question.

Blood cultures should be obtained in patients with fever and granulocytopenia; while awaiting culture results, infection should be assumed and broad-spectrum antibiotics begun empirically (Chapters 170 and 289). It is preferable to bring an infection under control before starting initial chemotherapy if the patient has an adequate granulocyte count. However, patients often have infection but essentially no granulocytes; in this situation, delaying chemotherapy is unlikely to be beneficial.

Patients with very high blast counts (>100,000/μL) may have symptoms attributable to the effect of masses of these immature cells on blood flow. The leukostasis may evolve into vascular injury and local hemorrhage. If this situation occurs in the CNS, the outcome can be fatal. Leukapheresis, immediate whole brain irradiation (600 cGy in one dose), and administration of hydroxyurea (3 g/m^2/day orally for 2 or 3 days) can usually prevent this complication.

Before treatment, management in all patients should be aimed at preventing the tumor lysis syndrome. Patients should be hydrated, have their urine alkalinized with acetazolamide 500 mg/day, and be given allopurinol 100 to 200 mg orally three times a day before chemotherapy is initiated. Patients with very high white cell counts may have uremia and anuria secondary to greatly increased serum uric acid levels, with subsequent intratubular crystallization, even before starting therapy. Hyperuricemia usually responds rapidly to rasburicase 0.20 mg/kg/day for up to 5 days intravenously, given over 30 minutes.

The diagnosis of leukemia usually comes as a profound psychological shock to the patient and family. Therefore, in addition to stabilizing the patient hematologically and metabolically, it is worthwhile to have at least one formal conference in which the patient and family are advised about the meaning of the diagnosis of leukemia and the consequences of therapy before treatment is initiated.

Treatment of Acute Lymphoblastic Leukemia

After the patient's condition has been stabilized, antileukemic therapy should be started as soon as possible. Treatment of newly diagnosed ALL can be divided into three phases: remission induction, postremission therapy, and CNS prophylaxis.

Remission Induction

The initial goal of treatment is to induce CR, defined as the reduction of leukemic blasts to undetectable levels and the restoration of normal marrow function. A number of different chemotherapeutic combinations can be used to induce remission; all include vincristine and prednisone, and most add L-asparaginase and daunorubicin, administered over a period of 3 to 4 weeks. With such regimens, CR is achieved in 90% of children and 80 to 90% of adults (Table 189-2). Because vincristine, prednisone, and L-asparaginase are relatively nontoxic to normal marrow precursors, the disease often enters CR after a relatively brief period of myelosuppression. Failure to achieve CR is usually due to either the leukemic cells' resistance to the drugs or progressive infection. These two complications occur with approximately equal frequency.

Postremission Chemotherapy

If no further therapy is given after induction of CR, relapse occurs in almost all cases, usually within several months. Chemotherapy after CR can be given in a variety of combinations, dosages, and schedules. The term *consolidation chemotherapy* refers to short courses of further chemotherapy given at doses

TABLE 189-2 COMMON REGIMENS FOR COMMON FORMS OF ACUTE LEUKEMIA

I. MANAGEMENT OF NEWLY DIAGNOSED ACUTE MYELOID LEUKEMIA

A. Induction—daunorubicin 60-90 mg/m^2/day for 3 days (or idarubicin 10-12 mg/m^2/day for 3 days) and cytarabine 200 mg/day for 7 days
B. Postremission
   1. Favorable risk—cytarabine 3 g/m^2 over 3 hr q12h on days 1, 3, and 5 every month for 4 mo
   2. Intermediate risk—as for favorable risk; or, if HLA-matched donor sibling exists, allogeneic hematopoietic cell transplantation
   3. Unfavorable risk—if HLA-matched donor is available, proceed to allogeneic transplantation; if not, treat as for intermediate risk

II. MANAGEMENT OF NEWLY DIAGNOSED ACUTE PROMYELOCYTIC LEUKEMIA

A. Induction—ATRA 45 mg/m^2/day until complete remission plus daunomycin 45-60 mg/m^2/day for 3 days and cytarabine 200 mg/m^2/day for 7 days
B. Consolidation #1—arsenic trioxide 0.15 mg/kg/day 5 days/wk for 5 wk; repeat course after 2-wk rest
   Consolidation #2—ATRA 45 mg/m^2/day for 7 days and daunomycin 50 mg/m^2/day for 3 days; repeat course 1 mo later
C. Maintenance—ATRA 45 mg/m^2/day for 15 days every 3 mo plus 6-MP 100 mg/m^2/day and MTX 10 mg/m^2/wk for 2 yr

III. MANAGEMENT OF NEWLY DIAGNOSED ADULT Ph-NEGATIVE ACUTE LYMPHOID LEUKEMIA

A. Induction (and courses 3, 5, 7)—cyclophosphamide 300 mg/m^2 over 3 hr q12h for 6 doses on days 1, 2, 3; doxorubicin 50 mg/m^2 on day 4; vincristine 2 mg/day on days 4 and 11; and dexamethasone 40 mg/day on days 1-4 and days 11-14
B. Consolidation (courses 2, 4, 6, 8)—MTX 200 mg/m^2 over 2 hr, followed by 800 mg/m^2 over 22 hr on day 1; high-dose cytarabine 3 g/m^2 over 2 hr q12h for 4 doses on days 2 and 3
C. Four intrathecal treatments of MTX 12 mg alternating with cytarabine 100 mg are given during the first four courses of systemic therapy

ATRA = all-*trans*-retinoic acid; HLA = human leukocyte antigen; 6-MP = 6-mercaptopurine; MTX = methotrexate; Ph = Philadelphia chromosome [t(9;22)].

similar to those used for initial induction (requiring rehospitalization). Usually, different drugs are selected for consolidation chemotherapy than were used to induce the initial remission. In the case of ALL, such drugs include high-dose methotrexate, cyclophosphamide, and cytarabine, among others. Maintenance involves the administration of low-dose chemotherapy on a daily or weekly outpatient basis for long periods. The most commonly used maintenance regimen in ALL combines daily 6-mercaptopurine and weekly or biweekly methotrexate. The optimal duration of maintenance chemotherapy is unknown, but it is usually given for 2 to 3 years. Optimal chemotherapy for ALL requires both consolidation and maintenance chemotherapy.

Central Nervous System Prophylaxis

Most chemotherapeutic agents that are given intravenously or orally do not penetrate the CNS well, and if no form of CNS prophylaxis is given, at least 35% of adults will develop CNS leukemia. With prophylaxis, relapse in the CNS as an isolated event occurs in less than 10% of patients. Systemic chemotherapy with high-dose methotrexate (e.g., 200 mg/m^2 intravenously over 2 hours, followed by 800 mg/m^2 over 22 hours) and cytarabine (e.g., 3 g/m^2 over 2 hours every 12 hours for 4 doses) can achieve therapeutic drug levels within the CNS. Alternatives are intrathecal methotrexate, intrathecal methotrexate combined with 2400 cGy radiation to the cranium, or 2400 cGy to the craniospinal axis.

Burkitt-Like ALL

Burkitt-like ALL (also called FAB L3 or mature B-cell ALL) is characterized by the presence of monoclonal surface immunoglobulin, cytogenetics showing t(8;14), and the constitutive expression of the *MYC* oncogene. Burkitt-like ALL, which accounts for 3 to 5% of adult cases of ALL, responds well to regimens that incorporate short, intensive courses of high-dose methotrexate (1.5 g/m^2 over 24 hours with leucovorin), cytarabine (3 g/m^2 over 2 hours every 12 hours for 4 doses), and cyclophosphamide (200 mg/m^2/day for 5 days); this regimen yields high rates of complete response and cures about 50% of patients. Recent results suggest that the addition of rituximab may further improve outcomes.

Philadelphia Chromosome–Positive ALL

Approximately 5% of pediatric cases and 25% of adult cases of ALL have cytogenetics showing t(9;22), the Ph chromosome. Historically, such patients had CR rates slightly lower than those seen in Ph-negative ALL and markedly reduced remission durations, averaging less than a year; few if any such patients were cured with conventional chemotherapy. Therefore, the general recommendation has been that such patients receive an allogeneic transplant from a matched sibling or a matched unrelated donor during the first remission, if possible. With this approach, approximately 50% of patients can be cured. More recently, the addition of the tyrosine kinase inhibitor imatinib mesylate to conventional chemotherapeutic regimens has increased complete response rates, equaling those seen in Ph-negative ALL, but the impact of the addition of imatinib mesylate on the duration of remission is not yet known. The general recommendation remains transplantation during the first remission for this high-risk group of patients.

Prognosis of ALL after Initial Chemotherapy

A number of factors are predictive of outcome in ALL, the most important of which are younger age, a lower white cell count at diagnosis, and favorable cytogenetics. With currently available treatment regimens, 80 to 85% of children and 35 to 40% of adults who initially achieve CR maintain that state for more than 5 years, and these patients are probably cured of their disease.

Treatment of Relapsed ALL

Most relapses occur within 2 years after diagnosis, and most occur in the marrow. Occasionally, relapse is initially found in an extramedullary site such as the CNS or testes. Extramedullary relapse is usually followed shortly by systemic (marrow) relapse and should be considered part of a systemic recurrence. With the use of chemotherapeutic regimens similar to those used for initial induction, 50 to 70% of patients achieve at least a short-lived second remission. A small percentage of patients for whom the initial remission was longer than 2 years may be cured with salvage chemotherapy. If the CNS or testes is the initial site of the relapse, specific therapy at that site is also required, along with systemic retreatment. Because the prognosis of relapsed leukemia treated with chemotherapy is so poor, marrow transplantation is usually recommended in this setting.

Hematopoietic Cell Transplantation

The use of high-dose chemoradiotherapy followed by hematopoietic cell transplantation (Chapter 181) from an HLA-identical sibling can cure 20 to 40% of patients with ALL who fail to achieve an initial remission or who have a relapse after an initial CR; it can cure 50 to 60% of patients who undergo transplantation during a first remission. Although there is still considerable debate, several recent studies have reported improved survival for adults with high-risk or standard-risk ALL who receive a stem cell transplant during a first remission rather than being treated with standard chemotherapy.[1,2] The major limitations of transplantation are graft-versus-host disease, interstitial pneumonia, and recurrence of disease. If an HLA-identical sibling is not available, transplantation from a matched unrelated donor or transplantation of cord blood from a partially matched unrelated donor can be conducted, with results that approach those seen with matched related donors.

Treatment of Acute Myeloid Leukemia

Remission Induction

Treatment with a combination of an anthracycline and cytarabine (100 to 200 mg/m^2/day for 7 days) leads to CR in 60 to 80% of patients with AML. Prospective randomized trials have demonstrated that idarubicin (10 to 12 mg/m^2/day for 3 days) or a higher dose of daunorubicin (60 to 90 mg/m^2/day for 3 days) is superior to the conventional daunorubicin dose of 45 mg/m^2/day for 3 days.[3-5] Profound myelosuppression always follows when these agents are used at doses capable of achieving CR. Failure to achieve CR is usually due to either drug resistance or fatal complications of myelosuppression.

Postremission Therapy

Intensive consolidation chemotherapy with repeated courses of daunorubicin and cytarabine at doses similar to those used for induction, high-dose cytarabine (1 to 3 g/m^2/day for 3 to 6 days), or other agents prolongs the average remission duration and improves the chances for long-term disease-free survival. The best results reported to date have generally been achieved with repeated cycles of high-dose cytarabine. Unlike the situation with ALL, low-dose maintenance therapy is of limited benefit after intensive consolidation treatment. In AML, leukemic recurrence occurs less often in the CNS (appropximately 10% of cases), most commonly in patients with the M4 or M5 variant. There is no evidence that CNS prophylaxis improves survival in AML.

Prognosis of AML after Initial Chemotherapy

Among patients in whom CR is achieved, 20 to 40% remain alive in continuous CR for more than 5 years, suggesting a probable cure. As with ALL, younger patients and those with a low white cell count at diagnosis have a more favorable outcome. Patients whose disease is characterized by certain chromosomal abnormalities, particularly t(8;21) and inv(16), or those with normal cytogenetics but mutated *CEBPA* and those with normal cytogenetics but mutated *NPM1* and wild-type *FLT3* do somewhat better, whereas those with 5q–, –7, 11q23, inv(3), or t(6;9) do worse. Patients who have a preleukemic phase before their condition evolves into acute leukemia and those whose leukemia is secondary to prior exposure to chemotherapy have a poorer prognosis. Increased expression of the multidrug resistance gene 1 *(MDR1)* is also associated with a worse outcome.

Treatment of Recurrent AML

Patients whose AML recurs after initial chemotherapy can achieve a second remission in about 50% of cases after retreatment with daunorubicin-cytarabine or high-dose cytarabine. The likelihood of achieving a second remission is predicted by the duration of the first remission: 70% in patients whose first remission persisted beyond 2 years, compared with less than 15% in those whose first remission lasted less than 6 months. Older patients may benefit from gemtuzumab ozogamicin (9 mg/m^2 on days 1 and 15), a form of antibody-targeted chemotherapy. Second remissions tend to be short-lived, however, and few patients in whom relapse occurs after first-line chemotherapy are cured by salvage chemotherapy.

Treatment of Acute Promyelocytic Leukemia

CR can be induced in at least 90% of patients with APL by using ATRA (45 mg/m^2/day until CR is achieved) in combination with an anthracycline. Patients treated with ATRA usually have their coagulation disorders corrected within several days. A unique toxicity of ATRA in the treatment of APL is the development of hyperleukocytosis accompanied by respiratory distress and pulmonary infiltrates. The syndrome responds to temporary discontinuation of ATRA and the addition of corticosteroids. By combining ATRA with anthracyclines for induction and consolidation and then using ATRA as maintenance therapy, approximately 70% of patients can be cured. Patients with higher white cell counts at diagnosis do worse. Arsenic trioxide (0.15 mg/kg/day until CR is achieved) is effective in patients with recurrent APL and appears to improve overall survival if used as part of consolidation therapy for patients in their first CR.

Hematopoietic Cell Transplantation

For patients with AML in whom an initial remission cannot be achieved or for those who have a relapse after chemotherapy, hematopoietic cell transplantation (Chapter 181) from an HLA-identical sibling offers the best chance for cure. Fifteen percent of patients with end-stage disease can be saved by this treatment. If the procedure is applied earlier, the outcome is better: approximately 30% of patients who undergo hematopoietic cell transplantation at first relapse or second remission are cured, and 50 to 60% of patients are cured if hematopoietic cell transplantation is performed during the first remission. A large number of studies have prospectively compared the outcome of allogeneic hematopoietic cell transplantation with that of chemotherapy in patients with AML in first remission. The trends in all these studies have been toward higher treatment-related mortality but improved disease-free and overall survival time with allogeneic transplantation. Meta-analyses conclude that survival is improved with allogeneic transplantation from a matched sibling in first remission when compared with continued chemotherapy.[6] This improvement is clearest in patients with high-risk or intermediate-risk cytogenetics and is not seen in those with good-risk cytogenetics. The major limitations of allogeneic hematopoietic cell transplantation are lack of a matched sibling donor, graft-versus-host disease, interstitial pneumonia, and disease recurrence. Because transplant-related toxicities increase with patient age, some centers limit hematopoietic cell transplantation to those 60 years of age or younger. However, recent studies of reduced-intensity or nonmyeloablative allogeneic transplantation have shown encouraging results in patients with AML in remission at ages up to 70 years. The results of allogeneic transplantation using matched unrelated donors are not too dissimilar from those using matched siblings, although there is a higher incidence of complications. Autologous hematopoietic cell transplantation offers an alternative for patients without matched siblings to serve as donors. In randomized trials, the use of autologous bone marrow transplantation after consolidation chemotherapy significantly prolonged the duration of disease-free survival for patients with AML in first remission but did not alter overall survival.

Treatment of AML in Older Patients

The benefits of intensive consolidation chemotherapy in younger patients do not translate to patients older than 60 years, in part because older patients are less able to tolerate therapy, but also because AML in older patients is more often associated with unfavorable cytogenetics (particularly abnormalities of chromosomes 5 and 7) and more often overexpresses P-glycoprotein, resulting in the multidrug resistance phenotype. Accordingly, long-term survival rates of only 10 to 15% are seen with chemotherapy in patients older than 60 years. Otherwise healthy older patients can usually tolerate intensive chemotherapy and should be offered this treatment. However, intensive chemotherapy can cause more harm than good in older patients with poor performance status, and such patients may be candidates for supportive care only or for alternative therapies currently under study.

Management of Complications

Treatment of acute leukemia, especially AML, is accompanied by a number of complications, the two most serious and frequent being infection and bleeding. During the granulocytopenic period that follows induction and consolidation chemotherapy, the risk of bacterial infection is high. A Cochrane review examined results of antibiotic prophylaxis compared with placebo in afebrile neutropenic patients. Antibiotic prophylaxis significantly decreased infection-related deaths, with the best results seen with quinolones.[7] Invasive fungal infections are also common following chemotherapy for AML. A review of randomized trials found a significant reduction in death from fungal infection in patients given antifungal prophylaxis. Posaconazole may be more effective than fluconazole or itraconazole. Despite antibiotic and antifungal prophylaxis, many patients are febrile while neutropenic. The most commonly isolated organisms vary somewhat from medical center to medical center, but gram-positive organisms such as *Staphylococcus epidermidis* and gram-negative enteric organisms such as *Pseudomonas aeruginosa*, *Escherichia coli*, and *Klebsiella* (*Aerobacter*) are the most commonly isolated bacteria. Even if no cause for fever is found, bacterial infection should be assumed, and, in general, all patients with fever and neutropenia should begin receiving broad-spectrum antibiotics (Chapters 170 and 289). Commonly used antibiotic approaches include monotherapy with imipenem or a combination of an antipseudomonal penicillin and a third-generation cephalosporin. Once begun, antibiotics should be continued until patients recover their granulocyte counts, even if they become afebrile first. If documented bacterial infection persists despite appropriate antibiotics, the physician should consider removal of indwelling catheters.

In addition to being granulocytopenic, patients undergoing induction chemotherapy for leukemia have deficient cellular and humoral immunity, at least temporarily, and therefore are subject to infections common in other immunodeficiency states, including *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) infection and a variety of viral infections. *P. jirovecii* infection can be prevented by the prophylactic use of trimethoprim-sulfamethoxazole. Cytomegalovirus (CMV) infection can be prevented in a CMV-seronegative patient by the sole use of CMV-seronegative blood products (Chapter 384). Herpes simplex (Chapter 382) can often complicate existing mucositis and can be prevented with prophylactic acyclovir. Acyclovir is also useful for the treatment of disseminated varicella-zoster virus infection (Chapter 383).

Myeloid growth factors (granulocyte or granulocyte-macrophage colony-stimulating factor; Chapter 159), if given shortly after the completion of chemotherapy, shorten the period of severe myelosuppression by, on average, 4 days. In most studies, this accelerated recovery has resulted in fewer days with fever and less use of antibiotics, but it has not improved the complete response rate or altered survival.

The platelet count that signals a need for platelet transfusion has been the subject of debate. Traditionally, platelet transfusions from random donors were used to maintain platelet counts greater than 20,000/μL, but more recently it has been demonstrated that lowering this threshold to 10,000/μL is safe in patients with no active bleeding. In 30 to 50% of cases, patients eventually become alloimmunized and require the use of HLA-matched platelets (Chapter 180). Transfusion-induced graft-versus-host disease (Chapter 180), manifesting as a rash, low-grade fever, elevated values in liver function tests, and decreasing blood counts, can be prevented by irradiating all blood products before transfusion.

Grade A

190 THE CHRONIC LEUKEMIAS

HAGOP KANTARJIAN AND SUSAN O'BRIEN

CHRONIC MYELOGENOUS LEUKEMIA

DEFINITION

Chronic myelogenous leukemia (CML), also called chronic myeloid leukemia, chronic myelocytic leukemia, and chronic granulocytic leukemia, is a clonal myeloproliferative disorder of the primitive hematopoietic stem cell that is characterized by overproduction of cells of the myeloid series, which results in marked splenomegaly and leukocytosis. Basophilia and thrombocytosis are common. A characteristic cytogenetic abnormality, the Philadelphia (Ph) chromosome, is present in the bone marrow cells in more than 90% of cases. Most patients (85 to 90%) present in the chronic phase. Eventually, if poorly controlled, CML evolves into the accelerated and blastic phases.

EPIDEMIOLOGY

CML constitutes one fifth of all cases of leukemia in the United States. It is diagnosed in 1 or 2 persons per 100,000 per year and has a slight male preponderance. This incidence of 5000 to 6000 cases annually has not changed significantly in the past few decades. The incidence of CML increases with age; the median age at diagnosis is 50 to 55 years. Ph-positive CML is uncommon in children and adolescents. No familial association of CML has been noted; for example, the risk is not increased in monozygotic twins or in relatives of patients with CML. Because of the availability of effective therapy, the annual mortality has been reduced from 15 to 20% before 2000 to 1 to 2% at present. Thus, the prevalence of CML is predicted to increase gradually, from 15,000 to 20,000 cases before 2000 up to 250,000 cases by 2040 in the United States.

Often, no etiologic agent is incriminated in CML. Exposure to ionizing radiation (e.g., in survivors of the atomic bomb explosions in Japan in 1945, in those undergoing radiation treatment of ankylosing spondylitis or cervical cancer) increases the risk of CML; the peak incidence occurs 5 to 12 years after exposure and is dose related. No increase in the risk of CML has been demonstrated among individuals working in the nuclear industry. Radiologists working without adequate protection before 1940 were more likely to develop myeloid leukemia, but no such association has been found in recent studies. Benzene exposure increases the risk of acute myelogenous leukemia (AML) but not of CML. CML is not a frequent secondary leukemia after treatment of other cancers with radiation, alkylating agents, or both.

PATHOBIOLOGY

Molecular Pathogenesis

The Ph chromosome abnormality, present in more than 90% of patients with typical CML (Fig. 190-1), results from a balanced translocation of genetic material between the long arms of chromosomes 9 and 22: t(9;22)(q34;q11.2). The breakpoint at band q34 of chromosome 9 results in translocation of the cellular oncogene *ABL1* (previously *c-ABL*) to a region on chromosome 22 coding for the major breakpoint cluster region (BCR). *ABL1* is a homologue of *v-ABL*, the Abelson virus that causes leukemia in mice. This translocation allows juxtaposition of a 5′ portion of a BCR and 3′ position of ABL; the two genetic sequences produce a new hybrid oncogene (*BCR-ABL*), which codes for a novel BCR-ABL oncoprotein with a molecular weight of 210 kD ($p210^{BCR-ABL}$). The $p210^{BCR-ABL}$ oncoprotein results in uncontrolled kinase activity of BCR-ABL, which triggers the excessive proliferation and reduced apoptosis of CML cells, thereby giving CML cells a growth advantage over normal cells and suppressing normal hematopoiesis. Although in most cases 100% of the metaphases on cytogenetic analysis show

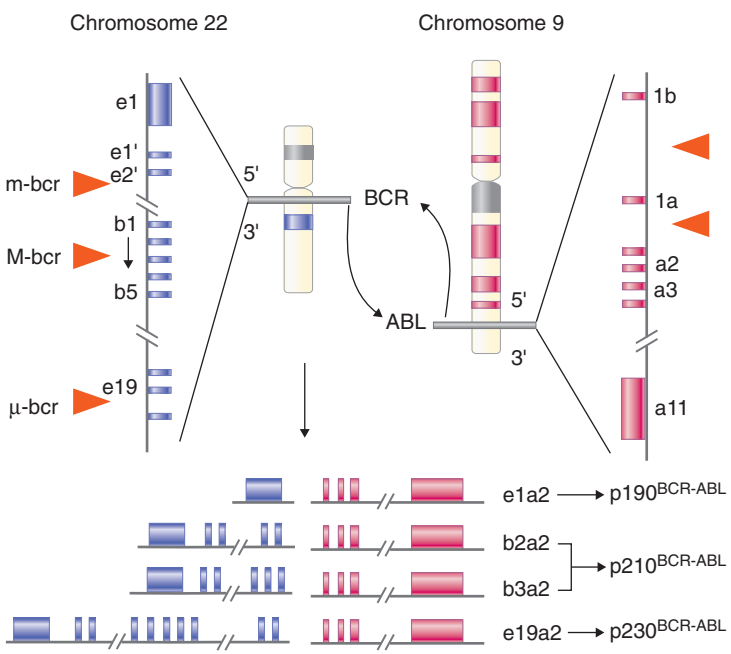

FIGURE 190-1. The Philadelphia chromosome. Originally described as a shortened long arm of chromosome 22, the Philadelphia chromosome (Ph) was later found to be the result of a balanced translocation of genetic material between the long arms of chromosomes 9 and 22: t(9;22)(q34;q11.2). This results in the juxtaposition of *ABL* to *BCR*, producing a hybrid *BCR-ABL* oncogene. Depending on the breakpoint on *BCR*, three oncoproteins may be produced: $p210^{BCR-ABL}$, which is associated with 98% or more of the cases of Ph-positive chronic myelogenous leukemia (CML); $p190^{BCR-ABL}$, which is associated with 60 to 80% of cases of Ph-positive acute lymphocytic leukemia (the other 20 to 40% of cases are $p210^{BCR-ABL}$); and $p230^{BCR-ABL}$, which is associated with rare cases of Ph-positive CML. The dysregulated expression of *BCR-ABL*, through phosphorylation of substrate proteins, triggers the abnormal signal transduction of multiple downstream events, some of them thought to cause excessive proliferation, reduced apoptosis, abnormal cytoskeletal regulation and cytoadhesion, and other events contributing to the growth advantage of CML cells.

BCR-ABL, some normal stem cells emerge on long-term bone marrow culture and after treatment with interferon-α (IFN-α), imatinib, high-dose chemotherapy, and autologous stem cell transplantation.

The constitutive activation of BCR-ABL results in autophosphorylation and activation of multiple downstream pathways that affect gene transcription, apoptosis, cytoskeletal organization, cytoadhesions, and degradation of inhibitory proteins. The signal transduction pathways implicated involve RAS, mitogen-activated-protein (MAP) kinases, signal transducers and activators of transcription (STAT), phosphatidyl inositol 3-kinase (PI3K), MYC, and others. Many of these interactions are mediated through tyrosine phosphorylation and require binding of the BCR-ABL to adapter proteins such as GRB-2, CRK, CRK-like protein (CRKL), and SCR-homology containing proteins (SHC). Although imatinib has been extremely successful at targeting BCR-ABL, understanding of the pathophysiology of the downstream events of BCR-ABL is important for the future development of agents that may target these events.

In Ph-positive acute lymphocytic leukemia (ALL), the breakpoint in BCR is proximal, in the minor BCR, resulting in a smaller *BCR* gene apposing *ABL*; the resulting fusion gene, messenger RNA, and BCR-ABL oncoprotein ($p190^{BCR-ABL}$) are smaller. A third rare, mu (μ) BCR breakpoint distal to the major BCR produces a $p230^{BCR-ABL}$ hybrid oncoprotein, which is associated with a more indolent CML course.

What induces this molecular rearrangement is unknown. Molecular techniques that amplify detection of *BCR-ABL* have demonstrated its presence in the marrow cells of 25 to 30% of healthy volunteers and 5% of infants, but not in cord blood. Because clinical CML develops in only 1 to 2 of 100,000 individuals (i.e., 1 to 2 per 25,000 to 30,000 individuals who express *BCR-ABL* in their bone marrow), immune regulatory processes or additional molecular events presumably contribute to the development of CML.

BCR-ABL is found only in hematopoietic cells and has its origin close to the pluripotent stem cell. For example, the Ph chromosome occurs in erythroid, myeloid, monocytic, and megakaryocytic cells; less commonly in B lymphocytes; rarely in T lymphocytes; and not at all in marrow fibroblasts. The fusion *BCR-ABL* gene and the p210 protein can be found in cases of

typical morphologic CML in which no cytogenetic abnormality occurs or in which changes other than the typical t(9;22) (q34;q11.2) are identified. These patients have a survival rate and a response to therapy similar to those of patients with Ph-positive CML. Patients with atypical CML (usually older and more frequently exhibiting anemia, thrombocytopenia, monocytosis, and dysplasia) who are Ph negative and *BCR-ABL* negative have a worse prognosis than those who are either Ph-positive or Ph-negative and *BCR-ABL*–positive; they more closely resemble patients with myelodysplastic syndrome (Chapter 188). Thus, three groups of patients with CML can be identified: (1) those who are positive for Ph and *BCR-ABL,* (2) those who are Ph negative but *BCR-ABL* positive, and (3) those who are negative for Ph and *BCR-ABL*. *PDGFB* (previously *SIS*), which codes for platelet-derived growth factor (PDGF) and is the homologue of the simian sarcoma virus, is also translocated from chromosome 22 to chromosome 9 in CML, but it is distant from the breakpoint and is not expressed.

CLINICAL MANIFESTATIONS

About 40 to 50% of patients diagnosed with CML are asymptomatic until the disease is found on routine physical examinations or blood tests. In these patients, the white blood cell (WBC) count may be relatively low at diagnosis. The degree of leukocytosis correlates with tumor burden, as defined by spleen size.

The symptoms of CML, when present, are due to anemia and splenomegaly; they include fatigue, weight loss, malaise, easy satiety, and left upper quadrant fullness or pain. Rarely, bleeding (associated with a low platelet count or platelet dysfunction) or thrombosis (associated with thrombocytosis or marked leukocytosis) occurs. Other rare presentations include gouty arthritis (from elevated uric acid levels), priapism (usually with marked leukocytosis or thrombocytosis), retinal hemorrhages, and upper gastrointestinal ulceration and bleeding (from elevated histamine levels due to basophilia). Headaches, bone pain, arthralgias, pain from splenic infarction, and fever are uncommon in the chronic phase but more frequent as CML progresses. Symptoms of leukostasis, such as dyspnea, drowsiness, loss of coordination, or confusion, which are due to leukocyte sludging in the pulmonary or cerebral vessels, are uncommon in the chronic phase despite WBC counts exceeding 50,000 cells/μL, but these symptoms appear more frequently in the accelerated or blastic phases.

Splenomegaly, the most consistent physical sign in CML, occurs in 50 to 60% of cases. Hepatomegaly is less common (10 to 20%) and usually minor (1 to 3 cm below the right costal margin). Lymphadenopathy is uncommon, as is infiltration of skin or other tissues. If present, these findings suggest Ph-negative CML or the accelerated or blastic phase of CML.

DIAGNOSIS

The diagnosis of typical CML is not difficult. Patients with untreated CML usually have leukocytosis ranging from 10,000 to 500,000/μL. The predominant cells are neutrophils, with a left shift extending to blast cells. Basophils and eosinophils are commonly increased. Monocytes may be slightly increased in some cases that overlap with chronic myelomonocytic leukemia (CMML; see later discussion). Thrombocytosis is common, whereas thrombocytopenia is rare and, if present, suggests a worse prognosis. A hemoglobin level of less than 11 g/dL is present in one third of patients. Biochemical abnormalities in CML include a low leukocyte alkaline phosphatase (LAP) score. A low LAP score also occurs in some patients with agnogenic myeloid metaplasia. Serum levels of vitamin B_{12}, lactate dehydrogenase, uric acid, and lysozyme are often increased. Some patients demonstrate a cyclic oscillation of the WBC count. The presence of unexplained myeloid leukocytosis (Fig. 190-2) with splenomegaly should lead to a bone marrow examination and cytogenetic analysis.

Bone Marrow

The bone marrow is hypercellular, with marked myeloid hyperplasia and, at times, evidence of increased reticulin or collagen fibrosis. The myeloid-erythroid ratio is 15 : 1 to 20 : 1. About 15% of patients have 5% or more blast cells in the peripheral blood or bone marrow at diagnosis.

Cytogenetics

The presence of the t(9;22)(q34;q11.2) abnormality establishes the diagnosis of CML. If the Ph chromosome is not found in a patient with suspected CML, molecular studies for the presence of the hybrid *BCR-ABL* gene should be performed. About 25 to 30% of patients with a typical morphologic picture of CML who are Ph negative have the *BCR-ABL* rearrangement. The Ph chromosome is usually present in 100% of metaphases, often as the sole abnormality. Between 10 and 15% of patients have additional chromosomal changes (loss of the Y chromosome, trisomy 8, an additional loss of material from 22q, or double Ph). Some patients have complex chromosomal changes involving chromosome 9 or chromosome 22 (Ph variants, three-way translocations).

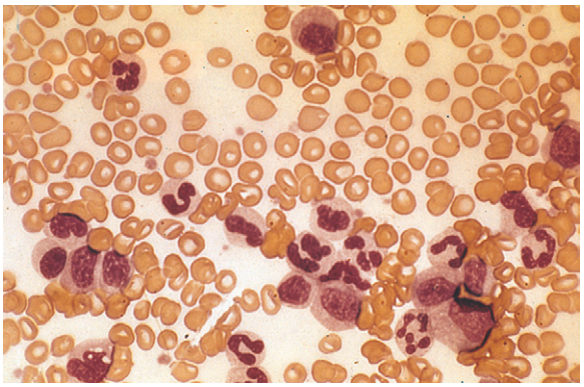

FIGURE 190-2. Chronic myelogenous leukemia, chronic phase. Peripheral smear shows leukocytosis, with representation by the entire spectrum of leukocyte differentiation, ranging from myeloblasts to mature neutrophils. (Courtesy of Andrew Schafer, MD.)

Differential Diagnosis

CML must be differentiated from leukemoid reactions (Chapter 170), which usually produce WBC counts lower than 50,000/μL, toxic granulocytic vacuolation, Döhle's bodies in the granulocytes, absence of basophilia, and normal or increased LAP levels; the clinical history and physical examination generally suggest the origin of the leukemoid reaction. Corticosteroids can rarely cause extreme neutrophilia with a left shift, but this abnormality is self-limited and of short duration.

CML may be more difficult to differentiate from other myeloproliferative or myelodysplastic syndromes (Chapters 169 and 188). Patients with agnogenic myeloid metaplasia with or without myelofibrosis frequently have splenomegaly, neutrophilia, and thrombocytosis. Polycythemia vera with associated iron deficiency, which causes normal hemoglobin and hematocrit values, can manifest with leukocytosis and thrombocytosis. Such patients usually have a normal or increased LAP score, a WBC count less than 25,000/μL, and no Ph chromosome.

The greatest diagnostic difficulty lies with patients who have splenomegaly and leukocytosis but do not have the Ph chromosome. In some, the *BCR-ABL* hybrid gene can be demonstrated despite a normal or atypical cytogenetic pattern. Patients who are Ph negative and *BCR-ABL* negative are considered to have Ph-negative CML or CMML (see later discussion). Rarely, patients have myeloid hyperplasia, which involves almost exclusively the neutrophil, eosinophil, or basophil cell lineage. These patients are described as having chronic neutrophilic, eosinophilic, or basophilic leukemia and do not have evidence of the Ph chromosome or the *BCR-ABL* gene. Isolated megakaryocytic hyperplasia can be seen in essential thrombocythemia (Chapter 169), with marked thrombocytosis and splenomegaly. Some patients who present with clinical characteristics of essential thrombocythemia (with marked thrombocytosis but without leukocytosis) have CML; cytogenetic and molecular studies showing the Ph chromosome, the *BCR-ABL* rearrangement, or both lead to the appropriate diagnosis and treatment.

Clinical Course

Evolution to Accelerated and Blastic Phases

More than 90% of patients present with CML in the benign or chronic phase, which becomes asymptomatic once the disease is controlled. Death rarely occurs during the chronic phase of CML.

When poorly controlled, CML evolves into an accelerated phase, usually defined by the presence of 15% or more blasts, 30% or more blasts plus promyelocytes, 20% or more basophils, thrombocytopenia less than 100,000/μL unrelated to therapy, or cytogenetic clonal evolution. The accelerated phase is also characterized by worsening anemia; increasing splenomegaly or hepatomegaly; infiltration of nodes, skin, bones, or other tissues; and fever, malaise, and weight loss. In the accelerated phase, bone marrow studies may

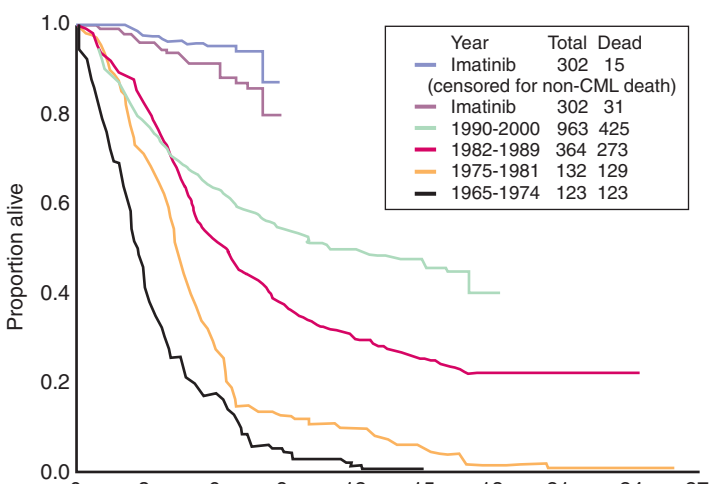

FIGURE 190-3. Survival of patients with Ph-positive chronic myelogenous leukemia in chronic phase. (M. D. Anderson data; 1884 patients from 1965 to 2008.)

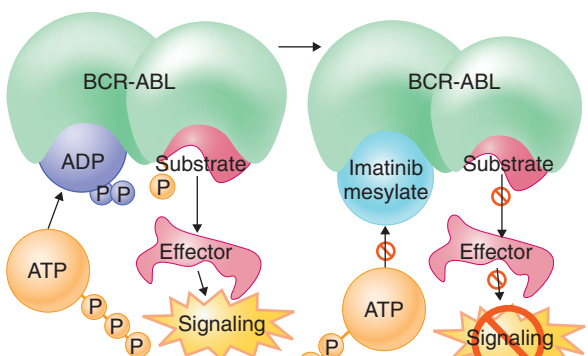

FIGURE 190-4. Mechanism of action of imatinib. By occupying the ATP binding pocket of the ABL kinase domain, imatinib prevents substrate phosphorylation and downstream activation of signals, thus inhibiting the leukemogenic effects of BCR-ABL on cells in chronic myelogenous leukemia. ADP = adenosine diphosphate; ATP = adenosine triphosphate; P = phosphate group.

show dysplastic changes, increased percentages of blasts and basophils, myelofibrosis, and chromosomal abnormalities in addition to the Ph chromosome (clonal evolution). About 5 to 10% of patients present in the accelerated phase.

Before the era of imatinib therapy, the risk of developing accelerated or blastic phase CML was 10% per year in the first 2 years after diagnosis and 15 to 20% per year thereafter, unless therapies such as IFN-α or allogeneic stem cell transplantation were used. With imatinib, the annual incidence of progression of CML from the chronic to the accelerated or blastic phase has been 2% in the first 10 years of observation (Fig. 190-3). Before imatinib therapy, the median survival of accelerated phase CML was 18 months or less, but survival has now increased to 4 years or more.

The blastic phase of CML is diagnosed when 30% or more blast cells are present in the bone marrow and/or peripheral blood or when extramedullary blastic disease is present. Most patients develop features of the accelerated phase before progressing to the blastic phase, but 20% of patients evolve quickly into a blastic phase without warning. Most patients in the accelerated or blastic phase have additional chromosomal abnormalities (clonal evolution) such as duplication of the Ph chromosome, trisomy of chromosome 8, or development of an isochromosome 17. The extramedullary blastic phase of CML can occur in the spleen, lymph nodes, skin, meninges (especially in the lymphoid blastic phase), bones, and other sites; extramedullary transformation is usually followed shortly by evidence of marrow involvement. Blastic phase CML is associated with a very poor median survival time of 5 months. About 25% of patients develop a lymphoid blastic phase; their response rate to anti-ALL–like chemotherapy and imatinib is about 60%, and their median survival time is about 1 year.

Ph-negative and *BCR-ABL*–negative CML often appear to overlap clinically with CMML in terms of behavior, progress, and response to therapy and seem to resemble the myelodysplastic syndromes (Chapter 188) more than Ph-positive CML. A male preponderance and older age are noted; splenomegaly is common (60 to 70%). The WBC count is usually in the range of 25,000 to 100,000/μL. Anemia, thrombocytopenia, and monocytosis are more common than in Ph-positive CML, whereas eosinophilia and basophilia are less common. The median survival time is 18 to 24 months; patients die of infection, bleeding, or transformation to acute leukemia.

TREATMENT

Rx

Choice of Therapy in Chronic Myelogenous Leukemia

Treatment decisions in CML are based on the phase of CML, the patient's age, and the availability of a stem cell donor. For patients presenting in chronic phase CML (>90% of newly diagnosed patients), imatinib mesylate, a selective BCR-ABL tyrosine kinase inhibitor, is first-line therapy in the vast majority of patients. Allogeneic stem cell transplantation is considered effective second-line therapy in chronic phase CML after imatinib failure. Alternative second-line therapies are more potent second-generation tyrosine kinase inhibitors, including dasatinib (dual SRC-ABL kinase inhibitor) and nilotinib (selective and more potent BCR-ABL kinase inhibitor). Patients with CML in the accelerated or blastic phase should consider allogeneic stem cell transplantation as immediate, definitive therapy; in this situation, the use of tyrosine kinase inhibitors as an interim measure before stem cell transplantation may reduce the CML burden significantly and improve the results of allogeneic stem cell transplantation.

Imatinib Mesylate

Since its discovery in 1999, imatinib mesylate has become standard therapy for CML. Imatinib is a 2-phenylaminopyrimidine derivative that binds to the canonical adenosine triphosphate (ATP) lining the groove between the N and C lobes of the ABL kinase domain, thus blocking the phosphorylation of tyrosine residues on substrate protein. Blocking of ATP binding inactivates the ABL kinase, because it cannot transfer phosphate to its substrate. By inhibiting phosphorylation, imatinib prevents the activation of signal transduction pathways that induce the leukemic transformation processes that cause CML (Fig. 190-4). Imatinib inhibits several tyrosine kinases, including $p210^{BCR\text{-}ABL}$, $p190^{BCR\text{-}ABL}$, v-ABL, c-ABL, C-kit, and PDGF receptor.

In a randomized trial of 1106 patients with newly diagnosed CML, imatinib 400 mg/day orally provided significantly higher rates of major cytogenetic response (87% vs. 35%) and complete cytogenetic response (76% vs. 14%), as well as lower rates of progression (8% vs. 26%) and transformation (3% vs. 9%) after 12 months of therapy, compared with the prior standard nontransplantation therapy (a combination of IFN-α and cytosine arabinoside).[1,2] The longer-term follow-up results continue to demonstrate outstanding outcomes with imatinib therapy (Table 190-1; see Fig. 190-3): with a median follow-up of 7 years, the complete cytogenetic response rate (occurring at least once on therapy) is 87%, the estimated 5-year durable complete cytogenetic response rate is 65 to 70%, the annual rate of progression to accelerated or blastic phase is only 1 to 2%, and the estimated 7-year survival rate is above 86% (94% if non-CML deaths are censored).[3] Imatinib plus peginterferon alfa-2a is somewhat superior to imatinib alone for providing a persisting molecular response at 12 months,[4] but its precise role in routine treatment remains to be determined.

Most CML experts and physicians now consider imatinib frontline therapy for all patients with newly diagnosed Ph-positive CML in the chronic phase, regardless of age and donor availability. The only possible exceptions are the rare patients who present with $p190^{BCR\text{-}ABL}$ CML, who may have a worse prognosis on imatinib.

Imatinib has a 5% or lower rate of serious side effects, which include nausea, vomiting, diarrhea, skin rashes, muscle cramps, bone aches, periorbital or leg edema, weight gain, and, rarely, hepatic, renal, or cardiopulmonary dysfunction; most of these are manageable with dose reductions or treatment interruptions. Drug-related myelosuppression occurs in 10 to 20% of patients with newly diagnosed CML and is manageable with brief treatment interruptions, dose modifications, or both or with the administration of growth factors (erythropoietin for anemia, granulocyte colony-stimulating factor for neutropenia). Hypophosphatemia associated with altered bone metabolism can occur, and the serum phosphate level should be monitored. Chromosomal abnormalities may appear in the Ph-negative diploid cells in 5 to 10% of responding patients, probably due to unmasking of a fragile stem cell prone to the development of CML or to chromosomal instability; such changes disappear spontaneously in 70% of cases and rarely evolve into a myelodysplastic syndrome or acute myeloid leukemia, probably as part of the natural course of CML.

Allogeneic Stem Cell Transplantation

Allogeneic stem cell transplantation, a potentially curative therapy in selected patients with CML, is most effective during the chronic phase, when

TABLE 190-1 EARLY RESULTS OF IMATINIB MESYLATE THERAPY IN CHRONIC MYELOGENOUS LEUKEMIA

	% Cytogenetic Response		
PHASE	COMPLETE (Ph 0%)	MAJOR (Ph < 35%)	ESTIMATED SURVIVAL
Blastic	7	10-20	10-15% at 4 yr
Accelerated	20-40	40-60	40-50% at 4 yr
Chronic, after failure of IFN-α	55-63	60-80	80-85% at 4 yr
Chronic, newly diagnosed	65-85	80-90	86-94% at 7-8 yr

IFN-α = interferon-α; Ph = Philadelphia chromosome.

it is associated with a 20-year survival rate of 40 to 50%. Transplant-related mortality ranges from 5 to 50%, depending on the patient's age, whether the donor is related or unrelated, the degree of matching, and other, less important factors such as positivity for cytomegalovirus, preparative and post-transplantation regimens, and institutional expertise. Disease-free survival rates with related allogeneic stem cell transplantation are 40 to 80% in chronic phase, 15 to 40% in accelerated phase, and 5 to 20% in blastic phase. In chronic phase CML, patients younger than 30 to 40 years have disease-free survival rates of 60 to 80%, compared with only 30 to 40% for patients older than 50 years. A major limitation of allogeneic stem cell transplantation is the availability of related donors. Human leukocyte antigen (HLA)–compatible unrelated donors can be found for 50% of patients; the median time from initiation of the donor search to transplantation is 3 to 6 months.

Nonmyeloablative preparative regimens have expanded the indications for allogeneic stem cell transplantation to older patients and have reduced transplant-related mortality and complications (Chapter 181). Early results show acceptable degrees of engraftment, less mortality and organ damage, more persistent residual disease, and similar degrees of graft-versus-host disease. Patients whose CML recurs after allogeneic stem cell transplantation may respond to donor lymphocyte infusions, imatinib or second-generation tyrosine kinase inhibitors (dasatinib, nilotinib), IFN-α, or a second allogeneic transplant.

The advantage of allogeneic stem cell transplantation is its proven track record, with an estimated cure rate of 40% at 20 years. However, it is associated with a 1-year mortality rate of 5 to 40% and with morbidities such as cataracts, infertility, second cancers (5 to 10%), immune-mediated complications, and chronic graft-versus-host disease. Delaying allogeneic stem cell transplantation beyond 1 to 3 years after diagnosis may be associated with worse results and with occasional sudden blastic transformation, which may not be salvageable. The outcome of allogeneic stem cell transplantation may be even better after imatinib exposure.

Treatment of CML after Imatinib Failure

Imatinib failure is strictly defined as (1) lack of any cytogenetic response after 6 months of imatinib therapy, (2) no major cytogenetic response (Ph ≤35%) after 12 months, (3) no complete cytogenetic response (Ph 0%) beyond the first year of therapy (generally at 18 months or later), or (4) hematologic or cytogenetic relapse or CML transformation at any time. Patients with chronic phase CML on imatinib should be considered for allogeneic stem cell transplantation only if imatinib therapy fails. Alternatively, a more potent tyrosine kinase inhibitor may be tried if imatinib resistance is noted. These include nilotinib (AMN107), which is 20 to 50 times more potent than imatinib, and dasatinib (BMS-354825), which is 300 times more potent than imatinib. Both agents are now approved for the treatment of CML after imatinib failure (dasatinib for all CML phases; nilotinib for chronic and accelerated phases). Dasatinib and nilotinib have been associated with complete hematologic response rates of 70 to 80% and complete cytogenetic response rates of 40 to 50% in chronic phase CML, with estimated 2-year survival rates of 90% (compared with annual mortalities of 10 to 20% after imatinib failure before their availability). They have also shown encouraging results in accelerated or blastic phase CML after imatinib failure.[5,6] An important question is whether these second-generation tyrosine kinase inhibitors can be used as more definitive therapy, thus delaying the consideration of allogeneic stem cell transplantation until the failure of drug therapy. This depends on the patient's age (patients 70 years or older may decide to forgo the risks of allogeneic stem cell transplantation, even though it might be curative), the availability of an ideal donor (e.g., related vs. unrelated; matched vs. mismatched), the initial response to tyrosine kinase inhibitors (major cytogenetic response by 12 months predicts long-term favorable disease control), and the presence and specific type of mutations (e.g., *T315I* mutations are resistant to all currently approved tyrosine kinase inhibitors; mutations with a high IC_{50} in vitro [drug concentration that suppresses 50% of clonal growth] to a particular agent are associated with poor long-term disease control).

Treatment of Accelerated and Blastic Phase Chronic Myelogenous Leukemia

Patients with accelerated or blastic phase CML may receive initial imatinib therapy to reduce the CML burden, but they should be considered for early allogeneic stem cell transplantation. Response rates to combination chemotherapy are 20% in nonlymphoid blastic phase CML and 60% in lymphoid blastic phase CML. Median survival times are 3 to 6 months and 9 to 12 months, respectively. The addition of imatinib to chemotherapy has improved the response rates and prolonged the median survival time in blastic phase CML from 3 to 5 months to 6 to 12 months.

At present, allogeneic stem cell transplantation is the only curative therapy for accelerated and blastic phase CML: overall cure rates are in the range of 15 to 40% and 5 to 20%, respectively, and patients with cytogenetic clonal evolution as the only accelerated phase criterion have a long-term event-free survival rate of about 60%. Otherwise, imatinib provides hematologic responses in 80% of patients and an estimated 4-year survival rate of 40 to 55% in accelerated phase CML, but only a 40% response rate and a median survival of 7 months in blastic phase CML. Patients in the accelerated or blastic phase should be encouraged to participate in investigational strategies to improve their prognosis. Combinations of imatinib with chemotherapy may improve results in CML transformation, as may the new tyrosine kinase inhibitors.

Special Therapeutic Considerations

Patients with severe leukocytosis and manifestations of leukostasis may benefit from initial leukapheresis. Severe thrombocytosis uncontrolled with anti-CML measures may respond to anagrelide, thiotepa, IFN-α, 6-mercaptopurine, 6-thioguanine, and platelet pheresis. CML during pregnancy may be controlled with pheresis in the first trimester and then with hydroxyurea until delivery. Use of IFN-α during pregnancy has been reported anecdotally to be safe. There is little experience with the use of imatinib during pregnancy. Splenectomy can be useful as a palliative measure in patients with massive painful splenomegaly, hypersplenism, or thrombocytopenia.

Follow-up

Monitoring Response to Therapy in CML

With improved therapy, the incidences of complete cytogenetic response and minimal residual disease have increased. This has required the development of new techniques to measure these responses more accurately (rather than relying on only 20 metaphases by cytogenetic analysis), less tedious and less painful procedures (peripheral blood rather than marrow studies), and techniques that can measure minimal (molecular) disease below the level of detection by routine cytogenetic studies. Fluorescence in situ hybridization (FISH) studies with improved probes can measure 200 interphase cells using peripheral blood, and they have false-positive rates of less than 2 to 3%. Quantitative polymerase chain reaction (QPCR) studies usually measure the ratio of the abnormal message, BCR-ABL, to a normal message, such as ABL. A BCR-ABL/ABL ratio of 0.1% (International Standard) or less, about a 3-log reduction of disease, has been associated with a very low risk of CML relapse on imatinib therapy. This is now referred to as a *major molecular response*. A negative QPCR analysis (i.e., undetectable BCR-ABL levels, usually $<10^{-5}$ to 10^{-6}) may be dependent on the technique used and could be referred to as a *complete molecular response*.

In monitoring the response to imatinib-based therapies, patients require a bone marrow analysis before therapy (to determine the percentages of blasts and basophils and clonal evolution), at 6 and 12 months (to assess cytogenetic response and confirm complete cytogenetic response), and once every 1 to 3 years in those with stable, durable complete cytogenetic responses (to look for chromosomal abnormalities in both Ph-positive and Ph-negative cells). Monitoring in patients with confirmed, durable complete cytogenetic responses can be continued with either FISH or QPCR studies every 6 months (or more often, such as every 3 months, if there are concerns about significant and consistent increases in QPCR levels). The frequency of monitoring depends on the treatment plan; monitoring is more frequent in younger patients, less frequent in very old patients.

"Resistance" to imatinib therapy can be defined as persistent 100% Ph positivity after 6 months of therapy, Ph positivity of more than 35% after 12 months of therapy, or cytogenetic or hematologic relapse. A positive QPCR in a patient with a complete cytogenetic response does not, at present, indicate imatinib resistance or the need to change therapy. The rate of resistance to imatinib in chronic phase CML is less than 4% per year; for those who achieve a complete cytogenetic response, the rate of resistance beyond year 3 of imatinib therapy is 1% or less, suggesting the durable stability of a complete cytogenetic response on imatinib and the predictability of the CML course once such a response is obtained. Several mechanisms of resistance have been identified; the most common are mutations in the BCR-ABL kinase domain. More than 50 different mutations have been reported and can involve any of the important domains in the BCR-ABL structure, including the P-loop (the area where ATP binds), the activation loop, and the catalytic domain, as well as the amino acids

where imatinib makes contact with BCR-ABL. The different mutations have considerable variability with respect to resistance to imatinib. Some mutations are overcome by slightly higher concentrations of imatinib than required to inhibit the wild-type form; others are completely insensitive to imatinib. Mutational analysis is useful in patients with imatinib resistance to identify those with the *T315I* mutation, who do not respond to imatinib or the second-generation tyrosine kinase inhibitors (dasatinib, nilotinib, bosutinib) and should be considered for immediate allogeneic stem cell transplantation or therapy with *T315I*-selective inhibitors. In addition, knowledge of the sensitivity of the different mutations, as determined by the IC_{50} for particular agents, can help select the tyrosine kinase inhibitor. Mutational studies may also be helpful in patients who develop cytogenetic or hematologic resistance or relapse on imatinib therapy.

FUTURE DIRECTIONS

Two second-generation tyrosine kinase inhibitors, dasatinib and nilotinib, are now approved for the treatment of CML after imatinib failure. Other tyrosine kinase inhibitors (bosutinib) are under investigation, with promising results. Three randomized studies of the more potent second-generation tyrosine kinase inhibitors nilotinib, dasatinib, and bosutinib against the standard of care, imatinib, are ongoing in patients with newly diagnosed CML. Maturing data suggest that they may significantly improve the complete cytogenetic and major molecular response rates, as well as reduce the transformation rate to the accelerated and blastic phases.[5,6] Equally important are the "third-generation" tyrosine kinase inhibitors such as AP24534, which are also active against CML with the *T315I* mutation. Other active anti-CML agents under development include omacetaxine (previously known as homoharringtonine), decitabine (a hypomethylating agent), and pegylated formulations of interferon. Immunotherapeutic strategies, including vaccines, may improve the eradication of minimal residual disease, potentially obviating the need for indefinite therapy with imatinib. Further understanding of the pathophysiology and events downstream of BCR-ABL may help in the development of new strategies to target these events. Such strategies may include inhibitors of pathways involving Raf, protein farnesylation, mTOR, JAK/STAT, proteasome, MEK/MAPK, PI3K/AKT, or others.

PROGNOSIS

Imatinib therapy has revolutionized the treatment of CML. In cases of newly diagnosed CML, imatinib therapy is associated with an estimated 7-year survival rate of 86% (94% if non-CML deaths are censored). If this favorable trend continues with longer follow-up, the median survival time in CML may exceed 25 years. During the first 7 years of follow-up, the annual mortality has been about 2%. Many well-established poor prognostic factors in CML (e.g., older age, splenomegaly, presence of marrow fibrosis, deletion of derivative 9q) have lost much of their importance since the advent of imatinib therapy. With allogeneic stem cell transplantation, cures can be expected in 40 to 80% of patients with chronic phase CML, 15 to 40% of those with accelerated phase CML, and 5 to 20% of those with blastic phase CML.

CHRONIC MYELOMONOCYTIC LEUKEMIA

DEFINITION AND EPIDEMIOLOGY

Although superficially resembling CML in its clinical and morphologic presentation, CMML should be considered a separate entity because of its particular clinical, therapeutic, and prognostic aspects. CMML is a hybrid entity manifesting as a proliferation of the myeloid monocytic series and dysplasia of the erythroid-megakaryocytic series. Patients with CMML are older (median age, 65 to 70 years) than most patients with CML.

PATHOBIOLOGY

The cytogenetic findings in patients with CMML are normal or involve an additional chromosome 8 or findings other than the Ph chromosome. Patients with CMML have *RAS* mutations in 40 to 60% of cases.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients often present with symptoms related to anemia and thrombocytopenia (fatigue, bleeding). Other typical features include splenomegaly, leukocytosis, and monocytosis. Organ infiltration (lymph nodes, skin, liver) is less common. Basophilia and thrombocytosis are not presenting features.

TREATMENT AND PROGNOSIS

Rx

Allogeneic stem cell transplantation (Chapter 181), which is the only curative modality, should be considered frontline therapy in candidate patients. Other therapies include hydroxyurea to control leukocytosis, erythropoietin to improve anemia, azacitidine or decitabine (both approved by the U.S. Food and Drug Administration [FDA] for the treatment of CMML), topotecan and cytarabine or other intensive anti-AML (Chapter 189) regimens for CMML transformation, splenectomy for symptomatic splenomegaly and/or hypersplenism, and investigational agents.

Poor prognostic factors include the presence of anemia (hemoglobin <10 g/dL), thrombocytopenia, and more than 5% blasts. Median survival time is 12 to 18 months.

HAIRY CELL LEUKEMIA

DEFINITION AND EPIDEMIOLOGY

Hairy cell leukemia (HCL) is an uncommon and indolent B-cell leukemia (1 to 2% of all leukemias). The median age at diagnosis is 50 years, and there is a 4 : 1 male preponderance.

PATHOBIOLOGY

The cell of origin of HCL is the B lymphocyte, as documented by the demonstration of heavy and light chain immunoglobulin gene rearrangements. Hairy cells express CD19, CD20, CD11C, CD103, FMC7, and CD22, but not CD21, CD5, CD10, or CD23. The cells demonstrate a κ or γ light chain phenotype excess. The cells also express CD25 (TAC), the low-affinity interleukin-2 (IL-2) receptor, and CD103, a unique hairy cell antigen. High levels of soluble IL-2 receptor (>5 times normal) are present in the sera of almost all patients with HCL, with extremely high levels noted in many cases. A number of different cytogenetic abnormalities have been reported in HCL, but none appears to be consistently present, and all have been described in other hematologic malignancies. Immune dysfunction is wide ranging in HCL. Monocytopenia is universal; B and T lymphocytes are decreased in number; the CD4/CD8 (T helper/T suppressor) ratio is often inverted; and skin test reactivity to recall antigens is impaired, as is antibody-dependent cellular cytotoxicity. Humoral immunity is relatively preserved, with normal immunoglobulin levels. Marrow failure in HCL may be due in part to inhibitory factors (e.g., tumor necrosis factor) produced by the leukemic infiltrate; the pancytopenia is often more marked than would be anticipated from the degree of leukemic infiltration.

CLINICAL MANIFESTATIONS

The majority of patients present with pancytopenia and splenomegaly. Patients may also have fatigue, fever, weight loss, and infection secondary to granulocytopenia or monocytopenia. Leukocytosis is uncommon, and lymphadenopathy is rare. Anemia is present in up to 85% of patients, whereas leukopenia and thrombocytopenia are present in 60 to 75%. The cytopenias are caused by a combination of bone marrow failure due to leukemic infiltration and hypersplenism. Patients may experience repeated infections and, rarely, a systemic vasculitis resembling polyarteritis nodosa. Although bacterial infections occur, as would be expected with neutropenia, patients with HCL have a predilection to develop tuberculosis, atypical mycobacterial infections, and fungal infections, perhaps related to the severe monocytopenia that is characteristic of this disorder.

DIAGNOSIS

In conjunction with the clinical features, careful examination of the peripheral blood smear may demonstrate the occasional typical cells with cytoplasmic projections, giving rise to the name *hairy cell leukemia* (Fig. 190-5). The hairy cells are 10 to 15 mm in diameter, with pale blue cytoplasm, a nucleus with a loose chromatin structure, and one or two indistinct nucleoli. Bone marrow aspiration is often inadequate owing to increased deposition of reticulin, collagen, and fibrin; bone marrow biopsy is usually necessary. Bone marrow involvement is interstitial or patchy, and the infiltrate is characterized by widely spaced nuclei due to the abundant cytoplasm, giving rise to the commonly described "fried egg" appearance.

Hairy cells exhibit a strong acid phosphatase (isoenzyme 5) cytochemical reaction in 95% of cases, a reaction that is resistant to the inhibitory effect of tartaric acid (TRAP). Other lymphoproliferative diseases are rarely TRAP positive. Electron microscopy clearly demonstrates the microvillar

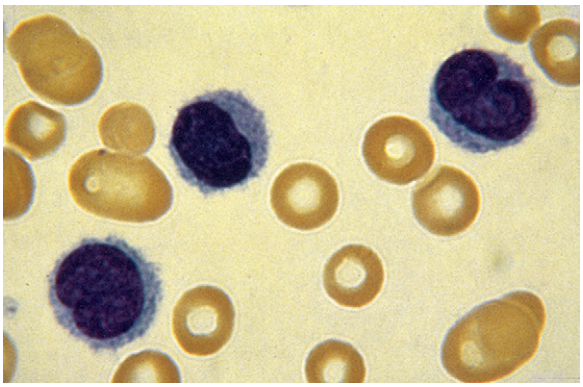

FIGURE 190-5. Hairy cell leukemia. Peripheral smear shows hairy cells with blue-gray cytoplasm; fine, hair-like projections (resembling ruffles); and oval or slightly indented nuclei with loose chromatin and indistinct nucleoli. (Courtesy of Andrew Schafer, MD.)

projections. Often, ribosomal-lamellar complexes, which are characteristic but not diagnostic of HCL, can be identified. The peroxidase stain is negative, and lysozyme activity is absent in hairy cells, thereby differentiating these cells from monocytes.

Differential Diagnosis

The differential diagnosis must distinguish HCL from lymphoma (Chapter 191) or chronic lymphocytic leukemia (CLL), which can manifest with predominant splenomegaly and minimal lymphadenopathy. Some patients with a myelodysplastic syndrome (Chapter 188) or a myeloproliferative syndrome (Chapter 169) have splenomegaly and pancytopenia with only a few atypical cells. Patients with other diseases, such as systemic lupus erythematosus (Chapter 274) and other autoimmune diseases, B-cell and T-cell prolymphocytic leukemias (see later), infiltrative splenomegaly (Chapter 171), or tuberculosis (Chapter 332), may have splenomegaly and cytopenia, but these diagnoses can usually be made by history, physical examination, and appropriate blood and bone marrow tests. Splenomegaly, cytopenia, and nonaspirable marrow in a middle-aged man should create a high index of suspicion for HCL. Splenectomy and lymph node biopsy are sometimes necessary to establish the diagnosis in difficult cases. Cases of HCL variant manifest with higher WBC counts, are TRAP negative, have prominent nucleoli, and are only occasionally positive for antibodies against CD25. HCL variant does not respond as well to the agents that are usually effective in the management of typical HCL.

TREATMENT

A small proportion (<5%) of patients with HCL do not require therapy. These patients have mild cytopenias, are not transfusion dependent, have no history of infections, and have a low level of marrow infiltration by hairy cells.

2-Chlorodeoxyadenosine (cladribine), an adenosine analogue that is resistant to deamination by adenosine deaminase, produces complete remission in more than 80% of HCL patients after a single course of 0.1 mg/kg/day for 7 days given by continuous intravenous infusion, and it is now the recommended first-line therapy. Remissions are durable, and patients who relapse can often attain a second remission after retreatment with cladribine. The drug is well tolerated, with a low infection rate. Despite long-lasting suppression of $CD4^+$ lymphocyte counts, there does not appear to be an increase in late opportunistic infections or second malignancies.

Deoxycoformycin (pentostatin; 4 mg/m^2 weekly or every 2 weeks for up to 6 months), an adenosine deaminase inhibitor, produces complete remission in 70 to 80% of patients. The response to treatment is rapid, and the drug is active in patients previously treated with IFN. Toxicity includes nausea and vomiting, infection, renal and hepatic dysfunction, conjunctivitis, and photosensitivity, albeit mild in most cases.

Human leukocyte interferon (HuIFN), or r-IFN-α, rapidly improves granulocyte, platelet, and hemoglobin levels (1 to 3 months); reduces spleen size; and decreases marrow infiltration. Peripheral blood cell counts return to normal in 80% of cases, but complete remission is uncommon. In addition, when treatment is discontinued, relapse occurs within 1 to 2 years.

Rituximab, the monoclonal antibody targeting CD20, can also produce responses; 8 weekly infusions appear to be more effective than four.

Two immunotoxins can produce responses in refractory patients. LMB2 is composed of the Fc portion of the anti-TAC antibody linked to a *Pseudomonas* exotoxin. BL22 also contains *Pseudomonas* exotoxin linked to an antibody targeting CD22. Splenectomy is recommended mainly for patients with splenic infarcts or massive splenomegaly.

PROGNOSIS

More than 85 to 90% of patients treated with cladribine or pentostatin are expected to be alive at 10 years.

CHRONIC LYMPHOCYTIC LEUKEMIA

DEFINITION

CLL is a neoplasm characterized by the accumulation of monoclonal lymphocytes of B-cell origin. The cells accumulate in the bone marrow, lymph nodes, liver, spleen, and occasionally other organs.

EPIDEMIOLOGY

CLL is the most common leukemia (one third of all cases) in the Western world and is twice as common as CML. The disease occurs rarely in those younger than 30 years; most patients with CLL are older than 60 years. CLL increases in incidence exponentially with time; by age 80, the incidence rate is 20 cases per 100,000 persons per year. The male-female ratio is approximately 2 : 1. The incidence of CLL among Asians in Japan and China is only 10% of that in the United States and other Western countries. Intermediate incidence rates are seen in persons of Hispanic origin.

The cause of CLL is unknown. Ionizing radiation and viruses have not been associated with CLL, although hepatitis C infection has recently been associated with splenic lymphoma with villous lymphocytes (another indolent B-cell disorder). Familial clustering in CLL is more common than in other leukemias; first-degree relatives of patients have a two- to four-fold higher risk and develop CLL at a younger age compared with the general population (anticipation). Farmers have a higher incidence of CLL than do those in other occupations, raising the possibility of an etiologic role for herbicides or pesticides. Agent Orange, the defoliating agent used in Vietnam, has been associated with the development of CLL.

PATHOBIOLOGY

Leukemia cells in CLL are homogeneous and have the appearance of normal mature lymphocytes. However, clonality can be documented by the presence of immunoglobulin gene rearrangements and the restriction to either κ or γ light chains on the cell surface. The cells express low-intensity monoclonal surface immunoglobulin (SmIg; usually immunoglobulin [Ig] M ± IgD) and the pan-B-cell antigens CD19, CD20, CD23, and CD24 in almost all cases, as well as CD21 (which includes the receptor for the Epstein-Barr virus and the C3d component of complement) in more than 75% of cases. Almost all cells exhibit Ia antigen and receptors for the Fc fragment of IgG and spontaneously form rosettes with mouse erythrocytes. In addition to B-cell antigens, CLL cells express CD5 (Leu 1, T1, and T101), a pan-T-cell antigen. Other T-cell antigens are absent. CD25 (TAC, IL-2 receptor) antigen is positive in about 25% of cases. T cells are increased in number at diagnosis, and the CD4/CD8 ratio is often inverted, owing to a relatively greater increase in $CD8^+$ cells. The CD4/CD8 ratio declines as the disease progresses and after therapy. The T cells have a blunted response to T-cell mitogens and decreased delayed hypersensitivity reactions to recall antigens. However, these T-cell functions may be impaired by factors produced by the CLL cells, because purified T cells have a normal response to T-cell mitogens.

GENETICS

Standard cytogenetic analysis identifies abnormalities in 40 to 50% of cases of CLL, but CLL cells have low mitotic activity. By FISH, the likelihood of detecting abnormalities increases to 80%. A 13q deletion is the most common abnormality; other abnormalities include 11q deletion (15 to 20%), trisomy 12 (15 to 20%), and 17p deletion (5 to 10%). The 17p deletion increases in frequency as the disease progresses, recurs after therapy, and is associated with a very poor prognosis. The 11q deletion also is associated with a poorer prognosis, whereas the 13q deletion, if present as the sole abnormality, is associated with a favorable prognosis.

CLINICAL MANIFESTATIONS

Most patients with CLL are asymptomatic, and the disease is diagnosed when absolute lymphocytosis is noted in the peripheral blood (see Fig. 190-6) during evaluation for other illnesses or when the patient undergoes a routine physical examination. Symptoms such as fatigue, lethargy, loss of appetite, weight loss, and reduced exercise tolerance are nonspecific. Many patients have enlarged lymph nodes. B symptoms (fever, night sweats, weight loss) are rarely present initially, and their presence in later stages of the disease suggests transformation to large cell lymphoma. The most common infections are sinopulmonary. As the disease progresses, the frequency of neutropenia, T-cell deficiency, and hypogammaglobulinemia increases, resulting in infections with gram-negative bacteria, fungi, and viruses such as herpes zoster and herpes simplex.

The major physical findings relate to infiltration of the reticuloendothelial system. Lymphadenopathy with discrete, rubbery, mobile lymph nodes is present in two thirds of patients at diagnosis. Later, as the lymph nodes enlarge, they can become matted. Enlargement of the liver or spleen is less common at diagnosis (approximately 10% and 40% of cases, respectively) but occurs more frequently with progression. Organ failure resulting from infiltration with CLL is uncommon. Infiltration of the central nervous system in CLL is rare, and central nervous system symptoms are more likely to be caused by opportunistic infections such as cryptococcosis or listeriosis.

DIAGNOSIS

CLL is characterized by absolute lymphocyte counts that typically range from 5000 to 600,000/μL in the peripheral blood. Even with markedly elevated WBC counts, hyperviscosity symptoms rarely occur, probably because of the small size and pliability of the cells. Anemia (hemoglobin <11 g/dL) is present in 15 to 20% of patients at diagnosis, and thrombocytopenia (platelet count <100,000/μL) in 10%. However, bone marrow replacement and hypersplenism, which are seen with progressive disease, increase the frequency of anemia and thrombocytopenia. The anemia is usually normochromic and normocytic, and the reticulocyte count is normal unless the patient has autoimmune hemolytic anemia (Chapter 163), which usually results from the development of a warm-reacting IgG antibody. The diagnosis of autoimmune hemolytic anemia, which occurs in 10% of cases, is confirmed by a positive direct Coombs test (80 to 90% of cases), reticulocytosis, a low serum haptoglobulin concentration, and an elevated unconjugated serum bilirubin level. In such patients, reactive erythroid hyperplasia as a response to the hemolysis may be masked in the bone marrow by the marked lymphocytic infiltration. Cold agglutinin hemolysis occurs rarely in CLL. Autoimmune thrombocytopenia (immune thrombocytopenic purpura; Chapter 175) can be diagnosed in 10 to 15% of cases. The antibodies causing red cell and platelet destruction are not produced by the CLL cells, and the mechanisms for the associated autoimmune diseases are not known. Pure red cell aplasia (Chapter 168) is an additional, underappreciated cause of anemia in CLL.

The lymphocytes in CLL are indistinguishable on light or electron microscopy from normal small B lymphocytes (Fig. 190-6). On bone marrow aspiration, the proportion of lymphocytes is greater than 30% and may be up to 100%. Four patterns of lymphocyte infiltration on bone marrow biopsy occur: nodular (15%), interstitial (30%), mixed nodular and interstitial (30%), and diffuse (35%). Most early-stage cases have one of the first three patterns; diffuse histology is common in advanced-stage disease and becomes more prominent as the disease evolves. A diffuse histologic pattern confers a poor prognosis regardless of the stage of disease.

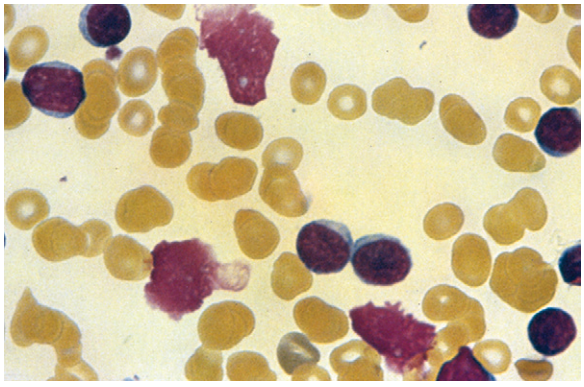

FIGURE 190-6. Chronic lymphocytic leukemia. Peripheral smear shows that the predominant leukocytes are "normal," mature-appearing lymphocytes, with occasional "smudge" cells. (Courtesy of Andrew Schafer, MD.)

Differential Diagnosis

There are many diseases that can cause lymphocytosis, including pertussis (Chapter 321), cytomegalovirus (Chapter 384), Epstein-Barr virus mononucleosis (Chapter 385), tuberculosis (Chapter 332), toxoplasmosis (Chapter 357), chronic inflammatory disorders, and autoimmune syndromes. These diseases are seldom confused with B-cell CLL, largely because the lymphocytosis in these conditions is usually less than 15,000/μL and is not sustained. If doubt persists, immunophenotypic or molecular studies can distinguish the monoclonal lymphocytosis in CLL from the T-cell or polyclonal B-cell proliferation in the other disorders.

In individuals 62 to 80 years old, monoclonal CLL-phenotype B cells are found in about 5% of individuals with normal blood counts. In patients with greater than 4000 lymphocytes/mL, about 45% have CLL, about 40% have reactive lymphocytosis, and about 15% have monoclonal CLL-phenotype B cells that confer a 1.1% per year risk of developing CLL. In patients ultimately diagnosed with CLL, B-cell clones were previously present in peripheral blood in 98% of patients, sometimes many years before diagnosis.

Other Chronic Lymphocytic Leukemias

The more difficult differential diagnosis is distinguishing CLL from other lymphoproliferative disorders such as prolymphocytic leukemia (PLL), splenic lymphoma with villous lymphocytes, HCL, the leukemic phase of mantle cell lymphoma, and Waldenström's macroglobulinemia. Although certain clinical features are more common in some of these disorders (e.g., marked splenomegaly with minimal or no lymphadenopathy in PLL, splenic lymphoma, and HCL vs. extensive lymphadenopathy with or without splenomegaly in CLL), none of these clinical features is specific. The differential diagnosis therefore depends largely on histopathologic and, more specifically, immunophenotypic features (Table 190-2).

Prolymphocytic Leukemia

PLL is an uncommon disease (incidence <5% that of CLL), and its characteristics of massive splenomegaly, minimal lymphadenopathy, and markedly elevated WBC count (often >100,000/μL), with 10 to 90% of the cells being prolymphocytes, distinguish this disease from typical B-cell CLL. Prolymphocytes are larger cells that have a distinct nucleolus and express FMC-7. The male-female ratio is 4:1, and the median age at diagnosis is 70 years. Survival is shorter than in CLL (median 3 years), and response to therapies usually applied in CLL is poor. A serum paraprotein, typically IgG or IgA, is present in one third of cases. The immunoglobulin on the surface of the cells is occasionally IgG or IgA, not IgM ± IgD, as in CLL. Several karyotypic abnormalities have been reported in PLL, including t(11;14)(q13;q32). Deletions of 11q3, 23, and 17p are more common in B-cell PLL than in CLL. Abnormalities in the *TP53* oncogene are found in 75% of cases of B-cell PLL. One fifth of PLL cases express a T-cell phenotype.

Small Lymphocytic Lymphoma

Small lymphocytic lymphoma (SLL) shares histopathologic and immunophenotypic features with CLL, differing only in the lack of lymphocytosis in the peripheral blood. The bone marrow in SLL may or may not have more than 30% lymphocytes. LFA-1 adhesion protein is much more commonly expressed on SLL cells than on CLL cells. Other lymphomas, such as follicular and mantle cell lymphomas (Chapter 191), occasionally manifest a leukemic phase on initial presentation. Follicular lymphoma cells are often cleaved on light microscopy, have bright staining for SmIg, and are positive for FMC-7 and CD10. Lymph node biopsy should be performed to identify these cases with greater precision. The presence of lymphoma cells in the blood in follicular lymphoma is more common with advanced disease. Follicular lymphoma can usually be identified by the presence of the translocation t(14;18) and consequent *BCL2* rearrangement, both of which are rare in CLL. The WBC count in Waldenström's macroglobulinemia (Chapter 193) is usually much lower than in CLL (<10,000/μL), and many patients are leukopenic. The cells have a plasmacytoid appearance, CD38 and PCA-1 positivity, and more SmIg and cytoplasmic Ig. A serum monoclonal IgM peak is present in almost all cases of Waldenström's macroglobulinemia but is uncommon in CLL.

TABLE 190-2 DIFFERENTIAL DIAGNOSIS OF INDOLENT LYMPHOPROLIFERATIVE DISORDERS

DISEASE	LYMPHADENOPATHY (%)	SPLENOMEGALY (%)	CELL OF ORIGIN (B/T)	Positive Markers* SmIg	CD5	CD19, CD20 (%)	OTHER
Chronic lymphocytic leukemia (CLL)	75	50	B (20 : 1)	Weak	>90%	≥90	Mouse red blood cell receptors
Prolymphocytic leukemia (PLL)	33	95	B (4 : 1)	Bright	T-cell PLL	75	FMC-7
Hairy cell leukemia	<10	80	B (T rare)	Bright	—	>90	CD25, CD11C, CD103
Lymphoma (leukemic phase)	90	90	B (T rare)	Bright	Some	>90	CD10
Splenic lymphoma with villous lymphocytes	10	80	B	Bright	20%	>90	FMC-7, CD22
Waldenström's macroglobulinemia	33	33	All B	Weak	Some	Many	CD38, PCA-1
Large granular lymphocytosis	10	10	All T	Absent	—	—	CD2, CD3, CD8

*CD2 = pan-T cell; CD3 = pan–mature T cell; CD5 = pan-T cell, B-cell CLL; CD8 = T cell (suppressor cytotoxic); CD10 = early B cell; CD11C = hairy cell, activated T cell, NK cell; CD19 = early pan-B cell; CD20 = pan-B cell; CD25 = low-affinity interleukin-2 receptor; CD38 = activated B cell, thymocyte, plasma cell; FMC-7 = PLL, hairy cell leukemia; PCA-1 = plasma cell; SmIg = monoclonal surface immunoglobulin.

TABLE 190-3 RAI AND BINET STAGING SYSTEMS IN CHRONIC LYMPHOCYTIC LEUKEMIA

STAGE	LYMPHOCYTOSIS	LYMPHADENOPATHY	HEPATOMEGALY OR SPLENOMEGALY	HEMOGLOBIN (G/DL)	PLATELETS $\times 10^3$/ML
RAI STAGING SYSTEM					
0	+	–	–	≥11	≥100
I	+	+	–	≥11	≥100
II	+	±	+	≥11	≥100
III	+	±	±	<11	≥100
IV	+	±	±	Any	<100
BINET STAGING SYSTEM					
A	+	±	± (<3 lymphatic groups* positive)	≥10	≥100
B	+	±	± (≥3 lymphatic groups* positive)	≥10	≥100
C	+	±	±	<10†	<100†

*The three lymphatic groups are (1) cervical, axillary, and inguinal nodes; (2) liver; and (3) spleen. Each group is considered one group whether unilateral or bilateral.
†The criterion is hemoglobin <10 g/dL and/or platelets <100 × 10^3/mL.

T-Cell Leukemias

The predominant clinical manifestation of Sézary's syndrome (a $CD4^+$ T-cell malignant disorder related to mycosis fungoides) is chronic exfoliative erythroderma with a low number of circulating monoclonal T cells. The clinical and laboratory differentiation from CLL is not difficult. Other T-cell malignant disorders with peripheral blood involvement are adult T-cell leukemia-lymphoma and large granular lymphocytosis, also referred to as large granular lymphoproliferative disorder, T-cell lymphocytosis with neutropenia, or T-gamma lymphocytosis syndrome. Adult T-cell leukemia-lymphoma is associated with a retrovirus (human T-lymphotropic virus I) and is common in Japan and the Caribbean. It frequently manifests with lytic bone lesions and hypercalcemia. In T-cell large granular lymphoproliferative disorders, the absolute lymphocyte count is usually low (<5000/μL), with a $CD2^+$, $CD3^+$, $CD8^+$, and $CD16^+$ (T-suppressor) phenotype (T-gamma cells). These patients often have splenomegaly, neutropenia, and rheumatoid arthritis–like symptoms. A subset, called natural killer (NK) cell large granular lymphocytosis, has an NK cell phenotype ($CD16^-$) and no molecular evidence of T-cell receptor rearrangement. The lymphocytes have abundant cytoplasm with azurophilic granules. Most patients have a benign course, although repeated infections can occur.

Staging and Prognostic Factors

The natural history of CLL is heterogeneous, with survival times ranging from 2 to 20 years after diagnosis. Either of two validated clinical staging systems can be used. The Rai staging system (1975) defines five stages and is most frequently used in the United States, whereas the Binet system (1981) defines three stages and is most frequently used in Europe (Table 190-3). Patients with anemia and thrombocytopenia (Rai III and IV, Binet C) have the worst prognosis; patients with lymphocytosis alone (Rai 0, some Binet A patients) have an excellent prognosis. A group of patients with a lymphocyte count less than 30,000/μL, hemoglobin greater than 13 g/dL, platelet count greater than 100,000/μL, fewer than three involved node areas, and lymphocyte doubling time greater than 12 months has been described as having "smoldering" CLL, with survival equal to that of an age- and sex-matched control population. Patients tend to progress through stages, with many patients developing more sites of involvement over time and eventually experiencing marrow failure; however, anemia and thrombocytopenia can develop abruptly, even without antibody-mediated destruction or markedly increased tumor burden.

Other adverse factors include a diffuse pattern of lymphocytic infiltration observed on bone marrow biopsy; molecular abnormalities, including deletion of 11q or 17p; advanced age; male sex; elevated serum levels of thymidine kinase, β_2-microglobulin, and soluble CD23; rapid lymphocyte doubling time; an increased proportion of large or atypical lymphocytes in the peripheral blood; and lack of somatic mutation of the *VH* gene within the B-CLL cell or the presence of the ZAP-70 protein or CD38 on the CLL cell surface.

TREATMENT Rx

The major therapeutic questions are when to treat and which therapeutic regimen to use. Patients with CLL are usually older, and the prognosis of the disease is variable (with some early-stage cases being stable for 10 to 20 years). Treatment of early-stage CLL (Rai 0, Binet A) is delayed until the disease progresses. In randomized trials, early treatment with alkylating agents did not prolong survival and was associated with a heightened risk of developing second malignant tumors. Two large clinical trials are currently investigating, in a randomized fashion, whether early treatment benefits asymptomatic patients with high-risk disease. Treatment of Rai stages III and IV (Binet stage C) is recommended at the time of diagnosis because of the morbidities associated with cytopenias and the poor survival time of these patients. Treatment

of intermediate-stage disease (Rai I and II, Binet B) is recommended if symptomatic disease (fever, sweats, weight loss, severe fatigue) or massive lymphadenopathy, with or without hepatosplenomegaly, is present.

Medical Therapy

Chemotherapy

Fludarabine monophosphate (25 mg/m^2/day for 5 days every 4 weeks), an adenosine analogue, is approved by the FDA for treatment of relapsed CLL, with overall response rates of 50 to 60%. The dose-limiting toxicity is myelosuppression. When used in conjunction with steroids, the treatment may be complicated by infections with organisms usually associated with immunodeficiency syndromes involving T lymphocytes (e.g., those caused by *Pneumocystis jirovecii* or herpesviruses). In a large randomized trial of initial therapy for CLL, fludarabine resulted in higher overall and complete remission rates, longer duration of remission, and improved response rates on crossover, but there was no survival advantage compared with chlorambucil, the prior standard therapy.[7] However, 10-year follow-up has now shown a survival benefit in the fludarabine arm. Cladribine is used primarily in Europe, where it appears to have efficacy similar to fludarabine; pentostatin has not been as widely studied in CLL as in HCL.

Before the advent of fludarabine, combination regimens were based on alkylating agents and borrowed from regimens used to treat lymphoma. The COP regimen (cyclophosphamide 100 to 300 mg/m^2/day orally on days 1 through 5, vincristine [Oncovin] 2 mg intravenously on day 1, and prednisone 100 mg orally on days 1 through 5) does not have any advantage over chlorambucil alone, usually given at a dose of 0.1 to 0.2 mg/kg/day for 3 to 6 weeks until the desired effect is obtained or until thrombocytopenia or neutropenia develops; the dose is then adjusted for maintenance and is continued for 6 to 12 months. Regimens using cyclophosphamide, doxorubicin, and prednisone with vincristine (CHOP) or without vincristine (CAP) have produced response rates of 50 to 70% in those with Binet stage C disease.

The combination of fludarabine and cyclophosphamide (FC) was a logical attempt to improve on the efficacy of fludarabine alone by combining it with the other most active agent in this disease, an alkylating agent. The FC combination has been compared to fludarabine alone in three randomized trials.[8-10] All these trials consistently showed a higher complete response rate, higher overall response rate, and longer progression-free survival with the FC combination.

After therapy, many patients remain stable for months to years before progressive disease indicates the need for further treatment. The goal of treatment is to achieve complete response (Table 190-4).

Bendamustine is a potent alkylating agent that has some structural similarity to nucleoside analogues, but preclinical data suggest that it does not function as a nucleoside analogue. Bendamustine was recently approved by the FDA for the treatment of CLL based on a randomized trial comparing this agent to chlorambucil as initial therapy for patients with CLL.[11] Complete and overall response rates were higher with bendamustine, and progression-free survival was longer. The main side effect is myelosuppression.

Monoclonal Antibodies

Rituximab, a monoclonal antibody targeting the CD20 antigen, is associated with response rates of about 50% when given at the standard dose (375 mg/m^2/week for 4 weeks) as initial therapy for CLL and significantly lower rates when used in the salvage setting, but complete responses are rare in either setting. The major benefit of this antibody appears to be its use in combination with chemotherapy. Fludarabine combined with rituximab appears to produce better responses than those seen historically with fludarabine alone. In addition, progression-free and overall survival are better than that seen in the historical cohort. A three-drug regimen of fludarabine, cyclophosphamide, and rituximab (FCR) appears to produce the best and most durable complete remission rates when used as first-line therapy. A recent randomized trial compared the activity of FC to that of FCR. More than 800 patients were accrued, and the patient characteristics were balanced between the two arms. FCR produced slightly more neutropenia than FC, but there was no difference in grade 3 or 4 infections. The complete response rate and the overall response rate were significantly higher with FCR, and progression-free and overall survival were significantly longer than with chemotherapy alone.[12] Alemtuzumab (Campath-1H; 30 mg intravenously three times a week for 4 to 12 weeks), a monoclonal antibody that binds to the CD52 antigen, was originally approved for the treatment of fludarabine-refractory CLL. One third of such patients can achieve remission. Recently, alemtuzumab was compared with chlorambucil as initial therapy for symptomatic patients with CLL. Alemtuzumab produced higher complete and overall response rates and longer progression-free survival.[13]

Ofatumumab is a humanized monoclonal antibody that binds to CD20, but to a different epitope than rituximab. This drug was recently approved by the FDA for the treatment of fludarabine- and alemtuzumab-refractory CLL. In the pivotal trial, the drug was given intravenously for 8 weeks and then monthly for 4 months. The overall response rate in this highly refractory population was 58%; the median progression-free survival was 6 months, with a median overall survival of 13.7 months. As with other monoclonal antibodies, the predominant side effects are infusion reactions, which tend to be more common with the initial doses.

TABLE 190-4 DEFINITION OF REMISSION IN CHRONIC LYMPHOCYTIC LEUKEMIA: THE INTERNATIONAL WORKSHOP IN CHRONIC LYMPHOCYTIC LEUKEMIA–NATIONAL CANCER INSTITUTE WORKING GROUP CRITERIA

CRITERION	COMPLETE REMISSION	PARTIAL REMISSION
Physical examination		
Nodes	None ≥1.5 cm	≥50% decrease
Liver/spleen	Not palpable	≥50% decrease
Symptoms	None	N/A
Peripheral blood		
Neutrophils	≥1500/mL	≥1500/mL or ≥50% increase from baseline
Platelets	>100,000/μL	100,000/μL or ≥50% increase from baseline
Hemoglobin	>11 g/dL	>11 g/dL or >50% increase from baseline
Lymphocytes	≤4000/mL	>50% decrease
Bone marrow	<30%, no B-lymphoid nodules	50% reduction in infiltrate or B-lymphoid nodules

Stem Cell Transplantation

Autologous stem cell transplantation has no proven benefit in terms of survival or long-term disease control in CLL. Data on allogeneic stem cell transplantation are limited to young patients with refractory disease, in whom a long-term control rate of 40 to 55% has been reported. Nonmyeloablative stem cell transplantation, which works mainly by its graft-versus-leukemia effect, has been used in older patients with CLL, with some success.

Radiation Therapy

In CLL, radiation therapy is used palliatively to shrink unsightly or painfully enlarged nodal masses or an enlarged spleen.

Autoimmune and Infectious Manifestations

Autoimmune hemolytic anemia and immune-mediated thrombocytopenia do not correlate closely with the activity of CLL. Prednisone (60 to 100 mg/day) is indicated as treatment for autoimmune hemolytic anemia (Chapter 163) and for some cases of immune-mediated thrombocytopenia (Chapter 175) in CLL. If there is no response in 3 to 4 weeks, the treatment has failed, and the dose should be tapered over 1 to 2 weeks. If a response is obtained, the dose is reduced by 25% each week over 4 weeks. Patients for whom corticosteroids fail often respond to low-dose oral cyclosporin 100 mg three times a day. Other therapeutic options include splenectomy, intravenous immunoglobulin, rituximab, and alemtuzumab.

Intravenous immunoglobulin (400 mg/kg every 3 to 4 weeks) significantly decreases the incidence of infections in patients with recurrent infections and hypogammaglobulinemia. However, the cost of this therapy is substantial.

PROGNOSIS

Approximately one third of patients who present with early-stage CLL never require therapy and have the same survival of age-matched controls. Frequent characteristics of such patients include WBC less than 30,000/μL, hemoglobin greater than 13 g/dL, nondiffuse pattern on bone marrow biopsy, and slow lymphocyte doubling time.

A poor response to therapy is an adverse factor in all phases of the disease. As CLL progresses, the development of a prolymphocytic transformation (10% of cases) or transformation to large cell lymphoma portends a median survival time of less than 6 months. Other factors that may suggest transformation are the development of B symptoms, a markedly elevated lactate dehydrogenase level, or fludeoxyglucose-avid disease on positron emission tomography. A high incidence of second malignant tumors (10 to 20% of patients) either precedes or follows the diagnosis of CLL; the roles of therapy versus impaired immune surveillance as causative factors are unclear. Skin

cancer, including melanoma, as well as colorectal and lung cancers are common. CLL tends to develop in older people; in indolent cases, death occurs from other intercurrent illnesses seen in this age group. Almost all patients younger than 60 years and those with progressive disease die as a result of CLL, primarily from infections. Gram-positive organisms usually cause nonfatal infections early in CLL, but most deaths due to infection are associated with gram-negative bacterial or fungal infections. Infection with other opportunistic organisms, such as *Mycobacterium tuberculosis,* herpesvirus, and *P. jiroveci*, may also be fatal.

191 NON-HODGKIN'S LYMPHOMAS

PHILIP J. BIERMAN AND JAMES O. ARMITAGE

DEFINITION

Lymphomas are solid tumors of the immune system. Rapidly increasing knowledge of the biology of the immune system has led to a corresponding increase in the understanding of these malignancies. In addition to better systems of classification and clinical evaluation, this new knowledge has led to the development of new therapies. Beneficial treatment is available for essentially every patient with non-Hodgkin's lymphoma, and many patients can be cured.

EPIDEMIOLOGY

In the United States, about 66,000 new cases of non-Hodgkin's lymphoma are diagnosed annually, and about 20,000 people are estimated to die each year of this disease. Non-Hodgkin's lymphomas account for about 4% of new cancers in the United States and result in about 4% of cancer deaths. The U.S. lifetime risk of developing non-Hodgkin's lymphoma is 2.18% (1 in 46) for men and 1.80% (1 in 56) for women. In 2002 the U.S. age-adjusted incidence rate for non-Hodgkin's lymphoma was about 23.2 per 100,000 for men and 16.3 per 100,000 for women. The incidence rate increases dramatically with age and is higher in whites than in other ethnic groups.

Geographic differences in the incidence of non-Hodgkin's lymphomas vary as much as five-fold. The highest rates are seen in the United States, Europe, and Australia, whereas lower rates are seen in Asia. Even more striking are geographic differences in the incidence of certain types of non-Hodgkin's lymphoma, such as Burkitt's lymphoma, follicular lymphoma, extranodal natural killer (NK)/T-cell nasal lymphoma, and adult T-cell leukemia/lymphoma (see later).

Between 1950 and the early 1990s, the incidence rate for non-Hodgkin's lymphomas in the United States increased by about 3 to 4% yearly, but it has declined slightly since the mid-1990s. Increases have occurred among both men and women in all parts of the world. This increase in incidence is partially related to the aging population (Fig. 191-1) and to the acquired immunodeficiency syndrome (AIDS) epidemic (Chapter 400); occupational and environmental exposures (e.g., farm chemicals) may also explain some of the increase. Finally, some of the increase may be explained by improvements in the ability of pathologists to diagnose lymphoma and by improvements in imaging techniques.

PATHOBIOLOGY

For most cases of non-Hodgkin's lymphoma, the cause is unknown, although genetic, environmental, and infectious agents have been implicated (Table 191-1).

Genetic Factors

Familial clusters have been described, and there is a slightly higher risk of non-Hodgkin's lymphoma among siblings and first-degree relatives of patients with lymphoma or other hematologic malignancies. Tumor necrosis factor (308G→A), interleukin (IL)-10 (3575 T→A), and other polymorphisms are associated with the development of diffuse large B-cell lymphoma.

Immune System Abnormalities

Several inherited disorders increase the risk of developing non-Hodgkin's lymphoma as much as 250-fold (see Table 191-1). In some of these conditions, the lymphoma may be related to Epstein-Barr virus (EBV; Chapter 385). For example, patients with X-linked lymphoproliferative disorder have mutations in the *SH2D1A* gene, which encodes proteins that regulate the host immune response against EBV-infected cells; they may develop fatal infectious mononucleosis or non-Hodgkin's lymphoma after primary

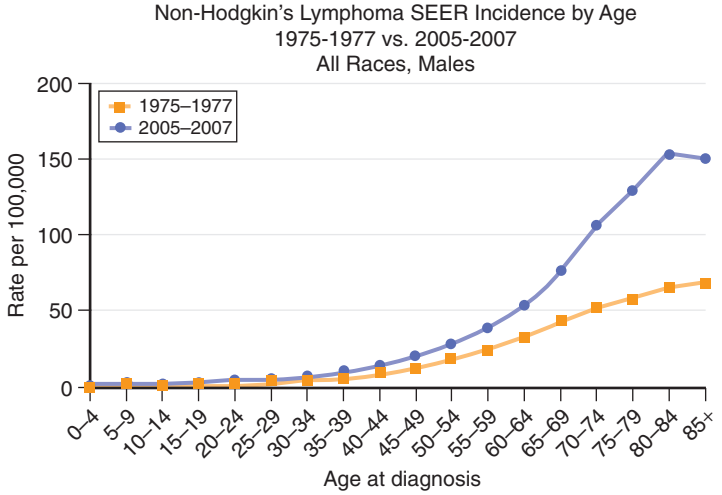

FIGURE 191-1. Non-Hodgkin's lymphoma incidence by age in men, 1975-1977 versus 2005-2007. (From the Surveillance, Epidemiology, and End Results [SEER] Program of the National Cancer Institute, http://seer.cancer.gov/csr/1975_2007/.)

exposure to EBV. Acquired immunodeficiency states are also associated with an increased risk of non-Hodgkin's lymphoma. For example, post-transplantation lymphoproliferative disorders occur in as many as 20% of solid organ transplant recipients, related to the proliferation of B lymphocytes that have been transformed during immunosuppressive therapy. The risk of non-Hodgkin's lymphoma is also increased more than 100-fold in patients infected with human immunodeficiency virus (HIV); almost all central nervous system (CNS) lymphomas and approximately 50% of other lymphomas in patients with AIDS are related to EBV. Some studies have shown a two-fold increase in the incidence of non-Hodgkin's lymphomas among patients with rheumatoid arthritis (Chapter 272), and the risk of marginal zone lymphomas is increased approximately 30- to 40-fold in patients with Sjögren's syndrome (Chapter 276). Increases in the incidence of thyroid lymphoma are seen in patients with Hashimoto's thyroiditis (Chapter 233). Enteropathy-type T-cell lymphomas are associated with celiac disease (Chapter 142).

TABLE 191-1 FACTORS ASSOCIATED WITH THE DEVELOPMENT OF NON-HODGKIN'S LYMPHOMA

Inherited immune disorders
Severe combined immunodeficiency disease
Common variable immunodeficiency disease
Wiskott-Aldrich syndrome
Ataxia-telangiectasia
X-linked lymphoproliferative disorder
Acquired immune disorders
Solid organ transplantation
Acquired immunodeficiency syndrome (AIDS)
Methotrexate therapy for autoimmune disorders
Rheumatoid arthritis and systemic lupus erythematosus
Sjögren's syndrome
Hashimoto's thyroiditis
Infectious agents
Epstein-Barr virus
Human T- lymphotropic virus type 1
Human herpesvirus 8
Hepatitis C virus
Helicobacter pylori
Borrelia burgdorferi
Chlamydia psittaci
Campylobacter jejuni
Occupational and environmental exposure
Herbicides
Organic solvents
Hair dyes
Ultraviolet light
Diet
Smoking

Infectious Agents

EBV is associated with the majority of post-transplantation lymphoproliferative disorders and many AIDS-associated lymphomas. This viral genome is detectable in more than 95% of cases of endemic Burkitt's lymphoma and in approximately 40% of cases of sporadic Burkitt's lymphoma and AIDS-associated lymphomas.

The human T-lymphotropic virus type 1 (HTLV-1; Chapter 386) is detectable in virtually all cases of adult T-cell leukemia/lymphoma. The risk of lymphoma is approximately 3% in patients infected with HTLV-1; in endemic areas, up to 50% of all non-Hodgkin's lymphomas may be related to HTLV-1. Reports of an association between simian virus 40 and non-Hodgkin's lymphoma have not been supported by further research.

Human herpesvirus 8 (HHV-8, Kaposi's sarcoma–associated herpesvirus; Chapter 400), which is associated with expansion of the B-cell population, is also associated with primary effusion lymphoma (see later) in immunocompromised patients and with multicentric Castleman's disease. Patients with primary effusion lymphoma are often coinfected with EBV.

Epidemiologic evidence has linked hepatitis C virus (Chapter 151) to lymphoplasmacytic lymphoma and splenic marginal zone lymphoma. Chronic antigenic stimulation from this virus may lead to the emergence of malignant B-cell clones.

Helicobacter pylori is associated with gastric lymphoma (Chapter 198) of extranodal marginal zone/mucosa-associated lymphoid tissue (MALT). Colonized patients develop gastritis from chronic antigenic stimulation mediated by T cells, which respond to *H. pylori*–specific antigens; malignant B-cell clones emerge. *Borrelia burgdorferi* (Chapter 329) has been associated with marginal zone B-cell lymphoma of the skin. Evidence also links *Chlamydia psittaci* (Chapter 326) with ocular adnexal lymphomas and *Campylobacter jejuni* with immunoproliferative small intestinal disease (Chapter 311).

Environmental and Occupational Exposure

Agricultural chemicals have been associated with an increased risk of developing non-Hodgkin's lymphomas, and the strongest associations involve phenoxy herbicides such as 2,4-dichlorophenoxyacetic acid (2,4-D), which was also a component of Agent Orange (Chapter 18). An increased risk has also been associated with ionizing radiation (Chapter 19), organic solvents, hair dyes, and nitrates in drinking water, although contradictory results have been reported. Some studies have also linked non-Hodgkin's lymphomas to high-fat diets and ultraviolet radiation (Chapter 183). The risk of non-Hodgkin's lymphomas is increased approximately 20-fold after treatment for Hodgkin's disease (Chapter 192). Heavy smokers (Chapter 31) have an increased risk of developing follicular lymphoma.

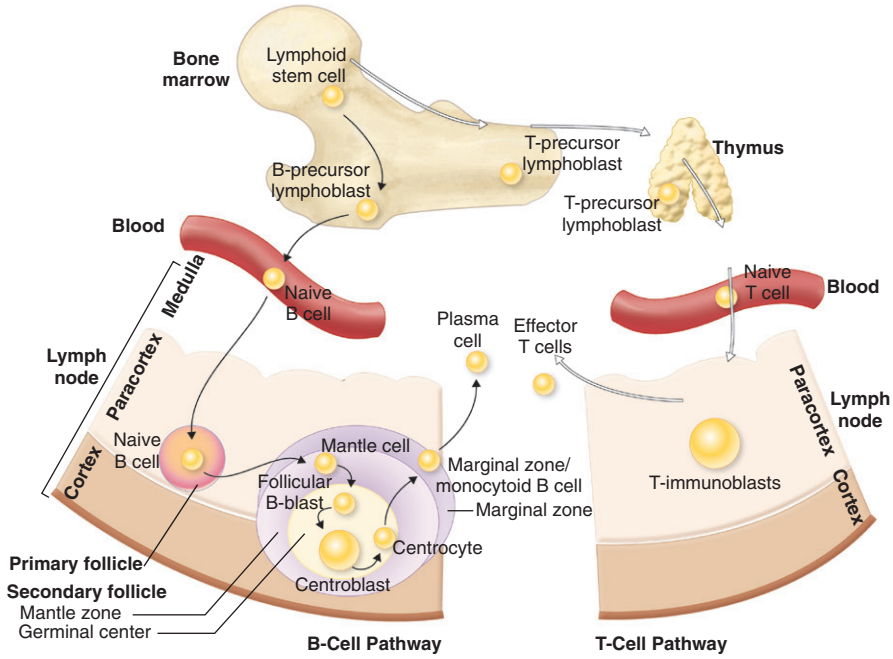
Pathology

Non-Hodgkin's lymphomas are derived from cells of the immune system at varying stages of differentiation. In some cases, the cell of origin is directly linked to the morphology, immunophenotype, and clinical behavior of the lymphoma (Fig. 191-2 and Table 191-2).

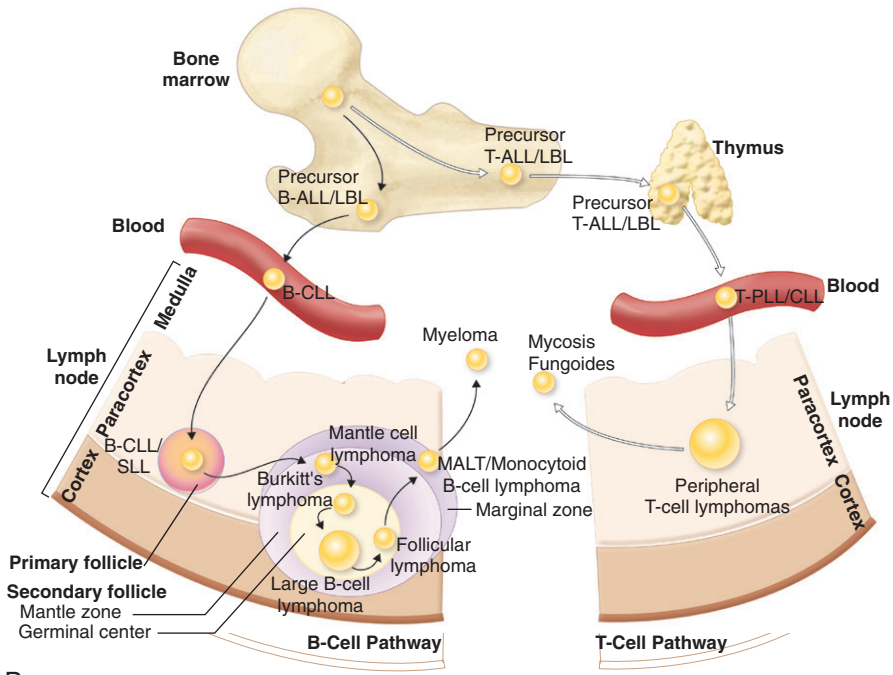
TABLE 191-2 TYPICAL IMMUNOPHENOTYPES OF COMMON NON-HODGKIN'S LYMPHOMAS

LYMPHOMA	CD20	CD3	CD10	CD5	CD23	OTHER
Small lymphocytic	+	–	–	+	+	
Lymphoplasmacytic	+	–	–	–	–	Cytoplasmic Ig+
Extranodal marginal zone MALT	+	–	–	–	–	
Nodal marginal zone	+	–	–	–	–	
Follicular	+	–	+	–		
Mantle cell	+		–	+	–	Cyclin D1+
Diffuse large B cell	+	–				
Mediastinal large B cell	+	–				
Burkitt's	+	–	+	–		TdT–
Precursor T lymphoblastic	–	+/–				TdT+, CD1a +/–, CD7+
Anaplastic large T cell	–	+/–				CD30+, CD15–, EMA+, ALK+
Peripheral T cell	–	+/–				Other pan-T variable

ALK = anaplastic lymphoma kinase; EMA = epithelial membrane antigen; MALT = mucosa-associated lymphoid tissue; TdT = terminal deoxynucleotidyl transferase.



A



B

FIGURE 191-2. Postulated normal counterparts of currently recognized B- and T-cell malignancies. A, Schema of normal B- and T-cell differentiation. Bone marrow–derived lymphoid stem cells differentiate into committed B-cell precursors or into T-cell precursors that undergo further maturation in the thymus. These B- and T-cell precursors mature into naïve B or T cells that circulate to lymph nodes. After antigen exposure, normal B blasts proliferate and undergo further differentiation in the germinal center of the secondary follicle. The germinal center is surrounded by a mantle zone and a marginal zone. Antigen-specific B cells generated in the germinal center leave the follicle and reappear in the marginal zone. Thereafter, immunoglobulin-producing plasma cells accumulate in the lymph node medulla and subsequently exit to the periphery. Antigen-dependent T-cell proliferation occurs in the lymph node paracortex. After antigen exposure, mature T cells become immunoblasts and, subsequently, antigen-specific effector T cells that exit to the periphery. The postulated normal counterparts of many currently recognized T- and B-cell neoplasms are shown. **B,** T- and B-cell malignancies derived from the postulated normal counterparts shown in **A.** ALL = acute lymphoblastic leukemia; CLL = chronic lymphocytic leukemia; LBL = lymphoblastic lymphoma; MALT = mucosa-associated lymphoid tissue; SLL = small lymphocytic lymphoma.

The transformation of cells from the normal immune system into malignant lymphoma reflects the acquisition of specific genetic abnormalities. In many cases, cytogenetic studies can identify chromosomal translocations that underlie the development or progression of the lymphoma. In most cases of non-Hodgkin's lymphoma, the activation of proto-oncogenes is the major abnormality, but occasionally chromosomal translocations can lead to fusion genes that code for chimeric proteins. In addition, some cases are associated with deletion of tumor suppressor genes. Specific genetic abnormalities are associated with some specific subtypes of non-Hodgkin's lymphoma (Table 191-3). It is becoming clear that the tumor microenvironment (i.e., stromal cells associated with the lymphoma cells) is important in tumor cell survival and response to therapy.

Classification

Recognition of the Reed-Sternberg cell approximately 100 years ago made it possible to define Hodgkin's disease (Chapter 192) as a distinct entity, whereas other lymphomas were included under the heading "non-Hodgkin's lymphomas." In the 1990s a classification system incorporating morphologic, immunologic, genetic, and clinical information (the Revised European-American Lymphoma classification, or REAL) was developed to identify distinct clinicopathologic subgroups representing diseases that can be recognized by clinicians. This system was subsequently adopted as the World Health Organization (WHO) classification of lymphomas in 2008 (Table 191-4).

The WHO classification divides lymphomas on the basis of B-cell or T/NK-cell origin and whether they are derived from primitive precursor cells or from more mature "peripheral" cells. Specific clinical and pathologic entities are recognized within each of these groupings. In the United States and Europe, 85 to 90% of non-Hodgkin's lymphomas are B cell in origin.

The most frequent type is diffuse large B-cell lymphoma, which represents 31% of all non-Hodgkin's lymphomas worldwide. The next most frequent type is follicular lymphoma, which represents 22% of cases; follicular lymphoma is relatively more frequent in North America and western Europe and less frequent in Asia. Less common types, each representing between 5 and

TABLE 191-3 CHROMOSOMAL TRANSLOCATIONS CHARACTERISTIC OF NON-HODGKIN'S LYMPHOMA

LYMPHOMA SUBTYPE	TRANSLOCATION	GENES INVOLVED	FREQUENCY (%)
Diffuse large B cell	t(3q27) t(14;18)(q32;q21) t(18;14)(q24;q32)	*BCL6* *IgH, BCL2* *MYC (c-Myc), IgH*	35 15-20 <5
Burkitt's	t(8;14)(q24;q32) t(8;22)(q24;q11) t(2;8)(p12;q24)	*MYC, IgH* *MYC, IgL* *IgK, MYC*	100% have one of these, most commonly t(8;14)
Follicular	t(14;18)(q32;q21)	*IgH, BCL2*	~90

ALCL = anaplastic large cell lymphoma; ALK = anaplastic lymphoma kinase; MALT = mucosa-associated lymphoid tissue.

TABLE 191-4 WORLD HEALTH ORGANIZATION CLASSIFICATION OF NON-HODGKIN'S LYMPHOMA (2008)

PRECURSOR LYMPHOID NEOPLASMS
B-lymphoblastic leukemia/lymphoma
T-lymphoblastic leukemia/lymphoma
MATURE B-CELL NEOPLASMS
Chronic lymphocytic leukemia/small lymphocytic lymphoma
Splenic marginal zone lymphoma
Lymphoplasmacytic lymphoma
Extranodal marginal zone lymphoma of MALT (MALT lymphoma)
Nodal marginal zone lymphoma
Follicular lymphoma
Primary cutaneous follicle center lymphoma
Mantle cell lymphoma
Diffuse large B-cell lymphoma, NOS
Burkitt's lymphoma
MATURE T-CELL NEOPLASMS
Adult T-cell leukemia/lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Enteropathy-associated T-cell lymphoma
Hepatosplenic T-cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Mycosis fungoides
Sézary's syndrome
Primary cutaneous $CD30^+$ T-cell lymphoproliferative disorders
Peripheral T-cell lymphoma, NOS
Angioimmunoblastic T-cell lymphoma
Anaplastic large cell lymphoma, ALK positive
Anaplastic large cell lymphoma, ALK negative

ALK = anaplastic lymphoma kinase; MALT = mucosa-associated lymphoid tissue; NK = natural killer; NOS = not otherwise specified.

FIGURE 191-3. Non-Hodgkin's lymphoma. Despite the redness of the skin over the enlarged lymph node in this patient, the lesion was completely painless. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

10% of all non-Hodgkin's lymphomas, are extranodal marginal zone/MALT lymphomas, peripheral T-cell lymphomas, small lymphocytic lymphoma, and mantle cell lymphoma. Other types each represent less than 2% of non-Hodgkin's lymphomas seen in the United States.

The non-Hodgkin's lymphomas recognized in the WHO classification have clinically distinctive characteristics (Table 191-5), such that an experienced hematopathologist can accurately classify 85% or more of patients by WHO criteria when adequate material is available. Some diagnoses, such as follicular lymphoma, can be made with a high degree of accuracy without immunologic or genetic studies. The diagnosis of T-cell lymphomas cannot be made accurately without immunophenotyping. Cytogenetic studies and molecular genetic studies can help resolve difficult differential diagnoses. For example, the presence of a t(8;14) translocation supports the diagnosis of Burkitt's lymphoma, whereas a t(11;14) with cyclin D1 overexpression can confirm the diagnosis of mantle cell lymphoma (see Tables 191-2 and 191-3).

The use of complementary DNA microarrays has allowed the identification of distinct subsets of patients with diffuse large B-cell lymphoma. Patients with histologically identical lymphomas can be divided into those with tumor gene expression patterns resembling normal germinal center B cells, those whose tumors resemble activated post–germinal center B cells, or those with patterns resembling that seen in Hodgkin's lymphoma; the last pattern is most frequently found in young women who present with large mediastinal masses.

CLINICAL MANIFESTATIONS

The most common presentation of non-Hodgkin's lymphoma is lymphadenopathy (Fig. 191-3; Chapter 171). In many cases, patients notice cervical, axillary, or inguinal adenopathy and seek a physician's advice. In general, lymph nodes containing lymphoma are firm, nontender, and not associated with a regional infection. However, patients are frequently treated with a course of antibiotics before a biopsy is performed to confirm the diagnosis of lymphoma. In other patients, lymphadenopathy occurring in sites such as the mediastinum or retroperitoneum causes symptoms that bring the patient to the physician. Chest pain, cough, superior vena cava syndrome, abdominal pain, back pain, spinal cord compression, and symptoms of renal insufficiency associated with ureteral compression are characteristic.

Non-Hodgkin's lymphomas are often associated with systemic symptoms that may lead to the diagnosis. The most obvious symptoms are fevers, night sweats, and unexplained weight loss. Any of these symptoms without an obvious cause should lead a physician to consider the diagnosis of lymphoma. Other, less characteristic symptoms include fatigue, which is frequently present at the time of diagnosis if the patient is questioned carefully, and pruritus.

Non-Hodgkin's lymphomas can involve essentially any organ in the body, and malfunction of that organ can cause symptoms that lead to the diagnosis.

TABLE 191-5 PRESENTING CLINICAL CHARACTERISTICS OF COMMON NON-HODGKIN'S LYMPHOMA SUBTYPES

TYPE OF LYMPHOMA	MEDIAN AGE (YR)	% MALE	Stage (%) I	Stage (%) IV	B SYMPTOMS (%)	BONE MARROW INVOLVED (%)	5-YR SURVIVAL (%)

B symptoms = fevers, night sweats, and weight loss; MALT = mucosa-associated lymphoid tissue.
Adapted from Armitage JO, Weisenburger DD, for the Non-Hodgkin's Lymphoma Classification Project. New approach to classifying non-Hodgkin's lymphomas: clinical features of the major histologic subtypes. *J Clin Oncol.* 1998;16:2780-2795.

Examples include neurologic symptoms with primary brain lymphoma (Chapter 195), shortness of breath with MALT lymphomas in the lung, epigastric pain and vomiting with gastric MALT lymphomas or diffuse large B-cell lymphomas (Chapter 198), bowel obstruction with small bowel lymphomas (Chapter 199), testicular masses with diffuse large B-cell lymphoma (Chapter 206), and skin lesions with cutaneous lymphomas (Chapter 448). Many lymphomas involve the bone marrow and occasionally cause extensive myelophthisis (Chapter 168) and bone marrow failure; these patients may present with infections, bleeding, and anemia.

Non-Hodgkin's lymphomas can also manifest with a variety of immunologic abnormalities. For example, autoimmune hemolytic anemia (Chapter 163) and immune thrombocytopenia (Chapter 175) can be the presenting manifestations of non-Hodgkin's lymphoma, especially small lymphocytic lymphoma/chronic lymphocytic leukemia as well as other subtypes, including diffuse large B-cell lymphoma. Peripheral neuropathies (Chapter 428), often associated with overproduction of a monoclonal protein, can be seen in a variety of subtypes but are most characteristic of lymphoplasmacytic lymphoma; sometimes they are also seen with POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M protein, skin changes; Chapter 193). Paraneoplastic neurologic complications of non-Hodgkin's lymphoma include demyelinating polyneuropathy, Guillain-Barré syndrome, autonomic dysfunction, and peripheral neuropathy. Paraneoplastic syndromes (Chapter 187) associated with non-Hodgkin's lymphoma can affect the skin (e.g., pemphigus), kidney (e.g., glomerulonephritis), and miscellaneous organ systems (e.g., vasculitis, dermatomyositis, cholestatic jaundice).

The differential diagnosis in patients with non-Hodgkin's lymphoma is broad. Any cause of lymphadenopathy or splenomegaly can potentially be confused with non-Hodgkin's lymphoma (Chapter 171). However, this confusion is resolved by an appropriate biopsy. It is extremely important to recognize that the diagnosis of non-Hodgkin's lymphoma must be considered in patients with compatible clinical presentations and then confirmed by an adequate biopsy read by an experienced hematopathologist. The diagnosis should never be inferred, and patients should not be treated until the diagnosis is confirmed by biopsy. This is also true for patients who achieve a complete remission with initial therapy; they should not be treated for presumed relapse on the basis of symptoms or abnormal images without a biopsy.

DIAGNOSIS

Each new patient with a non-Hodgkin's lymphoma should be thoroughly evaluated in a systematic manner (Table 191-6). Because subtle pathologic distinctions may alter therapy, the most important issue in managing non-Hodgkin's lymphoma is to establish an accurate diagnosis. Core needle biopsies can occasionally be used for a primary diagnosis if the specimen is handled properly. Fine-needle aspirates should not be used to diagnose lymphoma, and they preclude an accurate diagnosis of the specific subtype of non-Hodgkin's lymphoma. In most cases, an excisional biopsy is necessary (and is always preferred) for the initial diagnosis; another biopsy should be performed if sufficient material is not obtained. Review by an experienced hematopathologist is essential.

TABLE 191-6 TYPICAL EVALUATION OF A PATIENT NEWLY DIAGNOSED WITH NON-HODGKIN'S LYMPHOMA

1. Biopsy to establish diagnosis
2. Careful history and physical examination
3. Laboratory evaluation
   A. Complete blood count
   B. Chemistry screen, including lactate dehydrogenase
4. Imaging studies
   A. Computed tomography of chest, abdomen, and pelvis
   B. Positron emission tomography
5. Additional biopsies
   A. Bone marrow
   B. Any other suspicious site if results would change therapy

Staging and Prognostic Systems

After diagnosis, a meticulous staging evaluation is necessary to estimate prognosis and determine therapy. Staging requires a careful history and physical examination; complete blood count; renal and hepatic function tests; serum lactate dehydrogenase (LDH) level; computed tomography (CT) of the chest, abdomen, and pelvis; and bone marrow biopsy. Positron emission tomography (PET) can be helpful to identify initial sites of involvement and, after treatment, to distinguish persisting lymphoma from residual fibrosis in masses seen on CT. The most common staging system is the Ann Arbor classification, which separates patients into four stages based on anatomic sites of disease (Table 191-7). In addition, each stage is subdivided into A (no defined general symptoms) and B (unexplained weight loss >10% of body weight in the previous 6 months, unexplained temperature >38° C, or night sweats) categories. Known sites of disease can be reexamined later to evaluate the response to therapy.

Although a wide variety of patient factors (e.g., age, symptoms, LDH level) and tumor factors (e.g., bulk, gene expression pattern, proliferation rate) can affect treatment outcomes, two prognostic systems can help in choosing

TABLE 191-7 STAGING OF NON-HODGKIN'S LYMPHOMA

STAGE	DESCRIPTION
I	Involvement of a single lymph node region (I) or a single extralymphatic organ or site (I_E)
II	Involvement of ≥2 lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site and ≥1 lymph node regions on the same side of the diaphragm (II_E)
III	Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized involvement of an extralymphatic organ or site (III_E) or by involvement of the spleen (III_S) or both (III_{SE})
IV	Diffuse or disseminated involvement of ≥1 extralymphatic organ or tissues with or without associated lymph node enlargement
Subtypes	
A	No B symptoms
B	B symptoms: unexplained weight loss ≥10% of body weight in prior 6 months, unexplained fever >38° C, or night sweats

therapy and determining an accurate prognosis. The International Prognostic Index (IPI; Table 191-8) is the most widely used method to predict treatment outcome and survival. The IPI is based on five adverse factors (age older than 60 years, performance status ≤2, elevated serum LDH level, two or more extranodal sites of disease, Ann Arbor stage III or IV), which are summed to give the score. This index was developed for patients with diffuse aggressive lymphoma (predominantly diffuse large B-cell lymphoma), but it can be used to predict treatment outcome with any subtype. For young patients, an abbreviated index that uses only reduced performance status, elevated serum LDH level, and high stage can be applied. Because patients with follicular lymphoma rarely have a reduced performance status or a large number of extranodal sites, an alternative index termed the *Follicular Lymphoma International Prognostic Index* (FLIPI) was developed; it substitutes more than four nodal areas of involvement and a hemoglobin less than 12 g as staging criteria and does a somewhat better job of predicting treatment outcome in follicular lymphoma.

TREATMENT Rx

Lymphomas may behave in an indolent or an aggressive manner. The behavior of many of these neoplasms is distinctive, but within each category, behavior is frequently influenced by disease site, tumor bulk, and performance status of the patient. Some lymphomas can be managed, at least initially, with observation, whereas other situations are medical emergencies, such as spinal cord compression (Chapter 195). It is important to consider three questions before starting therapy: (1) Does treatment have curative potential? (2) Can treatment prolong survival? (3) Will treatment alleviate symptoms?

SPECIFIC TYPES OF NON-HODGKIN'S LYMPHOMAS

Precursor T-Cell and B-Cell Lymphomas

These tumors are nodal or other solid tissue infiltrates of cells that are morphologically and immunophenotypically identical to the immature cells seen in B-cell or T-cell acute lymphoblastic leukemia (Chapter 189). Patients who have predominantly nodal disease with minimal or no involvement of the bone marrow are frequently classified as having *lymphoblastic lymphoma,* whereas those with more than 25% neoplastic cells in the marrow are classified as having *lymphoblastic leukemia.* These distinctions are arbitrary and reflect the stage of disease rather than different diagnoses. These neoplasms are more common in children than in adults.

B-cell precursor lymphomas frequently manifest as solid tumors with involvement of the skin and bones, whereas T-cell neoplasms typically manifest as a mediastinal mass in a young male. Involvement of the CNS is common. Approximately 90% of patients who present with lymphoblastic lymphoma have a T-cell phenotype, whereas about 85% of patients who present with acute lymphoblastic leukemia have a B-cell phenotype. Adverse prognostic characteristics include CNS involvement, stage IV disease, and an elevated LDH level.

TREATMENT Rx

Patients with either T-cell lymphoblastic lymphoma or precursor B-cell lymphoblastic lymphoma are typically treated with regimens modeled after those used for acute lymphoblastic leukemia (Chapter 189). These regimens frequently contain cytarabine and high-dose methotrexate, and they often include maintenance therapy. CNS prophylaxis with intrathecal chemotherapy, high-dose methotrexate, or cranial irradiation is also a component of these regimens.

Mature B-Cell Lymphomas

SMALL LYMPHOCYTIC LYMPHOMA/CHRONIC LYMPHOCYTIC LEUKEMIA

Small lymphocytic lymphoma is defined as a lymph node or other tissue infiltrate that is morphologically and immunophenotypically identical to chronic lymphocytic leukemia (Chapter 190). Patients are frequently asymptomatic, and the diagnosis is often made when blood counts are performed for other reasons. Patients frequently have lymphadenopathy or splenomegaly. Fatigue is common. Hypogammaglobulinemia can occur and may lead to an increased susceptibility to infection.

A poor prognosis is associated with advanced stage and systemic symptoms, expression of high levels of CD38 and ZAP-70 on tumor cells, lack of rearranged immunoglobulin heavy chain genes, and genetic abnormalities such as del(17p) and del(11q). Approximately 10% of patients exhibit transformation to diffuse large B-cell lymphoma (Richter's syndrome), which is associated with a poor prognosis.

The median survival time is more than 10 years for patients without adverse characteristics, and these patients can often be managed with observation. Therapy is necessary for patients who have rapidly progressive or symptomatic lymphadenopathy and for those who develop cytopenias.

TREATMENT Rx

Management must be individualized because therapy is not curative, and patients are often elderly. A regimen consisting of fludarabine in combination with cyclophosphamide and rituximab (Table 191-9) is frequently used in the United States for relatively young, fit patients. Single-agent fludarabine plus rituximab is more commonly used in elderly patients. Fludarabine is more effective than chlorambucil, but because chlorambucil is administered orally

TABLE 191-9 COMBINATION CHEMOTHERAPY REGIMENS FOR NON-HODGKIN'S LYMPHOMA

REGIMEN	DOSE	DAYS OF ADMINISTRATION	FREQUENCY
CHOP-R			Every 21 days
Cyclophosphamide	750 mg/m^2 IV	1	
Doxorubicin	50 mg/m^2 IV	1	
Vincristine	1.4 mg/m^2 IV*	1	
Prednisone, fixed dose	100 PO	1-5	
Rituximab	375 mg/m^2 IV	1	
CVP-R			Every 21 days
Cyclophosphamide	1000 mg/m^2 IV	1	
Vincristine	1.4 mg/m^2 IV*	1	
Prednisone, fixed dose	100 mg PO	1-5	
Rituximab	375 mg/m^2 IV	1	
FCR			Every 28 days
Fludarabine	25 mg/m^2 IV	1-3	
Cyclophosphamide	250 mg/m^2 IV	1-3	
Rituximab	375 mg/m^2	1	

*Vincristine dose often capped at 2 mg total.

and has few side effects, it is sometimes used in older patients. Bendamustine is an active, newly available drug. Alemtuzumab, a monoclonal antibody directed against the CD52 antigen, is sometimes effective after other treatments have failed. Allogeneic hematopoietic stem cell transplantation may be curative, but few patients are candidates for this approach.

Patients may develop autoimmune thrombocytopenia (Chapter 175), autoimmune neutropenia (Chapter 170), and red blood cell aplasia (Chapter 168). These autoimmune disorders may respond to treatment with corticosteroids, intravenous immune globulin, or splenectomy, as used in patients without underlying lymphoma.

EXTRANODAL MARGINAL ZONE LYMPHOMA OF MUCOSA-ASSOCIATED LYMPHOID TISSUE (MALT LYMPHOMA)

MALT lymphomas are indolent tumors that originate in association with epithelial cells and are seen most commonly in the gastrointestinal tract, salivary glands, breast, thyroid, orbit, conjunctiva, skin, and lung. The majority of cases are stage I or II at diagnosis, although in some series as many as 30% disseminate to bone marrow or other sites. These lymphomas tend to remain localized for extended periods. Local treatment with surgery or radiation therapy cures a high proportion of localized neoplasms. Disseminated disease is treated similarly to follicular lymphoma (see later).

Gastric MALT lymphomas are usually associated with infection by *H. pylori*. Eradication of *H. pylori* with antibiotics leads to complete regression in more than 50% of gastric MALT lymphomas, although polymerase chain reaction analysis demonstrates minimal residual disease in many patients, and the long-term outcome of this approach is unknown. Response to antibiotic therapy is less likely if invasion is deeper, lymph node metastases are found, or the t(11;18) chromosomal translocation is present.

TREATMENT

Patients may have tumors in more than one extranodal site, and these locations can sometimes be successfully treated with local therapy. Asymptomatic patients can be monitored closely without antilymphoma therapy until symptoms progress. Gastric MALT lymphoma that does not respond to antibiotics can be treated with radiation, rituximab as a single agent (similar to its use in follicular lymphoma), or several traditional combination chemotherapy regimens (see Table 191-9).

FOLLICULAR LYMPHOMA

Follicular lymphoma accounts for the majority of indolent or "low-grade" lymphomas in the United States. Follicular lymphoma is divided into three grades based on the proportion of large, transformed cells (centroblasts).

Patients with follicular lymphoma are frequently asymptomatic. The most common presenting complaint is painless lymphadenopathy. Some patients have cough or dyspnea related to pulmonary or mediastinal involvement or pleural effusions. Other patients have symptoms of abdominal pain or fullness related to subdiaphragmatic or splenic disease. A minority of patients have systemic symptoms of fevers, night sweats, or weight loss.

The clinical behavior and treatment of follicular lymphoma grades 1 and 2 are the same and are discussed in this section. Grade 3 follicular lymphoma may have a more aggressive clinical course and is frequently treated similarly to diffuse large B-cell lymphoma (see later).

TREATMENT

Localized Disease

Approximately 5 to 15% of patients have localized disease (stage I or minimal stage II disease) at diagnosis. These lymphomas are usually treated with involved-field radiation, and most series report 10-year disease-free survival rates of approximately 50% and overall survival rates of 60 to 70%. Some retrospective series have reported improved outcomes when chemotherapy is combined with radiation.

Advanced Disease

Most patients with follicular lymphoma have extensive disease at diagnosis. The median survival time of these patients is more than 10 years. Although spontaneous regression has been described, 30 to 50% of patients experience transformation to a more aggressive histology—usually diffuse large B-cell lymphoma. Transformation is frequently associated with new systemic symptoms and rapidly progressive lymphadenopathy, an aggressive clinical course, and a poor prognosis.

Asymptomatic patients, especially elderly patients and those with other medical illnesses, are frequently managed with a "watch and wait" approach. Prospective trials have demonstrated that this approach does not influence overall survival, and patients can sometimes be observed for long periods before treatment is required.

Most patients with follicular lymphoma eventually require treatment because of systemic symptoms, symptomatic or progressive lymphadenopathy, splenomegaly, effusions, or cytopenias. In elderly patients, those who are poor candidates for intensive chemotherapy regimens, and those who want to avoid the side effects (e.g., alopecia) of chemotherapy, single-agent rituximab (375 mg/m^2 intravenously, given weekly for 4 consecutive weeks) yields an objective response rate of well over 50%. The median duration of response is approximately 1 to 2 years for patients who receive no additional therapy, but the response can be extended with ongoing administration of rituximab once every 2 or 3 months or by repeating the initial four doses every 6 months. When rituximab is combined with standard chemotherapy regimens such as CVP (cyclophosphamide, vincristine, prednisone) or CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) (see Table 191-9), the response rate, duration of response, and survival are increased compared with the chemotherapy regimen alone, and maintenance rituximab further extends the duration of remission.■ For aggressive lymphomas, high dose intensity doxorubicin can significantly improve survival.■ Fludarabine, used alone or in combination with mitoxantrone, is also effective. In one study, ^{131}I-tositumomab radioimmunotherapy appeared to provide a prolonged benefit. Interferon-α may be beneficial in follicular lymphoma when combined with initial chemotherapy,■ but it is rarely used as primary therapy in the United States because of its side effects. Some studies have shown an improvement in failure-free survival with the use of autologous bone marrow transplantation in patients who achieve an initial remission, but overall survival is not prolonged.

Salvage Therapy

Most patients respond to initial chemotherapy, and initial responses typically persist for 1 to 3 years. However, follicular lymphoma eventually progresses in most patients with advanced-stage disease. Patients who have a relapse usually respond to additional therapy, often with the same agents, although the duration of response becomes progressively shorter with repeated courses of therapy. Approximately 50 to 60% of patients with relapsed follicular lymphoma respond to rituximab, and maintenance therapy prolongs remission in responding patients; however, less than 10% attain a complete response. Some patients who do not respond to rituximab respond to the radiolabeled antibodies tositumomab or ibritumomab. Radiation therapy may also be useful for patients with a localized site of symptomatic disease.

Prolonged remissions have been observed after autologous hematopoietic stem cell transplantation. Allogeneic hematopoietic stem cell transplantation may cure some patients with relapsed follicular lymphoma.

MANTLE CELL LYMPHOMA

Mantle cell lymphoma is a B-cell neoplasm composed of small lymphoid cells that may resemble small lymphocytic lymphoma or follicular lymphoma. It is most common in elderly patients and is usually at an advanced stage at the time of diagnosis. Males are more frequently affected, and extranodal disease, especially involvement of the bone marrow, Waldeyer's ring, and the gastrointestinal tract, is common. Mantle cell lymphoma is the most common cause of multiple lymphomatous polyposis, and the gastrointestinal tract should be evaluated with endoscopy during the initial evaluation.

Some patients present with involvement of the peripheral blood as well as the bone marrow, a clinical picture that resembles chronic lymphocytic leukemia (Chapter 190). The lymphocytes in both disorders are $CD5^+$, but the t(11;14) and overexpression of cyclin D1 seen in mantle cell lymphoma usually allow an accurate diagnosis.

Mantle cell lymphoma usually has a poor prognosis, with a median survival of 3 to 4 years, although occasional patients may have an indolent course. There is some evidence that prognosis may be improved with aggressive chemotherapy, but mantle cell lymphoma is usually not curable with standard chemotherapy regimens. Autologous hematopoietic stem cell transplantation for patients in their first remission may improve survival, but randomized trials have not been performed. Allogeneic transplantation can be curative but is associated with considerable morbidity and mortality.

DIFFUSE LARGE B-CELL LYMPHOMA

These tumors are the most common type of non-Hodgkin's lymphoma, but their morphology and genetic features are heterogeneous. Signs and symptoms are similar to those of other subtypes, although patients are more likely to have B symptoms or symptoms from the local tumor than are patients with follicular lymphoma.

The WHO classification of non-Hodgkin's lymphomas has identified several variants and subtypes of diffuse large B-cell lymphoma (Table 191-10). Many of these are histologic or genetic subtypes or variants for which treatment is the same as the standard approach for diffuse large B-cell lymphoma. Other subtypes present unusual clinical syndromes or specific therapeutic problems.

TABLE 191-10 DIFFUSE LARGE B-CELL LYMPHOMA, VARIANTS AND SUBTYPES

Diffuse large B-cell lymphoma, not otherwise specified (NOS)
Common morphologic variants
Centroblastic
Immunoblastic
Anaplastic
Immunohistochemical subgroups
$CD5^+$ DLBCL
Germinal center B-cell–like (GCB)
Non–germinal center B-cell–like (non-GCB)
Diffuse large B-cell lymphoma, subtypes
T-cell/histiocyte-rich large B-cell lymphoma
Primary DLBCL of the CNS
Primary cutaneous DLBCL, leg type
EBV-positive DLBCL of the elderly
Other large B-cell lymphomas
Primary mediastinal (thymic) large B-cell lymphoma
Intravascular large B-cell lymphoma
DLBCL associated with chronic inflammation
Lymphomatoid granulomatosis
ALK-positive large B-cell lymphoma
Plasmablastic lymphoma
Large B-cell lymphoma arising in HHV-8-associated multicentric Castleman's disease
Primary effusion lymphoma

ALK = anaplastic lymphoma kinase; CNS = central nervous system; DLBCL = diffuse large B-cell lymphoma; EBV = Epstein-Barr virus; HHV = human herpesvirus.

TREATMENT

Localized Disease

As many as 30% of patients with diffuse large B-cell lymphoma have stage I or minimal stage II disease. These patients are occasionally cured with radiation therapy alone, but initial treatment with chemotherapy is more effective. Although one study in France suggested that a very intensive chemotherapy regimen alone might be better than CHOP plus radiation, most patients in the United States receive CHOP plus rituximab (CHOP-R; see Table 191-9), followed by consolidative radiation therapy.[4] Although the necessity of radiation therapy after CHOP-R has not been tested, this combination is still widely used.

Advanced Disease

CHOP-R is generally considered the "gold standard" treatment for adults of all ages with advanced-stage diffuse large B-cell lymphoma. Among patients older than 60 years, 75% achieve a complete response, with a 5-year event-free survival rate of 47% and a 5-year overall survival rate of 58%. In younger patients the outcome is better.[5]

Salvage Therapy

A variety of chemotherapy regimens have been developed for patients who relapse after attaining a remission with initial chemotherapy. These regimens commonly contain agents such as cisplatin, cytarabine, etoposide, carboplatin, and ifosfamide. Response rates exceeding 50% can be observed with these combinations, although no more than 10% of patients achieve long-term disease-free survival. High-dose therapy followed by autologous hematopoietic stem cell transplantation has become accepted therapy for patients with relapsed diffuse large B-cell lymphoma; approximately 20 to 40% of these patients attain long-term disease-free survival with transplantation if they are still responsive to conventional salvage chemotherapy.

Subtypes of Diffuse Large B-Cell Lymphoma

Primary mediastinal large B-cell lymphoma originates in the thymus and is most common in young women. This entity is distinguished by the presence of a mediastinal mass, which usually causes symptoms of cough, chest pain, or superior vena cava syndrome. A very large mass (>10 cm) or the existence of a malignant pleural effusion is associated with a worse prognosis. Mediastinal large B-cell lymphoma is treated with the same chemotherapy regimens used for diffuse large B-cell lymphoma, followed, in some cases, by consolidative radiation therapy. The prognosis is similar to that of other diffuse large B-cell lymphomas. Relapses often occur in extranodal sites such as the CNS, lungs, gastrointestinal tract, liver, ovaries, and kidneys.

Intravascular large B-cell lymphoma is an aggressive lymphoma caused by cells that infiltrate the lumens of small blood vessels. Widespread extranodal involvement is common. Focal neurologic deficits and mental status changes are frequent. Cases are often diagnosed at autopsy, although durable responses to combination chemotherapy have been described.

Primary effusion lymphoma is associated with HHV-8 and is seen in HIV-infected and other immunosuppressed patients. Effusions occur in serous body cavities; peripheral lymphadenopathy is not seen. Prognosis is poor despite chemotherapy.

Plasmablastic lymphoma is most often seen in patients with HIV infection and frequently presents with involvement of the head and neck. This tumor does not express CD20 and thus does not benefit from treatment with rituximab.

Primary cutaneous diffuse large B-cell lymphoma of the leg (leg type) is one of two presentations of B-cell lymphoma in the skin. This tumor occurs mostly in older patients and follows an aggressive course. This neoplasm must be distinguished from primary cutaneous follicle center lymphoma, which might also be diagnosed as a cutaneous diffuse large B-cell lymphoma but follows an indolent course and requires only local therapy.

BURKITT'S LYMPHOMA

Burkitt's lymphoma is a highly aggressive B-cell lymphoma that is more common in children and immunosuppressed individuals than in healthy adults (see later). Widespread extranodal involvement is common. The endemic form of Burkitt's lymphoma is seen most frequently in children who reside in equatorial Africa. Involvement of bones of the jaw is common in this form. The sporadic form of Burkitt's lymphoma is seen most commonly in children in the United States. Males are more frequently affected. Both children and adults frequently have bulky abdominal disease, sometimes with involvement of the kidneys, ovaries, and breasts. Bone marrow involvement is seen in about one third of cases.

TREATMENT

Tumors may progress extremely rapidly, so therapy should be started as soon as possible. Tumor lysis syndrome may occur because of the frequent presence of bulky disease, the high rate of tumor proliferation, and the extreme sensitivity of the tumor to chemotherapy. Patients are usually treated

with specialized high-intensity regimens, including rituximab, of relatively short duration. Treatment with the CHOP-R regimen used for diffuse large B-cell lymphoma has a poor outcome. CNS prophylaxis with intrathecal chemotherapy or high-dose methotrexate is required. Cure rates well in excess of 50% are typical with appropriate therapy.

RARE TYPES OF B-CELL LYMPHOMA

Several rare types of lymphoma have distinct clinical features.

Lymphoplasmacytic lymphoma is an indolent lymphoma that frequently involves the bone marrow, peripheral blood, and spleen. Patients frequently have an immunoglobulin M paraprotein (and therefore could be called Waldenström's macroglobulinemia) that may lead to symptoms of hyperviscosity, autoimmune phenomena, or neuropathies (Chapter 193). Plasmapheresis can reduce symptoms of hyperviscosity. Chemotherapy with alkylating agents, combination chemotherapy, or fludarabine may be used. Rituximab is also effective, as are new agents such as the proteosome inhibitor bortezomib.

Splenic marginal zone lymphoma is an indolent lymphoma that usually manifests with splenomegaly and lymphocytosis. A monoclonal gammopathy is frequently seen. Peripheral lymphadenopathy is unusual. Anemia and thrombocytopenia may respond to splenectomy. Chemotherapy with single agents or anthracycline-based combinations may be useful, and when the lymphoma is associated with hepatitis C, antiviral therapy may be effective. Responses to interferon have been described. This lymphoma appears to be particularly responsive to rituximab.

Nodal marginal zone B-cell lymphoma is an indolent disorder that is usually associated with generalized lymphadenopathy. The clinical course and prognosis are similar to those of follicular lymphoma, and it is usually treated in a similar manner.

Small intestinal immunoproliferative disease, a disorder seen most frequently in the Middle East, begins as a polyclonal process and can progress to a large B-cell lymphoma. The process is often associated with *Campylobacter jejuni* infection. Early in the disease, patients may respond to antibiotics, and frank lymphoma may respond to combination chemotherapy regimens.

Mature T-Cell Lymphomas (Peripheral T-Cell Lymphomas)

Peripheral (or mature) T-cell lymphomas are neoplasms of post-thymic T cells. These include relatively indolent disorders such as mycosis fungoides and $CD30^+$ cutaneous lymphoproliferative disorders, but most patients diagnosed with peripheral T-cell lymphoma have an aggressive neoplasm. Peripheral T-cell lymphomas represent only 10% of the non-Hodgkin's lymphomas occurring in the United States. Unfortunately, the treatment for these lymphomas has not progressed as rapidly as the treatments for B-cell lymphomas.

MYCOSIS FUNGOIDES

Mycosis fungoides (often referred to as *cutaneous T-cell lymphoma*) is an indolent malignancy that is most common in middle-aged and older adults. The clinical course is usually a slow progression from isolated patches or plaques to thickened, more widespread plaques and then to multiple cutaneous tumors that may ulcerate (Chapter 446). A subset of patients presents with generalized erythroderma and circulating tumor cells, called *Sézary's syndrome*. Lymph node and visceral involvement may occur late in the course of the disease.

TREATMENT Rx

Cutaneous radiation therapy may be curative for patients with limited patch or plaque disease. Patients with early-stage disease (<10% body surface area) are frequently treated with skin-directed therapy that may include ultraviolet radiation, topical steroids, or topical nitrogen mustard.

Patients with more advanced disease frequently benefit from total skin electron beam therapy or extracorporeal photopheresis. Medical treatments include interferon-α, retinoids, monoclonal antibodies, histone deacetylase inhibitors (vorinostat, depsipeptide), the fusion toxin denileukin diftitox, and traditional cytotoxic chemotherapeutic agents; however, these treatments are usually only palliative. Results with autologous hematopoietic stem cell transplantation are usually poor, although allogeneic stem cell transplantation has yielded promising results in some cases.

ADULT T-CELL LYMPHOMA/LEUKEMIA

Adult T-cell lymphoma/leukemia, which is associated with HTLV-1 infection (Chapter 386), is most commonly seen in southern Japan and the Caribbean. Most infected patients are asymptomatic, and the lifetime risk of developing adult T-cell lymphoma/leukemia is approximately 3%.

Patients may have acute leukemia, aggressive lymphoma, or an indolent lymphoproliferative disease. Patients with aggressive disease present with generalized lymphadenopathy, hepatosplenomegaly, cutaneous infiltration, and hypercalcemia. Many patients have characteristic circulating tumor cells with a "flower" or "cloverleaf" nucleus.

TREATMENT Rx

Patients with indolent disease can sometimes be monitored without therapy. Aggressive disease is usually treated with combination chemotherapy, but there is no consensus on the best regimen. Historically, the 5-year survival rate has been less than 10%, although recent trials have reported better outcomes.

$CD30^+$ CUTANEOUS LYMPHOPROLIFERATIVE DISORDERS

These disorders represent a spectrum of diseases that may have an identical histologic appearance and overlapping clinical manifestations. Treatment decisions are often based on the clinical behavior of the lesions. These lymphomas express CD30 but do not express the anaplastic lymphoma kinase (ALK) protein (see later).

Lymphomatoid papulosis is a "histologically malignant" clonal disorder consisting of erythematous or skin-colored papules that frequently undergo spontaneous ulceration and necrosis over a period of weeks. The prognosis is excellent, although patients may eventually develop lymphoma.

Primary cutaneous anaplastic large cell lymphoma occurs most commonly in older men and also undergoes frequent spontaneous regression. The 5-year survival rate is greater than 90%. Treatment usually consists of local measures (surgery or radiation), although chemotherapy may be required.

PRIMARY SYSTEMIC ANAPLASTIC LARGE CELL LYMPHOMA

Anaplastic large cell lymphoma (ALCL) is an aggressive, $CD30^+$, T-cell non-Hodgkin's lymphoma that is seen most frequently in young males. B-cell lymphomas with similar morphology can occur, but they have clinical features identical to other diffuse large B-cell lymphomas and are not considered part of this disease. A morphologically similar but biologically unrelated and clinically distinct neoplasm, primary cutaneous ALCL, occurs predominantly in older adults and represents part of the spectrum of cutaneous $CD30^+$ lymphoproliferative disorders (see earlier). Primary systemic ALCL frequently has a t(2;5) chromosomal translocation that leads to overexpression of ALK, a protein not normally detectable in lymphoid cells.

Patients usually have lymphadenopathy, and involvement of the skin, bone, and gastrointestinal tract may be observed.

TREATMENT Rx

Patients are usually treated with chemotherapy regimens such as CHOP. Patients whose tumors express ALK have an excellent outcome, and 5-year survival rates of 70 to 90% have been observed. ALK-negative ALCL is more common in older patients and is associated with an inferior response rate and shorter survival time. Autologous hematopoietic stem cell transplantation may be curative for patients who relapse.

PERIPHERAL T-CELL LYMPHOMAS, UNSPECIFIED

The largest group of patients with peripheral T-cell lymphomas are defined in the WHO classification as having "peripheral T-cell lymphoma, unspecified." These patients' signs and symptoms are similar to those of patients with aggressive B-cell lymphomas, although systemic symptoms (fevers, night sweats, and weight loss) and extranodal involvement are frequent. The diagnosis of peripheral T-cell lymphoma requires immunophenotyping to demonstrate the T-cell origin.

TREATMENT Rx

Patients are generally treated with the same regimens used for diffuse large B-cell lymphomas (e.g., CHOP), although the outcome is substantially worse (see Table 191-5). Patients who relapse after complete remission can sometimes be cured with hematopoietic stem cell transplantation.

UNUSUAL SUBTYPES OF T-CELL LYMPHOMA

Angioimmunoblastic T-cell lymphoma is associated with generalized lymphadenopathy, fever, weight loss, skin rash, and polyclonal hypergammaglobulinemia. Results of therapy are similar to those for peripheral T-cell lymphoma, unspecified.

Extranodal NK/T-cell lymphoma usually occurs in extranodal sites, especially the nose, palate, and nasopharynx. Involvement of the nose and face leads to the syndrome that was previously called lethal midline granuloma. This disorder is unusual in the United States, but it is frequent in Southeast Asia and Latin America. The prognosis is extremely poor, although patients with localized disease can sometimes be cured with aggressive combination radiation therapy and chemotherapy.

Hepatosplenic T-cell lymphoma is characterized by sinusoidal infiltration of the spleen, liver, and bone marrow, which leads to hepatosplenomegaly, systemic symptoms, and cytopenias. Lymphadenopathy is unusual. Patients are typically young males, and this disease can occur in allograft recipients and in the setting of immune dysfunction. The prognosis is poor, and remissions are rarely observed with chemotherapy.

Enteropathy-type T-cell lymphoma is usually seen in patients with gluten-sensitive enteropathy (Chapter 142). Patients typically present with abdominal pain and diarrhea and sometimes with bowel perforation. Treatment of celiac disease with a gluten-free diet appears to reduce the risk of lymphoma. The prognosis in these often undernourished patients is poor.

Subcutaneous panniculitis-like T-cell lymphoma manifests with multiple subcutaneous nodules and is often misdiagnosed as panniculitis. Patients with disseminated disease can have a syndrome consisting of fevers, weight loss, hepatosplenomegaly, pancytopenia, and phagocytosis of blood cells (hemophagocytic syndrome). Patients sometimes respond to combination chemotherapy regimens used for diffuse large B-cell lymphoma, interferon, and radiation therapy, but long-term disease-free survival is unusual.

SPECIAL CLINICAL SITUATIONS

The diagnosis and management of patients with the various types of non-Hodgkin's lymphoma can be profoundly influenced by the site of origin of the lymphoma and by certain clinical characteristics of the patients. Examples of the latter include pregnant patients with lymphoma, elderly patients with lymphoma, and lymphoma in patients who are severely immunosuppressed.

Specific Primary Sites of Diffuse Large B-Cell Lymphoma

Approximately 30% of diffuse large B-cell lymphomas originate in extranodal sites. Presentation in certain extranodal sites is associated with unique clinical behaviors that may necessitate diagnostic studies or additional therapy beyond that used for patients with nodal presentations.

Patients with primary CNS lymphoma (Chapter 195) commonly have ocular involvement, and all patients with this diagnosis should have a slit lamp examination. Surgical resection of primary CNS lymphoma is not beneficial, and the only role for surgery is in diagnosis. Primary lymphomas of the CNS are very sensitive to corticosteroids, but the best results have been observed with chemotherapy regimens that use high-dose methotrexate alone or in combination with other agents such as cytarabine. By comparison, conventional chemotherapy regimens, such as CHOP, are of little benefit. Whole brain irradiation is also effective therapy, although the incidence of leukoencephalopathy is extremely high, especially in elderly patients. Radiation therapy is frequently reserved for relapse rather than being used as adjunctive treatment with primary chemotherapy.

Treatment of primary testicular lymphoma, the most common testicular cancer in men older than 60 years (Chapter 206), usually consists of orchiectomy followed by combination chemotherapy. Relapse in the contralateral testicle is common, and most oncologists recommend adjuvant radiation to the scrotum. CNS involvement is common, and prophylactic intrathecal chemotherapy is usually recommended. Late relapses occur frequently.

Diffuse large B-cell lymphoma of the stomach and gastrointestinal tract is treated differently from gastric MALT lymphoma, even if there is a history of prior MALT lymphoma. Patients can be cured with surgery and adjunctive radiation or chemotherapy, although surgery is rarely performed for gastric lymphomas because of the morbidity associated with gastric resection. Patients should be treated with chemotherapy regimens used for other diffuse large B-cell lymphomas. Radiation therapy is sometimes used after chemotherapy, although the role of combined-modality treatment is not defined.

Lymphoma in AIDS and Post-Transplantation Lymphoproliferative Disorders

Non-Hodgkin's lymphoma is an AIDS-defining illness in HIV-infected individuals (Chapter 400), and the risk of developing a non-Hodgkin's lymphoma is increased more than 150-fold after the diagnosis of another AIDS-defining illness. Most cases are diffuse large B-cell lymphomas or Burkitt's lymphomas. AIDS-associated lymphomas behave aggressively and frequently involve the CNS and other unusual sites, such as the gastrointestinal tract, anus, rectum, skin, and soft tissue (Chapter 400). Factors associated with poor survival include low CD4 counts, poor performance status, older age, and advanced stage. The prognosis of these lymphomas is poor, with median survival times of approximately 6 months in the absence of concomitant aggressive therapy for HIV. If chemotherapy is given in association with highly active antiretroviral agents to patients with a good performance status, the likelihood of controlling the lymphoma is similar to that in patients without HIV infection. Intrathecal prophylaxis is generally recommended because of a higher risk of CNS involvement.

The risk of developing a non-Hodgkin's lymphoma is also markedly increased in patients who have received a solid organ transplant. The histologic appearance of these lymphomas is variable, but they frequently resemble aggressive lymphomas in nonimmunocompromised patients. Similar disorders can be seen in patients who are treated with methotrexate and other drugs for autoimmune disorders and in recipients of allogeneic hematopoietic stem cell transplants, especially if the transplants are T-cell depleted. These post-transplantation lymphoproliferative disorders, which may develop within weeks after surgery, are more common in patients who receive aggressive immunosuppression after transplantation. Involvement of extranodal sites is common, and lymphoma frequently involves the transplanted organ. Post-transplantation lymphoproliferative disorders may respond to reduction or withdrawal of immunosuppression. Some investigators have advocated the use of acyclovir or ganciclovir, because these lymphomas are usually related to EBV, but this practice is controversial. High response rates are also seen with rituximab. Other patients require treatment with combination chemotherapy regimens.

Non-Hodgkin's Lymphoma in Elderly Patients

More than 50% of patients who develop non-Hodgkin's lymphomas are older than 60 years, and the prognosis is generally worse for elderly patients. These poorer outcomes are related to increased toxicity of drug therapy, lower remission rates, increased rates of relapse, and higher death rates from cardiovascular disease and causes other than the lymphoma itself. Older patients are more likely to have other adverse prognostic characteristics (see Table 191-8), which also contribute to poorer outcomes. The practice of arbitrary dose reductions based solely on age should be discouraged if patients have a good performance status and no comorbid illnesses.■

Non-Hodgkin's Lymphoma and Pregnancy

Non-Hodgkin's lymphoma in pregnancy involves major clinical and ethical issues, and a multidisciplinary approach is needed (Chapter 247). Although chest radiographs are generally considered safe, ultrasound examination is usually used instead of CT for staging in the abdomen and pelvis.

Treatment can occasionally be delayed until after delivery; however, most women have a tumor that is potentially curable, and treatment delays may decrease the chance for cure. Other patients have conditions such as superior vena cava syndrome that require immediate treatment. After the first trimester, full-dose standard therapy such as CHOP-R may be used; several studies indicate high probabilities of cure without adverse long-term physical or intellectual deficits for the child. Although it is reasonable to offer therapeutic abortion for women in the first trimester, chemotherapy may also be successful in this situation. Regimens using methotrexate must be avoided.

DISEASES SOMETIMES CONFUSED WITH LYMPHOMA

The most common atypical lymphoid proliferations that can be confused with lymphoma are florid reactions to immune stimulation. Follicular hyperplasia with diffuse proliferation of B cells and T cells can be seen in a variety of autoimmune diseases (e.g., Sjögren's syndrome, systemic lupus erythematosus, rheumatoid arthritis) and infectious processes (e.g., EBV, cytomegalovirus, cat-scratch disease) (Chapter 171). If the definitive diagnosis of lymphoma cannot be made even after immunologic and molecular studies, the patient should be closely observed. The clinical course or subsequent biopsies can usually resolve the confusion.

Castleman's disease, or angiofollicular lymph node hyperplasia, usually appears with a hyaline vascular pattern of lymphoid proliferation, but a subset of patients has hyperplastic lymphoid follicles and sheets of plasma cells. Patients with Castleman's disease often present with a localized lymphoid mass, but some patients have a systemic illness with fevers, night sweats, weight loss, and fatigue. Frequently, the systemic symptoms of Castleman's disease are related to excessive production of interleukin-6 (IL-6). Castleman's disease in HIV-infected patients is frequently associated with HHV-8. Patients with disseminated and plasma cell–rich forms of Castleman's disease may occasionally progress to lymphoma. Patients with localized Castleman's disease can be treated with surgical removal or radiation therapy. Patients with systemic disease may respond to treatment with high-dose corticosteroids. Patients with overexpression of IL-6 frequently benefit from treatment with an anti–IL-6 antibody. If other treatments fail, patients sometimes benefit from combination chemotherapy regimens, autologous or allogeneic hematopoietic stem cell transplantation, or both.

Sinus histiocytosis with massive lymphadenopathy, also known as *Rosai-Dorfman disease,* manifests as bulky lymphadenopathy in children and young adults. Extranodal sites such as the skin, upper airways, gastrointestinal tract, and CNS can be involved. The disease is usually self-limited, but it has been associated with autoimmune hemolytic anemia.

Kikuchi's disease (histiocytic necrotizing lymphadenitis) is a disease of unknown origin that most commonly affects young women. Symptoms most commonly consist of painless cervical lymphadenopathy that is often accompanied by fever, flu-like symptoms, and rash. Treatment is symptomatic, and manifestations usually resolve within weeks or months.

HODGKIN'S LYMPHOMA

JOSEPH M. CONNORS

DEFINITION

Hodgkin's lymphoma, formerly called Hodgkin's disease, is one of the B-cell lymphomas. It has a characteristic neoplastic cell, the Hodgkin-Reed-Sternberg cell, a distinct natural history, and most important, an excellent response to treatment, with the large majority of patients being cured. Its management, which requires careful multidisciplinary cooperation, serves as a paradigm for the successful application of modern oncologic concepts. Highly effective chemotherapy is the cornerstone of treatment. Carefully selected patients may require the addition of radiation or, if the lymphoma recurs after primary treatment, high-dose chemoradiation therapy and autologous hematologic stem cell transplantation (HDC/HSCT). The current challenge to clinicians managing this neoplasm is to cure the disease while minimizing long-term toxicity.

EPIDEMIOLOGY

The incidence of Hodgkin's lymphoma varies substantially around the world. The highest rates occur in the United States, Canada, Switzerland, and northern Europe. Intermediate rates are seen in southern and eastern Europe and low rates in eastern Asia. No clear explanation for this variation in incidence has been found. Postulated reasons include differences in the age at onset or genotype of any associated Epstein-Barr virus (EBV) infection; crowding during childhood as a result of lower socioeconomic status, predisposing to passage of an as yet undiscovered infectious vector; and intrinsic genetic differences in susceptibility.

Approximately 20,000 new cases are seen annually in North America and Europe. The age-adjusted incidence of Hodgkin's lymphoma declined modestly over the 20 years before 1990 at a rate of approximately 0.9% per year but has leveled off since then and is now approximately 2.7 per 100,000. Age-adjusted annual mortality is 0.5 per 100,000. Hodgkin's lymphoma occurs slightly more often in men and is seen more frequently in whites than African Americans and much less frequently in Asian populations. Much of the difference in incidence between whites and blacks in North America can be attributed to the higher incidence seen in higher socioeconomic classes. The cumulative lifetime risk for development of Hodgkin's lymphoma is approximately 1 in 250 to 1 in 300 in North America.

The incidence of Hodgkin's lymphoma rises from a very low level in childhood to a plateau in early adulthood and then remains stable. In the Western world, only about 5% of cases occur in persons younger than 15 years and 5% in persons older than 70 years. In contrast, however, the age distribution in the Indian subcontinent is strongly shifted into childhood.

PATHOBIOLOGY

The cause of Hodgkin's lymphoma remains unclear. Hodgkin's lymphoma is not associated with exposure to radiation, chemicals, biocidal agents, working in health care–related professions, or previous tonsillectomy. The leading suspect remains EBV, based on much suggestive evidence but no definitive proof.

Epstein-Barr Virus

EBV is a large B-lymphocyte tropic herpesvirus (Chapter 385). Approximately 90% of the general population acquires infection with EBV by early adulthood. In the developing world, this infection usually occurs in childhood, but in developed countries, infection is often delayed into the teens, when it is associated with the syndrome of infectious mononucleosis in up to 30% of new cases. A history of infectious mononucleosis increases the likelihood for subsequent Hodgkin's lymphoma three-fold. Antibodies to the viral capsid antigen reach higher levels in patients with Hodgkin's lymphoma than in controls, and these higher levels appear several years before the neoplasm. In situ hybridization studies have demonstrated that the Hodgkin-Reed-Sternberg cells in approximately 50% of cases of Hodgkin's lymphoma contain EBV-encoded small RNA (EBER), and in these cases, virtually all the Hodgkin-Reed-Sternberg cells are positive for the virus. The EBV genome

is amplified 50-fold or more in Hodgkin-Reed-Sternberg cells and is monoclonal in an individual patient's Hodgkin-Reed-Sternberg cells. In some populations, virtually all cases of Hodgkin's lymphoma occur in EBV-positive individuals, but up to 50% of patients in developed countries do not have EBV in their Hodgkin-Reed-Sternberg cells. Thus, although EBV may play an important role in the development of Hodgkin's lymphoma, that role is neither straightforward nor universal.

Genetic Factors

Circumstantial evidence for a genetic contribution to the etiology of Hodgkin's lymphoma comes from studies showing that Hodgkin's lymphoma is almost 100-fold more likely to develop in the monozygotic twin of an affected individual than in a dizygotic twin. First-degree relatives of individuals with the disease have up to a five-fold increased risk for development of the lymphoma. Perhaps genetically predisposed individuals react differently to EBV, thereby increasing the chance that a lymphoid neoplasm will develop.

Polymerase chain reaction–based genotypic analysis has demonstrated the clonal derivation of Hodgkin-Reed-Sternberg cells, including identical *p53* mutations from multiple Hodgkin-Reed-Sternberg cells extracted from a single biopsy specimen, thereby unequivocally establishing clonality. The presence of clonal immunoglobulin gene rearrangements from multiple cells in the same biopsy specimen also confirms a B-cell origin. Only a few rare cases with a T-cell genotype have been reported, but these are obviously exceptional. The presence of clonal somatic mutations provides proof of the germinal center origin of the neoplastic cells. Finally, identification of cells with identical immunoglobulin gene rearrangements both at diagnosis and at relapse verify that the B-cell clonality of the disease is preserved over time.

Despite their B-cell origin, the neoplastic cells of Hodgkin's lymphoma are incapable of making intact antibodies, perhaps because they lack the ability to make the transcription factors necessary to activate the immunoglobulin promoter. B cells that are incapable of manufacturing antibody should undergo apoptosis, but the Hodgkin-Reed-Sternberg cells avoid this self-destruction. The observation that the antiapoptotic nuclear transcription factor NFκB is constitutively activated in these cells may provide an explanation.

Classic cytogenetics has been unrevealing in Hodgkin's lymphoma. Aneuploidy and hyperploidy consistent with the multinucleated nature of Hodgkin-Reed-Sternberg cells are frequent, but no consistent translocations have been detected.

CLINICAL MANIFESTATIONS

Hodgkin's lymphoma is usually manifested as lymphadenopathy (Chapter 171), typically in the cervical, axillary, or mediastinal areas, and only about 10% of the time as nodal disease below the diaphragm. Although peripherally located nodes seldom reach large size, very large mediastinal masses or, less often, retroperitoneal masses can develop with only modest symptoms. Lymph node involvement in Hodgkin's lymphoma is usually painless, but an occasional patient notes discomfort in involved nodal sites immediately after drinking alcohol.

Approximately 25% of patients with Hodgkin's lymphoma have constitutional symptoms. The classic B symptoms, significant weight loss (>10% of baseline), night sweats, and persistent fever, usually signal widespread or locally extensive disease and imply a need for systemic treatment. Generalized pruritus, occasionally severe, can antedate the diagnosis of Hodgkin's lymphoma by up to several years. Some patients have symptoms suggestive of a growing mass lesion, such as cough or stridor as a result of tracheobronchial compression from mediastinal disease or bone pain secondary to metastatic involvement. Because Hodgkin's lymphoma can involve the bone marrow extensively, an occasional patient has symptomatic anemia or incidentally noted pancytopenia. Paraneoplastic neurologic or endocrine syndromes have been reported with Hodgkin's lymphoma but are rare.

DIAGNOSIS

The diagnosis of Hodgkin's lymphoma is based on recognition of Hodgkin-Reed-Sternberg cells (Fig. 192-1) or Hodgkin's cells (or both) in an appropriate cellular background in tissue sections from a lymph node or extralymphatic organ, such as bone marrow, lung, or bone. Fine-needle aspiration biopsy is not adequate for the diagnosis of Hodgkin's lymphoma. Open biopsy and standard histochemical staining are required to establish the diagnosis unequivocally and to determine the histologic subtype. Immunohistochemical studies can prove helpful in difficult cases or to distinguish special subtypes such as lymphocyte-rich classic Hodgkin's lymphoma and the nodular lymphocyte-predominant type. In classic Hodgkin's lymphoma, scattered large Hodgkin-Reed-Sternberg cells either are multinucleated or have large polyploid nuclei. Variations include mononuclear cells that are similar to the usual polylobated or multinuclear cells but have only one large nucleus with a prominent nucleolus, as well as lacunar cells, which are Hodgkin-Reed-Sternberg variants with abundant cytoplasm that has retracted as an artifact of formalin fixation. The infrequent Hodgkin-Reed-Sternberg cells are usually present in a background mixture of polyclonal lymphocytes, eosinophils, neutrophils, plasma cells, fibroblasts, and histiocytes. Recently, a high number of associated macrophages have been demonstrated to be a strong predictor of treatment resistance. Occasionally, granulomas form with a prominent histiocytic component.

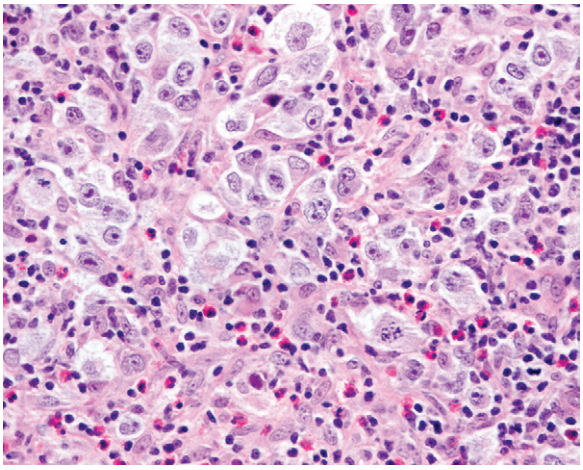

FIGURE 192-1. Nodular sclerosing Hodgkin's lymphoma. This figure shows a typical case of classic nodular sclerosing Hodgkin's lymphoma with many lacunar cells, occasional diagnostic Hodgkin-Reed-Sternberg cells, and the characteristic background of lymphocytes and eosinophils. (Photomicrograph courtesy of Randy D. Gascoyne, MD, British Columbia Cancer Agency.)

TABLE 192-1 WORLD HEALTH ORGANIZATION CLASSIFICATION OF HODGKIN'S LYMPHOMA SUBTYPES

SUBTYPE NAME	FREQUENCY (%)*
Classic Hodgkin's lymphoma	
Nodular sclerosis	70
Lymphocyte rich	3
Mixed cellularity	10
Lymphocyte depleted	1
Nodular lymphocyte-predominant Hodgkin's lymphoma	7
Hodgkin's lymphoma, not otherwise classifiable	9

*Frequency based on all new cases ($N = 1043$) seen in British Columbia since January 1998 when the category of lymphocyte-rich classic Hodgkin's lymphoma became well established.

Hodgkin's lymphoma can typically be classified into one of five well-described subtypes (Table 192-1). Reproducibility of the distinctions among these subtypes has been confirmed in the current widely accepted World Health Organization classification of lymphoid neoplasms. With addition of the new category of lymphocyte-rich classic Hodgkin's lymphoma, this newest classification scheme permits confident identification of nodular lymphocyte-predominant Hodgkin's lymphoma as a separate entity. The most common subtype is nodular sclerosing, which has characteristic course bands of sclerosis surrounding nodules composed of typical Hodgkin-Reed-Sternberg cells in the usual background mixture of reactive and inflammatory cells.

The immunophenotype of the neoplastic cells in Hodgkin's lymphoma can help identify the specific subtype. Typically, the Hodgkin-Reed-Sternberg cells stain positively for CD30 (80 to 100% of cases), CD15 (75 to 85% of cases), and B-cell-specific activating protein (BSAP), which is the product of the *PAX5* gene (>90% of cases). However, often only a minority of the malignant cells stain positively for the CD15 and BSAP markers. CD20, a generally reliable marker of B-cell lineage, is positive in about 40% of cases of classic

Hodgkin's lymphoma, but usually only in a minority of cells, and the staining can be weak. In contrast, nodular lymphocyte-predominant Hodgkin's lymphoma almost always stains strongly positive for CD20 and for the specialized B-cell markers CD79a and CD45, but it is negative for CD30 and CD15. Finally, anaplastic large cell lymphoma (Chapter 191) is reliably negative for CD15, CD20, and CD79a but frequently positive for anaplastic lymphoma kinase (ALK).

Differential Diagnosis

Depending on the site of occurrence and associated symptoms, the differential diagnosis of Hodgkin's lymphoma includes non-Hodgkin's lymphoma (Chapter 191), germ cell tumors (Chapter 206), thymoma (Chapter 430), sarcoidosis (Chapter 95), and tuberculosis (Chapter 332). However, the specific diagnosis is readily determined by obtaining an adequate biopsy specimen for review by an experienced hematopathologist. Proceeding to such a biopsy early in the assessment of patients with lymphadenopathy (Chapter 171), especially of the mediastinum, often saves time and spares the patient needless testing and delay in diagnosis.

With computed tomography (CT) and appropriate biopsy procedures to investigate enlarged central thoracic or intra-abdominal lymph nodes, the diagnosis of Hodgkin's lymphoma seldom presents difficulty. The immunophenotype helps distinguish Hodgkin's lymphoma from other diseases. For example, T-cell-rich B-cell lymphoma (Chapter 191) is distinguished from classic Hodgkin's lymphoma by being CD30 and CD15 negative but positive for CD20 and CD45. However, T-cell-rich B-cell lymphoma (Chapter 191) can be very difficult to distinguish from nodular lymphocyte-predominant Hodgkin's lymphoma because both are negative for CD30 and CD15 but positive for CD45. This distinction is best made by focusing on the histologic pattern of the neoplastic cells. In fact, the combination of appropriate immunohistopathologic evaluation by an expert hematopathologist and clinical assessment has virtually eliminated difficulties with the differential diagnosis. Problems mostly arise when inadequate or improperly processed material is all that is available for diagnosis.

Staging

Physical Examination

Given its tendency to spread in an orderly fashion, usually from initially involved lymph nodes, the stage of Hodgkin's lymphoma can be established by using readily available imaging and laboratory tests (Fig. 192-2 and Table 192-2). The evaluation should start with a careful history to search for the presence of localizing signs, such as bone pain, or the constitutional symptoms of fever, weight loss, or night sweats. The history may also reveal comorbid conditions that may affect the safe delivery of planned treatment. The physical examination may identify lymphadenopathy or organomegaly.

Laboratory Testing

Laboratory testing should include blood cell counts and the erythrocyte sedimentation rate, assessment of liver and renal function, serum albumin level, serum protein electrophoresis, and serologic testing for hepatitis B. Also, the patient should be tested for hepatitis C if liver enzyme abnormalities are detected and human immunodeficiency virus (HIV) antibody if the history indicates an increased risk or if the sites of disease are unusual. Bone marrow aspiration and biopsy are only useful for the minority of patients with constitutional (B) symptoms or those with lower than normal peripheral blood counts at diagnosis.

Imaging

Imaging techniques to evaluate Hodgkin's lymphoma continue to evolve (Fig. 192-3). All patients should undergo contrast-enhanced CT scanning of the thorax, abdomen, and pelvis with slices at intervals of 1 cm or less. Magnetic resonance imaging is occasionally useful when the extent of bone or soft tissue involvement must be determined precisely or for a patient with an absolute contraindication to the use of intravenous contrast agents.

Positron Emission Tomography

Positron emission tomography (PET) is more sensitive and specific than CT or gallium scanning both for staging and for assessment of residual masses after treatment. However, it has not been proved that the addition of PET to standard staging imaging tests for Hodgkin's lymphoma will actually improve outcome, so whether PET could replace other studies is not clear. The greatest usefulness of PET presently appears to be the assessment of residual masses during or after planned treatment so that the minority of patients who should receive altered or additional therapy, especially radiotherapy, can be identified.

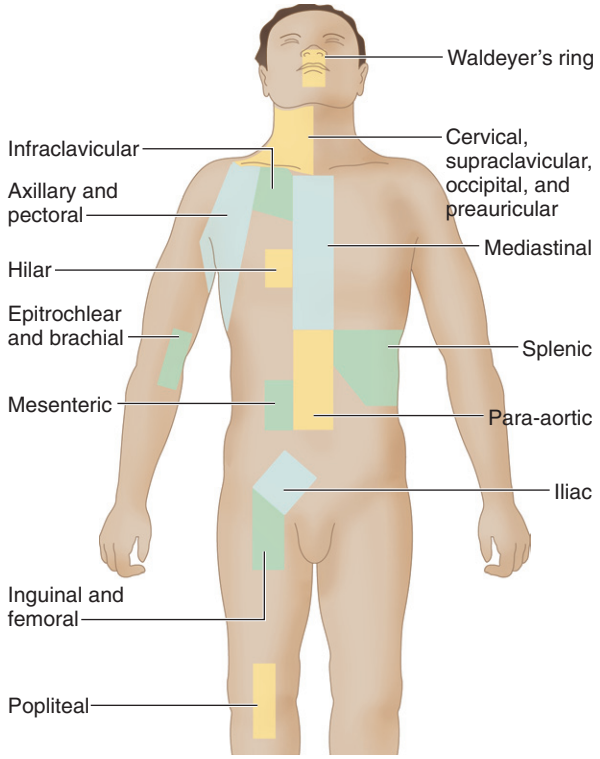

FIGURE 192-2. Anatomic definition of lymph node regions for staging of Hodgkin's disease. (From Kaplan HS, Rosenberg SA. The treatment of Hodgkin's disease. *Med Clin North Am.* 1966;50:1591-1610.)

TABLE 192-2 TESTS REQUIRED FOR STAGING OF HODGKIN'S LYMPHOMA

Complete history to search for B symptoms (fever, weight loss, night sweats) or other symptomatic problems suggesting more advanced disease
Physical examination for lymphadenopathy or organomegaly
Complete blood count
Serum creatinine, alkaline phosphatase, lactate dehydrogenase, bilirubin, and protein electrophoresis (including serum albumin level)
Chest radiograph, posteroanterior and lateral views
Computed tomography scan of the neck, thorax, abdomen, and pelvis
Certain tests are required only for specific manifestations

MANIFESTATION/CONDITION	TEST
B symptoms or WBC count <4.0 × 10^9/L, Hgb <120 g/L (women) or 130 g/L (men), or platelets <125 × 10^9/L	Bone marrow biopsy and aspiration
Stage IA or IIA disease with upper cervical lymph node involvement (suprahyoid)	ENT examination

ENT = ear, nose, and throat; Hgb = hemoglobin; WBC = white blood cell.

Staging System

The Ann Arbor staging system with the Cotswold modification (Table 192-3) categorizes patients into four stages. The first three indicate the expanding extent of lymph node disease (see Fig. 192-2): stage I, a single nodal area; stage II, two or more nodal areas but still on one side of the diaphragm; and stage III, nodal disease on both sides of the diaphragm. The spleen and the lymphoid tissue of Waldeyer's ring each count as nodal sites in this system. Stage IV is reserved for extranodal disease, which for all practical purposes is disease in the bone marrow, lung, bone, or liver. Hodgkin's lymphoma at any other extranodal site should prompt questioning of the diagnosis or a search for HIV infection.

Bulky disease is defined as the presence of any tumor mass with the largest diameter greater than 10 cm or a mediastinal mass with a transverse diameter exceeding one third of the largest transverse transthoracic diameter. With CT scanning, use of the mediastinal mass ratio is obsolete, and the term *bulky* is best assigned to tumors exceeding 10 cm in largest single diameter.

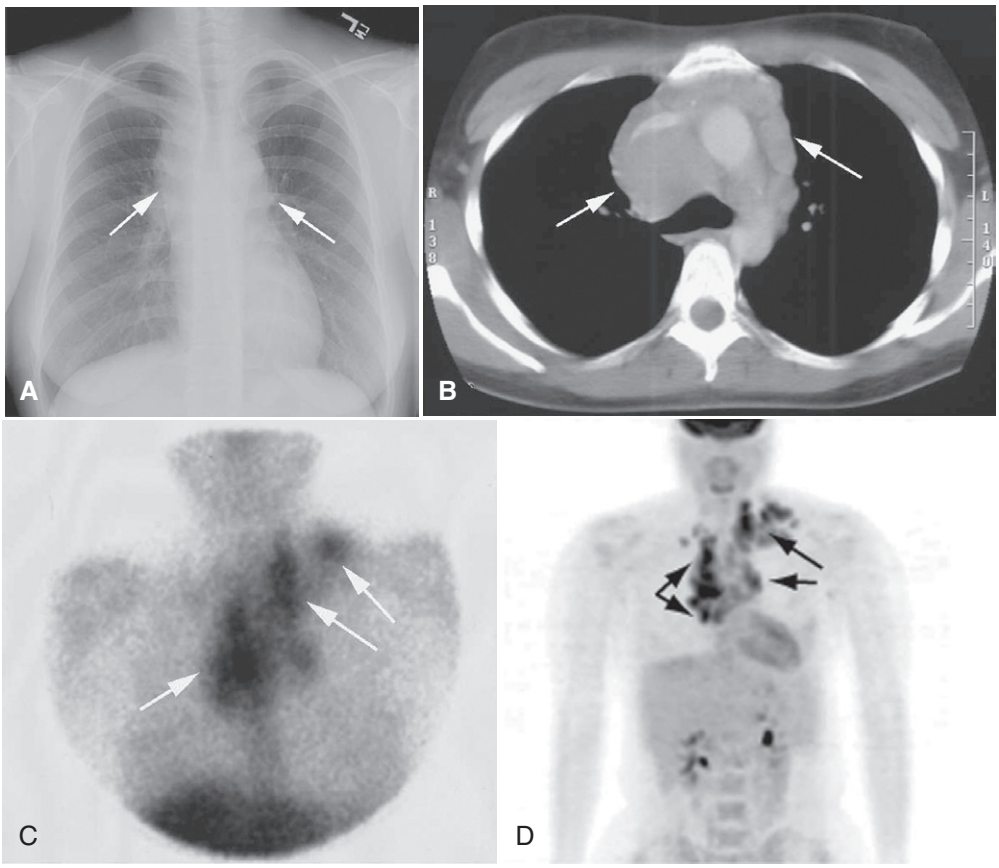

FIGURE 192-3. Imaging of Hodgkin's lymphoma. Bulky Hodgkin's disease as seen on chest radiograph (**A**), computed tomography (CT) of the chest (**B**), gallium scan (**C**), and positron emission tomography (PET) (**D**). The *arrows* indicate sites of disease. Note that the PET and CT scans provide more detailed information than the chest radiograph and gallium scan.

TABLE 192-3 MODIFIED ANN ARBOR STAGING SYSTEM FOR HODGKIN'S LYMPHOMA

STAGE	INVOLVEMENT
I	Single lymph node region (I) or one extralymphatic site (I_E)
II	Two or more lymph node regions, same side of the diaphragm (II), or local extralymphatic extension plus one or more lymph node regions, same side of the diaphragm (II_E)
III	Lymph node regions on both sides of the diaphragm (III); may be accompanied by local extralymphatic extension (III_E)
IV	Diffuse involvement of one or more extralymphatic organs or sites
A	No "B" symptoms
B	Presence of at least one of the following: Unexplained weight loss >10% of baseline during 6 mo before staging Recurrent unexplained fever >38° C Recurrent night sweats

TABLE 192-4 RATES OF PROGRESSION IN 5 YEARS IN PATIENTS WITH ADVANCED-STAGE HODGKIN'S LYMPHOMA

NO. OF FACTORS*	FREQUENCY (%)	PERCENTAGE WITH PROGRESSION-FREE SURVIVAL AT 5 YEARS
0-3	81	70
4-7	19	47

*Male sex, age older than 45 years, stage IV, hemoglobin level less than 10.5 g/dL, white blood cell count greater than 15,000/mL, lymphocyte count less than 600/mL or less than 8% of the white cell count, or serum albumin less than 4 g/dL.

The E lesion designation identifies patients whose limited extranodal extension of Hodgkin's lymphoma could be included in a reasonable involved field of irradiation. After staging, patients are further subdivided into those with or without fever, night sweats, or weight loss (B symptoms).

TREATMENT

Over the past 60 years, Hodgkin's lymphoma has been transformed from a nearly uniformly fatal illness to one that is usually cured. This remarkable success has provided a paradigm on which much of modern oncologic treatment is based. The principles underlying combined-modality treatment and multiagent chemotherapy, the mainstays of today's successful treatment of many malignancies, were first demonstrated to be effective with Hodgkin's lymphoma. The essential involvement of a multidisciplinary team, including pathologists, experts in diagnostic imaging, medical and radiation oncologists, nurses, and support staff, has served as a model for all cancer. The necessity to balance greater efficacy of initial treatment, which often requires an increase in intensity and therefore toxicity, against troublesome and occasionally fatal late complications has encouraged a long-term perspective.

From a practical therapeutic viewpoint, patients with stage III or IV disease, bulky disease, or B symptoms are defined as having advanced disease, whereas patients without these characteristics have limited-stage disease. In Europe, patients with limited disease are further subdivided into those with favorable and unfavorable outcomes, but cure rates exceed 90 to 95% for all patients with nonbulky stage IA or IIA (limited) disease. However, for patients with advanced-stage disease, independent predictors of progression include gender, age, stage, hemoglobin level, white blood cell count, lymphocyte count, and serum albumin level (Table 192-4). Based on results obtained in the 1980s, the 80% of patients with fewer than four factors had a progression-free survival of 70%, but for the 20% who had four or more factors, the progression-free survival rate fell to less than 50%. However, with better attention to dose delivery, more current results indicate a spread of only 80% to 60% between these two groups. A straightforward plan of treatment for the 90% of patients in whom Hodgkin's lymphoma is diagnosed between the ages of 16 and 70 years can be based on clinical stage, the presence of B symptoms, and bulk of the largest tumor mass (Table 192-5).

Treatment of Limited-Stage Hodgkin's Lymphoma

More than 95% of the one third of patients with Hodgkin's lymphoma initially found to have limited-stage disease can be cured regardless of the site

TABLE 192-5 TREATMENT PLAN FOR ADULT PATIENTS WITH HODGKIN'S LYMPHOMA

STAGE	PROGNOSTIC CATEGORY	TREATMENT
IA or IIA, no bulky disease*		ABVD† × 4 if CR after 2 cycles or ABVD × 2 + IRRT
IB, IIB, or any stage III or IV or bulky disease, any stage	≤3 adverse factors†	ABVD† until 2 cycles past CR (minimum 6, maximum 8)
	≥4 adverse factors†	Escalated BEACOPP‡

*Bulky refers to disease with the largest diameter of any single mass equal to or greater than 10 cm.
†See Table 192-4 note.
‡See text for drugs in each regimen. Optimal dosing must be individualized.
CR = complete response; IRRT = involved-region radiation therapy.

of occurrence, the presence of disease above or below the diaphragm, or the histologic subtype. The challenge is to achieve this goal with the least toxicity and cost.

Two cycles of ABVD (Adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine) chemotherapy followed by involved-field irradiation cures nearly 95% of patients with limited-stage disease and nearly completely eliminates the risk for infertility, premature menopause, and leukemia and minimizes cardiopulmonary toxicity.[1,2] The chemotherapy in the combined-modality treatment of limited-stage Hodgkin's lymphoma eradicates subclinical disease and allows smaller fields of irradiation to be used. However, a substantial proportion of the excess, long-term mortality in patients with limited-stage Hodgkin's lymphoma is due to cardiovascular disease and second neoplasms that are closely related to the use of irradiation. In a randomized trial that compared four to six cycles of ABVD chemotherapy alone versus irradiation, either alone or augmented with two cycles of ABVD chemotherapy, the strategy of chemotherapy alone proved equivalent to irradiation-based treatment in terms of event-free and overall survival, although the irradiation-based approach did produce a modest improvement in progression-free survival.[3] Longer follow-up will be necessary to see whether the goal of a reduction in cardiovascular events and second neoplasms was accomplished. This trial suggests that more than 90% of patients with limited-stage Hodgkin's lymphoma can be treated with four to six cycles of ABVD alone; for the minority whose lymphoma does not completely regress after two cycles, probably best assessed by PET scanning, the addition of radiation may be optimum.

Treatment of Advanced-Stage Hodgkin's Lymphoma

In advanced-stage Hodgkin's lymphoma (stages IIIA, IIIB, IVA, and IVB), both ABVD and MOPP (mechlorethamine, Oncovin [vincristine], procarbazine, and prednisone)/ABVD are superior to MOPP alone in terms of progression-free survival. Today, ABVD is the most widely used regimen for patients with advanced-stage Hodgkin's lymphoma. The addition of radiation therapy significantly improves progression-free survival at 10 years in patients with advanced-stage Hodgkin's lymphoma, but it does not improve overall survival because it causes significantly more deaths unrelated to lymphoma. Even the addition of radiation therapy for patients in complete remission after chemotherapy for advanced-stage Hodgkin's lymphoma has no significant impact. The adverse long-term effects of radiation therapy and its lack of improvement in overall survival appear to outweigh any benefits for the usual patient with advanced-stage disease. The ability of PET scanning to distinguish between residual fibrosis and persistent lymphoma may provide a mechanism to identify selected patients who might benefit from localized radiation therapy.

Recently devised regimens for patients with advanced Hodgkin's lymphoma are the Stanford V regimen (doxorubicin, vinblastine, mechlorethamine, etoposide, vincristine, bleomycin, and prednisone) and escalated BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, prednisone, and procarbazine) (see Table 192-5). As originally described, both include postchemotherapy irradiation to sites of initial or residual tumor bulk (≥5 cm). Although initial results appeared quite promising, recent results indicate that the Stanford V regimen is no more effective than standard ABVD.[4] BEACOPP plus radiation therapy provides better progression-free and overall survival at a median follow-up of 6.9 years than COPP/ABVD plus radiation therapy despite a higher rate of hematologic toxicity and infertility.[5]

The overall approach to managing advanced-stage Hodgkin's lymphoma must factor in the fact that about 50% of patients who are not cured by primary chemotherapy can be effectively treated with HDC/HSCT (Chapter 181). Thus, for the 80% of patients with zero to three adverse prognostic factors at presentation, who have a 75% chance of cure with primary chemotherapy, the most widely used approach is to start with ABVD. For the 20% of these low-risk patients in whom progressive lymphoma develops despite primary treatment, HDC/HSCT (Chapter 181) should be offered. Such a strategy confines the high cost and toxicity of intensified treatment to the minority of patients whose disease demands it. Conversely, for the 20% of patients with high-risk disease who have four or more adverse factors and only a 60% likelihood of cure with primary chemotherapy, more intense initial treatment with the BEACOPP protocol is reasonable.

Management of Refractory or Relapsed Hodgkin's Lymphoma

HDC/HSCT has become the established treatment for most patients whose Hodgkin's lymphoma persists or recurs despite primary chemotherapy.[6] However, the treatment-related mortality, high levels of toxicity, and cost associated with HDC/HSCT demand that it be reserved for patients in whom it clearly increases the chance of cure over alternative treatments; such patients include those whose disease progresses during or within 3 months of initial multiagent chemotherapy (refractory Hodgkin's lymphoma) and those who relapse more than 3 months after multiagent chemotherapy (relapsed Hodgkin's lymphoma). For relapsed lymphoma, controversy remains, however, for two special subgroups: patients who relapse solely in originally involved but unirradiated lymph nodes and without B symptoms or extranodal disease, who may obtain up to a 40 to 50% cure rate with wide-field irradiation, and patients who relapse without B symptoms more than 1 year after completion of primary chemotherapy, who may achieve up to a 30 to 40% cure rate with additional chemotherapy with or without irradiation. However, even these two subgroups may achieve up to an 80% 10-year disease-free survival rate after HDC/HSCT. Thus, data suggest that standard treatment for patients with progressive Hodgkin's lymphoma after primary chemotherapy for advanced-stage disease should be HDC/HSCT regardless of the characteristics of the relapse.

HDC/HSCT should be reserved for patients who have progressive lymphoma after primary chemotherapy because randomized trials of HDC/HSCT for patients in complete or partial remission after primary chemotherapy for advanced Hodgkin's lymphoma failed to show a difference in outcome.[7]

Management of Complications

Follow-up and Late Complications of Treatment

Most adult patients with Hodgkin's lymphoma are cured and experience minimal long-term toxicity from their treatment. However, the risk for certain predictable and occasional rare and less predictable late effects warrants careful but not intrusive follow-up and selective intervention (Table 192-6). At the conclusion of treatment, a thorough reassessment of the initial sites of lymphoma should be completed to provide post-treatment baseline measurements. Patients should be seen by a specialist knowledgeable in the management of lymphoma, preferably about every 3 months for 2 years, then every 6 months for 3 years, then annually. Patients should be strongly encouraged to refrain from smoking, to perform careful breast and skin examinations on a regular basis, and to undergo regular immunizations for influenza annually, pneumococcus at diagnosis and 5 years after treatment, and diphtheria and tetanus every 10 years (Chapter 17). Patients who have received radiation to the head or neck area should follow a vigorous program of dental prophylaxis in anticipation of the deleterious effect of reduced saliva production and have their thyroid-stimulating hormone (TSH) level checked annually in recognition of the 50% risk for eventual hypothyroidism.

Special Problems in the Management of Hodgkin's Lymphoma

Hodgkin's Lymphoma during Pregnancy

Between 0.5 and 1.0% of cases of Hodgkin's lymphoma occur coincident with pregnancy (Chapter 247). When the lymphoma is discovered during pregnancy, it is almost always possible to keep it under control and allow the pregnancy to go to full term.

Standard staging tests (see Table 192-2) should be completed, except that imaging requiring radiation must be minimized. For example, abdominal ultrasonography can identify bulky retroperitoneal disease, and a single posteroanterior radiograph of the chest, with proper shielding, can identify bulky mediastinal disease.

More than 50% of patients can continue the pregnancy to term without any treatment of the lymphoma. If symptomatic or progressive disease develops, systemic chemotherapy can be given in the second and third trimester with very small risk of injuring the fetus. An attractive alternative is intermittent single-agent vinblastine, given in the lowest dose that can control symptoms until delivery, followed by a full course of six to eight cycles of multiagent chemotherapy after delivery.

Hodgkin's Lymphoma and Acquired Immunodeficiency Syndrome

In patients with HIV infection, the incidence of Hodgkin's lymphoma is increased as much as five- to ten-fold, and the lymphoma manifests differently and pursues a more aggressive natural history (Chapter 400). Hodgkin's lymphoma in HIV-positive individuals is almost always associated with EBV within Hodgkin-Reed-Sternberg cells. The histology is much more likely to be mixed cellularity or lymphocyte depleted. The disease most commonly develops in extranodal sites, especially the bone marrow. More than 80% of patients have advanced-stage disease, and most patients have B symptoms.

TABLE 192-6 MONITORING AFTER SUCCESSFUL PRIMARY TREATMENT OF HODGKIN'S LYMPHOMA

RISK/PROBLEM	INCIDENCE/RESPONSE
Relapse	Ten to 30% of patients experience relapse. Careful attention should be directed to lymph node sites, especially if previously involved with disease and not treated with radiation. New persistent focal symptoms such as bone pain should be investigated with appropriate laboratory and imaging studies.
Dental caries	Neck or oropharyngeal irradiation may cause decreased salivation. Patients should have regular dental care and should make their dentist aware of the previous irradiation.
Hypothyroidism	After external beam thyroid irradiation at doses sufficient to cure Hodgkin's lymphoma, at least 50% of patients eventually become hypothyroid. All patients who have been exposed to neck irradiation should have an annual TSH level determined. Patients whose TSH level becomes elevated should be treated with lifelong thyroxine replacement in doses sufficient to suppress TSH levels to low normal (Chapter 233).
Infertility	ABVD is not known to cause permanent gonadal toxicity, although temporary oligospermia or irregular menses may persist for 1 to 2 years after treatment. Direct or scatter radiation to gonadal tissue may cause infertility, amenorrhea, or premature menopause, but this adverse event seldom occurs with the current fields used for the treatment of Hodgkin's lymphoma. In general, women who continue menstruating are fertile, but men require semen analysis to provide a specific answer.
Secondary neoplasms	Although uncommon, certain secondary neoplasms occur with increased frequency in patients who have been treated for Hodgkin's lymphoma: acute myelogenous leukemia; thyroid, breast, lung, cervical, and upper gastrointestinal carcinoma; and melanoma. It is appropriate to "be vigilant" for these neoplasms for the remainder of the patient's life because they may have a lengthy induction period.

ABVD = doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine; TSH = thyroid-stimulating hormone.

Patients are prone to opportunistic infections, and the interaction of chemotherapeutic agents with other medications may compromise the patient's ability to tolerate treatment. The best approach is a combination of highly active antiretroviral agents (Chapter 396), vigorous supportive care with antiherpetic and antifungal agents and neutrophil-stimulating growth factors, and standard multiagent chemotherapy. With appropriate supportive care, regimens such as ABVD can be delivered. However, more severe than normal toxicity must be anticipated, and cure rates are much lower than in the non-HIV-infected population. Median survival is typically 3 to 4 years.

Hodgkin's Lymphoma in the Elderly Population

Elderly patients with Hodgkin's lymphoma have a worse outcome. For example, the 5-year overall survival rate falls from 80% in patients younger than 65 years to less than 50% in patients older than 65 years. Explanations include more advanced stage at diagnosis, comorbid diseases, delay in diagnosis, incomplete staging, inadequate adherence to treatment protocols, and failure to maintain full dose intensity.

Of note is that elderly patients achieve outcomes equivalent to those of younger patients when they receive similar doses of chemotherapy. The best approach for elderly patients is to attempt to treat them in a manner similar to younger patients, with vigorous supportive care and the addition of neutrophil growth factors if necessary to enable safe delivery of full doses. For patients with preexisting pulmonary or cardiac disease, it might be necessary to reduce or eliminate bleomycin or doxorubicin, respectively.

FUTURE DIRECTIONS

The ability to profile multigene expression patterns and identify genetic polymorphisms associated with specific malignancies may provide better insight into the molecular genesis of Hodgkin's and other lymphomas. Therapeutic agents more specifically targeted at the malignant Hodgkin-Reed-Sternberg cells, such as those coupling an antibody to the CD30 antigen with a cellular toxin, hold substantial promise to improve treatment outcome.

PLASMA CELL DISORDERS

S. VINCENT RAJKUMAR

INTRODUCTION

Plasma cell disorders are neoplastic or potentially neoplastic diseases associated with the clonal proliferation of immunoglobulin-secreting plasma cells (Table 193-1). They are characterized by the secretion of electrophoretically and immunologically homogeneous (monoclonal) proteins that represent intact or incomplete immunoglobulin molecules. Monoclonal proteins are commonly referred to as M proteins, myeloma proteins, or paraproteins.

Syndromes associated with plasma cell disorders and monoclonal proteins include monoclonal gammopathy of undetermined significance, multiple myeloma, Waldenström's macroglobulinemia, cryoglobulinemia, and primary amyloidosis (see Table 193-1). Occasionally, free hemoglobin-haptoglobin complexes resulting from hemolysis, large amounts of transferrin in patients with iron deficiency anemia, or increased levels of fibrinogen may simulate the presence of a monoclonal protein in serum.

Serum Immunoglobulins

Intact immunoglobulins consist of two heavy (H) polypeptide chains of the same class and subclass and two light (L) polypeptide chains of the same type (Chapter 44). The heavy polypeptide chains are designated by Greek letters: γ in immunoglobulin G (IgG), α in immunoglobulin A (IgA), μ in immunoglobulin M (IgM), δ in immunoglobulin D (IgD), and ε in immunoglobulin E (IgE). The light chain types are kappa (κ) and lambda (λ). Both heavy

V. Immunoglobulin light chain amyloidosis

Ig = immunoglobulin; POEMS = polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes.

chains and light chains have "constant" and "variable" regions with respect to the amino acid sequence. The class specificity of each immunoglobulin is defined by a series of antigenic determinants on the constant regions of the heavy chains (γ, α, μ, δ, and ε) and the two major classes of light chains (κ and λ). The amino acid sequence in the variable regions of the immunoglobulin molecule corresponds to the active antigen-combining site of the antibody.

In the majority of clonal plasma cell disorders, intact immunoglobulin molecules are secreted as monoclonal (M) proteins. In some patients, however, heavy chain expression is completely lost, and only monoclonal light chains (Bence Jones proteins) are secreted. Even less frequently, only heavy chains are secreted, resulting in heavy chain diseases (HCDs). Rare patients with multiple myeloma secrete no identifiable immunoglobulin ("nonsecretory myeloma").

Identification of Monoclonal Proteins

Protein electrophoresis of the serum and urine detects M protein as a narrow peak (like a church spire) on the densitometer tracing or as a dense, discrete band on agarose gel (Fig. 193-1). Electrophoresis also permits quantitation of M proteins. Monoclonal light chains (Bence Jones proteinemia) are rarely seen on serum electrophoresis but are easily detected on urine electrophoresis. Urine electrophoresis requires a 24-hour urine collection.

Immunofixation of the serum and urine is performed when a peak or band is first seen on protein electrophoresis to identify the heavy and light chain type of the M protein. Immunofixation is also a more sensitive test than protein electrophoresis, and it should always be performed in conjunction with electrophoresis when multiple myeloma or related disorders are first suspected in order to detect small, unmeasurable M proteins that may be missed on electrophoresis. This is particularly important in oligosecretory myeloma, primary amyloidosis, and solitary plasmacytoma and after successful treatment of multiple myeloma or macroglobulinemia. In these instances, a small M protein can be concealed in the normal β or γ areas of the electrophoresis gel and may be overlooked. In 5% of patients there is an additional M protein of a different immunoglobulin class; this condition is designated a biclonal gammopathy.

In some patients the M protein has specificity to one of the various antigens. Examples include actin, dextran, antistreptolysin O, antinuclear antibody, riboflavin, von Willebrand's factor, thyroglobulin, insulin, double-stranded DNA, and apolipoprotein. Binding of calcium by an M protein may produce hypercalcemia without symptomatic or pathologic consequences. M proteins have also been found to bind to copper and to phosphate.

Monoclonal proteins must be distinguished from an excess of polyclonal immunoglobulins (one or more heavy chain types and both κ and λ light chains, usually limited to the γ region), which produce a broad-based peak or broad band (Fig. 193-2). This finding is associated with chronic infectious or inflammatory states.

Washington, DC: ASM Press; 1997:156, with permission of the American Society for Microbiology.)

Detection of Serum Free Light Chains

The serum free light chain assay measures the level of free κ and λ immunoglobulin light chains (i.e., light chains that are not bound to intact immunoglobulin). An abnormal κ/λ free light chain ratio (normal range, 0.26 to 1.65) indicates an excess of one light chain type versus the other and is interpreted as representing a monoclonal elevation of the corresponding light chain type. The serum free light chain assay is more sensitive than electrophoresis or immunofixation in detecting free monoclonal light chains and is useful in the diagnostic evaluation of plasma cell disorders and in risk stratification.

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

DEFINITION

Monoclonal gammopathy of undetermined significance (MGUS; formerly called *benign monoclonal gammopathy*) is a premalignant clonal plasma cell

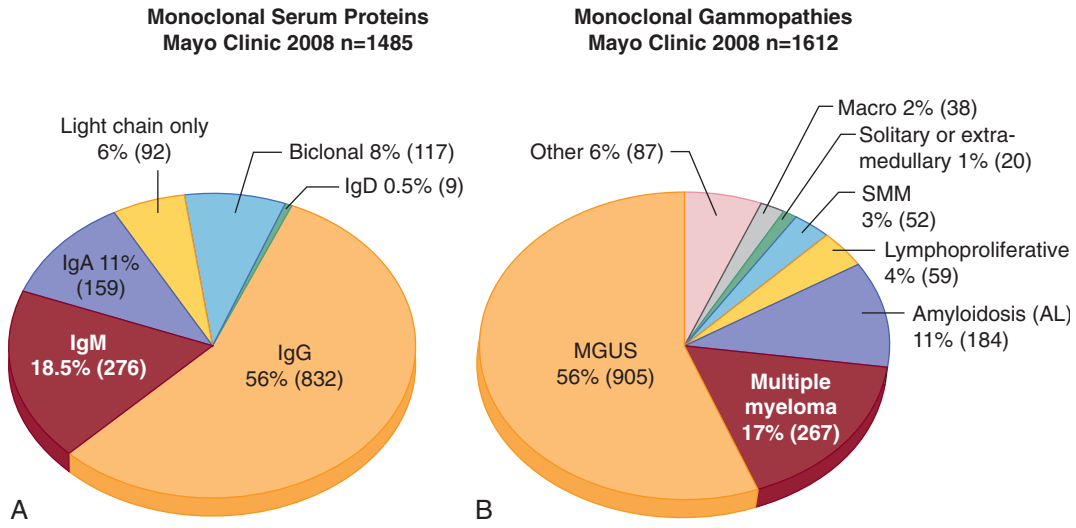

FIGURE 193-3. Monoclonal gammopathy. **A,** Distribution of serum monoclonal proteins in 1485 patients seen at the Mayo Clinic during 2008. **B,** Diagnoses in 1612 cases of monoclonal gammopathy seen at the Mayo Clinic during 2008. Ig = immunoglobulin; Macro = Waldenström's macroglobulinemia; MGUS = monoclonal gammopathy of undetermined significance; SMM = smoldering multiple myeloma.

disorder characterized by the presence of a serum M protein in persons who lack evidence of multiple myeloma, macroglobulinemia, amyloidosis, or other related diseases. MGUS is defined by a serum M protein concentration lower than 3 g/dL, less than 10% clonal plasma cells in the bone marrow, and absence of lytic bone lesions, anemia, hypercalcemia, and renal insufficiency that can be attributed to a plasma cell disorder. The main clinical significance of MGUS is its lifelong risk of transformation to myeloma or related malignancy at a fixed but unrelenting rate of 1% per year.

EPIDEMIOLOGY

More than 50% of patients in whom a serum M protein is detected have MGUS (Fig. 193-3). The prevalence of MGUS in the general population increases with age, from approximately 1% in persons 50 to 60 years old to greater than 5% in those older than 70 years. The age-adjusted prevalence is higher in males than in females and is twice as high in blacks compared with whites.

PATHOBIOLOGY

MGUS represents a limited, nonmalignant expansion of monoclonal plasma cells. The etiology of MGUS is unknown, but age, male gender, family history, immunosuppression, and exposure to certain pesticides are known risk factors. It is hypothesized that infection, inflammation, or other antigenic stimuli, acting in concert with the development of cytogenetic abnormalities in the plasma cells, are the initiating pathogenetic events in most patients. Approximately 50% of MGUS is associated with plasma cell translocations involving the immunoglobulin heavy chain (IgH) locus on chromosome 14q32 (IgH translocated MGUS). These primary IgH translocations commonly involve one of five recurrent partner chromosome loci: 11q13 (*CCND1* [cyclin D1 gene]), 4p16.3 (*FGFR-3* and *MMSET*), 6p21 (*CCND3* [cyclin D3 gene]), 16q23 (*c-maf*), and 20q11 (*mafB*). The remaining 50% lack IgH translocations but are usually associated with hyperdiploidy (hyperdiploid MGUS).

CLINICAL MANIFESTATIONS

MGUS is asymptomatic and is usually diagnosed incidentally on laboratory testing. Patients with MGUS progress to multiple myeloma or related malignancy at a rate of approximately 1% per year. The interval from the time of recognition of the M protein to the diagnosis of serious disease ranges from 1 to 32 years (median, 10.6 years), and the relative risk versus a control population is 25.0 for progression to multiple myeloma, 8.4 for primary amyloidosis, 46.0 for Waldenström's macroglobulinemia, 2.4 for the development of other forms of non-Hodgkin's lymphoma, and 8.5 for plasmacytoma. The relative risk for chronic lymphocytic leukemia (CLL) is not increased. In addition, in a small percentage of patients, the M protein level increases to greater than 3 g/dL and/or the percentage of plasma cells in bone marrow increases to more than 10% without progression to overt myeloma or a related disorder (smoldering multiple myeloma).

DIAGNOSIS

MGUS is differentiated from multiple myeloma and smoldering multiple myeloma by the size of the M protein, the bone marrow plasma cell percentage, and the presence or absence of anemia, renal failure, hypercalcemia, or lytic bone lesions (Table 193-2). Because anemia and renal insufficiency are relatively common in the elderly population with MGUS, the causes of these conditions should be carefully investigated with adequate laboratory studies. For example, in a patient with anemia, tests to exclude iron, vitamin B_{12}, or folate deficiency must be performed. In certain instances, such as unexplained renal failure, a renal biopsy may be needed. Only patients with strong evidence of end-organ damage thought to be directly related to a plasma cell disorder can be considered to have myeloma or a related malignancy.

Levels of the immunoglobulin classes other than M protein (i.e., the normal polyclonal or background immunoglobulins) are generally reduced in multiple myeloma or Waldenström's macroglobulinemia, but a reduction also occurs in almost 40% of patients with MGUS. The presence of osteolytic lesions strongly suggests multiple myeloma, but metastatic carcinoma may produce lytic lesions as well as polyclonal plasmacytosis and must be differentiated from MGUS.

Association of MGUS with Other Diseases

MGUS is associated with numerous diseases. However, because 3% of the general population older than 50 years has MGUS, it is often difficult to determine whether these reported associations are causal or coincidental. Some associations have been verified based on epidemiologic studies; these include peripheral neuropathy (Chapter 428), deep vein thrombosis (Chapter 81), osteoporosis (Chapter 251), and lymphoproliferative disorders (Chapter 191). A secondary form of MGUS also occurs with immunosuppression after organ transplantation (Chapter 48) and autologous or allogeneic stem cell transplantation (Chapter 181). M proteins also occur in the sera of some patients with CLL (Chapter 190) but have no recognizable effect on the clinical course.

Approximately 5% of patients with sensorimotor peripheral neuropathy of unknown cause (Chapter 428) have an associated monoclonal gammopathy (MGUS-associated neuropathy). In half of such patients, the M protein binds to myelin-associated glycoprotein. These patients have a slowly progressive sensory neuropathy more than motor neuropathy, beginning in the distal ends of the extremities and extending proximally. The clinical and electrodiagnostic manifestations of MGUS neuropathy resemble those of a chronic inflammatory demyelinating polyneuropathy. A causal relationship is usually assumed in younger patients and those without other conditions known to cause neuropathy in whom the neuropathy is severe and progressive. Therapeutic approaches include plasmapheresis and, occasionally, chemotherapy (similar to myeloma for IgG or IgA monoclonal proteins, and rituximab or chlorambucil for IgM monoclonal proteins; see the later section on the treatment of multiple myeloma).

TABLE 193-2 CRITERIA FOR THE DIAGNOSIS OF PLASMA CELL DISORDERS

DISORDER	DISEASE DEFINITION
Monoclonal gammopathy of undetermined significance (MGUS)	All 3 criteria must be met: 1. Serum monoclonal protein (IgG, IgA, or IgM) <3 g/dL 2. Clonal bone marrow plasma cells <10% 3. Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, and bone lesions that can be attributed to the plasma cell proliferative disorder (or, in the case of IgM MGUS, no evidence of anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly)
Smoldering multiple myeloma (also referred to as *asymptomatic multiple myeloma*)	Both criteria must be met: 1. Serum monoclonal protein (IgG or IgA) ≥3 g/dL and/or clonal bone marrow plasma cells ≥10% 2. Absence of end-organ damage such as lytic bone lesions, anemia, hypercalcemia, or renal failure that can be attributed to a plasma cell proliferative disorder
Multiple myeloma	All 3 criteria must be met, except as noted: 1. Clonal bone marrow plasma cells ≥10% 2. Presence of serum and/or urinary monoclonal protein (except in patients with true nonsecretory multiple myeloma) 3. Evidence of end-organ damage that can be attributed to the underlying plasma cell proliferative disorder, specifically hypercalcemia, renal insufficiency, anemia, or bone lesions
Waldenström's macroglobulinemia	Both criteria must be met: 1. IgM monoclonal gammopathy (regardless of the size of the M protein) 2. >10% bone marrow lymphoplasmacytic infiltration (usually intertrabecular) by small lymphocytes that exhibit plasmacytoid or plasma cell differentiation and a typical immunophenotype (surface IgM^+, $CD5^{+/-}$, $CD10^-$, $CD19^+$, $CD20^+$, $CD23^-$) that satisfactorily excludes other lymphoproliferative disorders, including chronic lymphocytic leukemia and mantle cell lymphoma
Smoldering Waldenström's macroglobulinemia (also referred to as *indolent* or *asymptomatic Waldenström's macroglobulinemia*)	1. Serum IgM monoclonal protein ≥3 g/dL and/or bone marrow lymphoplasmacytic infiltration ≥10% 2. No evidence of end-organ damage such as anemia, constitutional symptoms, hyperviscosity, lymphadenopathy, or hepatosplenomegaly that can be attributed to a lymphoplasma cell proliferative disorder
Solitary plasmacytoma	All 4 criteria must be met: 1. Biopsy-proven solitary lesion of bone or soft tissue with evidence of clonal plasma cells 2. Normal bone marrow with no evidence of clonal plasma cells 3. Normal skeletal survey and MRI of spine and pelvis (except for the primary solitary lesion) 4. Absence of end-organ damage such as hypercalcemia, renal insufficiency, anemia, or bone lesions that can be attributed to a plasma cell proliferative disorder
POEMS syndrome	All 4 criteria must be met: 1. Presence of a monoclonal plasma cell disorder (almost always λ-type) 2. Peripheral neuropathy 3. Any one of the following 3 major features: sclerotic bone lesions, Castleman's disease, elevated levels of vascular endothelial growth factor (VEGF) 4. Any one of the following 6 minor features: organomegaly, edema, endocrinopathy (excluding diabetes mellitus or hypothyroidism), typical skin changes, papilledema, thrombocytosis, polycythemia The features should have a temporal relationship to one another, with no other attributable cause

Modified from Rajkumar SV, Dispenzieri A, Kyle RA. Monoclonal gammopathy of undetermined significance, Waldenstrom macroglobulinemia, AL amyloidosis, and related plasma cell disorders: diagnosis and treatment. *Mayo Clin Proc.* 2006;81:693-703; and Kyle RA, Rajkumar SV. Criteria for diagnosis, staging, risk stratification and response assessment of multiple myeloma. *Leukemia.* 2009;23:3-9.

Certain skin disorders are known to be associated with MGUS. Lichen myxedematosus (papular mucinosis, scleromyxedema) is associated with a cathodal IgG γ protein. Pyoderma gangrenosum and necrobiotic xanthogranuloma are other associated skin disorders.

PREVENTION AND TREATMENT

Rx

No treatment is necessary for MGUS. Low-risk patients (Table 193-3) can be evaluated when symptoms suggestive of myeloma or related disorders occur. In all other patients with MGUS, the M protein level in serum and urine should be measured serially, together with periodic reevaluation of clinical and other laboratory findings, to determine whether multiple myeloma or another related disorder is present. In general, electrophoresis, complete blood count, and creatinine and calcium levels should be repeated at 6 months and, if stable, yearly thereafter.

PROGNOSIS

Differentiating a patient with MGUS in whom the disorder will remain stable for life from one in whom multiple myeloma, macroglobulinemia, or a related disorder will eventually develop is difficult when the M protein is first recognized. The size and type of the M protein at diagnosis of MGUS and an abnormal serum free light chain ratio are prognostic factors for progression (see Table 193-3).

BICLONAL GAMMOPATHIES

Biclonal gammopathies occur in at least 5% of patients with clonal plasma cell disorders. A biclonal gammopathy of undetermined significance (analogous to MGUS) accounts for about two thirds of such patients. The remainder have multiple myeloma, macroglobulinemia, or other lymphoproliferative diseases. Rarely, triclonal gammopathies may occur.

LIGHT CHAIN MGUS AND IDIOPATHIC BENCE JONES PROTEINURIA

The diagnosis of typical MGUS requires expression of an intact heavy chain type. In some patients a premalignant clonal plasma cell disorder characterized by the presence of monoclonal immunoglobulin light chains without expression of heavy chains can occur (light chain MGUS). Some patients with light chain MGUS may secrete adequate amounts of monoclonal light chains in the urine, resulting in idiopathic Bence Jones proteinuria. Idiopathic Bence Jones proteinuria is analogous to MGUS, and the urinary excretion of monoclonal light chains can persist for many years without evidence of end-organ damage suggestive of multiple myeloma or related disorders. No therapy is indicated unless progression to malignancy occurs.

MULTIPLE MYELOMA

DEFINITION

Multiple myeloma is a malignancy of plasma cells characterized by bone marrow infiltration and extensive skeletal destruction resulting in anemia, bone pain, and fractures. Multiple myeloma (commonly referred to as *myeloma*) is defined by the presence of 10% or more clonal plasma cells on bone marrow examination, M protein in serum or urine (except in the case of nonsecretory myeloma), and evidence of hypercalcemia, renal insufficiency, anemia, or bone lesions thought to be related to the plasma cell proliferative disorder. Patients with multiple myeloma must be differentiated from those with MGUS and smoldering multiple myeloma (see Table 193-2).

TABLE 193-3 RISK OF PROGRESSION OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE TO MYELOMA OR RELATED DISORDERS

RISK GROUP	RELATIVE RISK	CUMULATIVE ABSOLUTE RISK OF PROGRESSION AT 20 YEARS (%)*	CUMULATIVE ABSOLUTE RISK OF PROGRESSION AT 20 YEARS ACCOUNTING FOR DEATH AS A COMPETING RISK (%)†
Low risk: serum M protein <1.5 g/dL, IgG subtype, normal free light chain ratio (0.26-1.65)	1	5	2
Low-intermediate risk: any 1 factor abnormal	5.4	21	10
High-intermediate risk: any 2 factors abnormal	10.1	37	18
High risk: all 3 factors abnormal	20.8	58	27

*Estimates in this column represent the risk of progression assuming that patients do not die of other causes during this period.
†Estimates in this column represent the risk of progression calculated by using a model that accounts for the fact that patients can die of unrelated causes during this time.
Ig = immunoglobulin.

EPIDEMIOLOGY

Multiple myeloma accounts for 1% of all malignant disease and slightly more than 10% of hematologic malignancies in the United States. The annual incidence of multiple myeloma is 4 per 100,000. Its incidence in blacks is almost twice that in whites. Multiple myeloma is slightly more common in men than in women. The median age of patients at the time of diagnosis is about 65 years; only 2% of patients are younger than 40.

PATHOBIOLOGY

The cause of multiple myeloma is unclear. Exposure to radiation, benzene, and other organic solvents, herbicides, and insecticides may play a role. Multiple myeloma has been reported in familial clusters of two or more first-degree relatives and in identical twins.

Almost all cases of myeloma evolve from a premalignant MGUS phase, although the MGUS is clinically recognized before the diagnosis of myeloma in only a small minority of patients. The progression of MGUS to myeloma suggests a simple, random, two-hit genetic model of malignancy in which the risk of progression is fixed (approximately 1% per year) regardless of the duration of MGUS. Unfortunately, the precise mechanisms of progression are unknown, although several potentially pathogenetic abnormalities have been described in the clonal plasma cells. These include *RAS* and *p53* mutations, p16 methylation, *MYC* abnormalities, and secondary translocations. Changes in the bone marrow microenvironment may also play a role in the pathogenesis, including induction of angiogenesis and abnormal paracrine loops involving cytokines such as interleukin-6 (IL-6), which serves as a major growth factor for plasma cells.

The lytic bone lesions, osteopenia, hypercalcemia, and pathologic fractures in patients with myeloma are a result of abnormal osteoclast activity induced by the neoplastic plasma cells, as well as inhibition of osteoblast differentiation. Osteoclasts are activated by stimulation of the transmembrane receptor RANK (receptor activator of nuclear factor κB), which belongs to the tumor necrosis factor (TNF) receptor superfamily. The ligand for this receptor (RANKL) also has a decoy receptor, osteoprotegerin (OPG). In myeloma, there is an increase in RANKL expression by osteoblasts (and possibly plasma cells), accompanied by a reduction in the level of OPG. The resultant increase in the RANKL/OPG ratio causes osteoclast activation and increased bone resorption and turnover (Chapter 250).

Cytogenetic Abnormalities

As discussed earlier (see Pathobiology of MGUS), primary translocations involving the immunoglobulin heavy chain loci (chromosome 14q32) are seen in up to 50% of patients with multiple myeloma (IgH-translocated or nonhyperdiploid myeloma). The remaining 50% of patients do not have IgH translocations but have evidence of hyperdiploidy (hyperdiploid myeloma). In a small percentage of patients the disease cannot be classified into either of these two types (unclassified). Besides these cytogenetic abnormalities, other secondary cytogenetic abnormalities occur as late events during the course of symptomatic myeloma; these include activating mutations of N- and K-*RAS*, inactivating mutations of *p53*, and dysregulation of c-*MYC*. Complete or partial deletions of chromosome 13 are well described in myeloma and have prognostic value, but they also occur at the MGUS stage.

TABLE 193-4 MAJOR CLINICAL MANIFESTATIONS OF MULTIPLE MYELOMA

CLINICAL FINDINGS	APPROXIMATE PERCENTAGE OF PATIENTS WITH ABNORMALITY AT DIAGNOSIS
Skeletal involvement: pain, reduced height, lytic bone lesions, pathologic fractures	80
Anemia (hemoglobin ≤12 g/dL): caused mainly by decreased erythropoiesis; produces weakness and fatigue	75
Renal insufficiency (serum creatinine ≥2 mg/dL): caused mainly by "myeloma kidney" from light chains or hypercalcemia, rarely from amyloidosis	20
Hypercalcemia (≥11 mg/dL)	15
Light chain amyloidosis	10
Evidence of monoclonal protein by immunofixation and serum free light chain assay	97
Evidence of clonal plasma cells ≥10% in bone marrow	96

CLINICAL MANIFESTATIONS

History

Bone pain, particularly in the back or chest and less often in the extremities, is present at the time of diagnosis in more than two thirds of patients (Table 193-4). The patient's height may be reduced by several inches because of vertebral collapse. Weakness and fatigue are common and are often associated with anemia. Fever is rare and, when present, is generally from an infection; in some patients the infection itself is the initial feature. Other symptoms may result from renal insufficiency, hypercalcemia, nephrotic syndrome, radiculopathy, or amyloidosis (Chapter 194).

Physical Examination

Pallor is the most frequent physical finding. The liver is palpable in about 5% of patients, and the spleen in 1%. Tenderness may be noted at sites of bone involvement. Radiculopathy may be caused by spinal compression fractures. Occasionally, extramedullary plasmacytomas are palpable.

DIAGNOSIS

Laboratory Findings

A normocytic, normochromic anemia (Chapter 161) is present initially in approximately 75% of patients, but it eventually occurs in nearly every patient with multiple myeloma. Serum protein electrophoresis shows an M protein in 80% of patients. With serum immunofixation, an M protein can be detected in 93% of patients. When these serum studies are combined with urine electrophoresis plus immunofixation, an M protein can be detected in 97% of patients with myeloma. The serum free light chain assay is more convenient and can be used in place of urine studies in the diagnostic evaluation. The

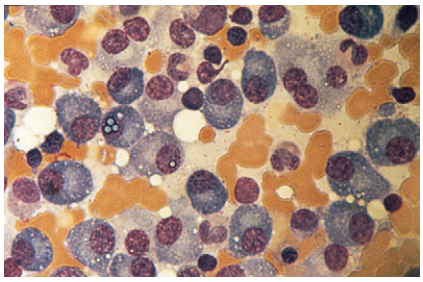

FIGURE 193-4. Multiple myeloma. A bone marrow aspirate shows a predominance of plasma cells.

type of M protein is IgG in 52%, IgA in 21%, light chain only (Bence Jones proteinemia) in 16%, IgD in 2%, and biclonal gammopathy in 2%; the light chain type is κ in 65% of cases and λ in 35%. In 3% of patients, no secreted M protein can be identified; these patients are considered to have nonsecretory myeloma.

In the bone marrow, plasma cells account for greater than 10% of all nucleated cells in 96% of patients (Fig. 193-4). In 4% of patients, bone marrow examination shows less than 10% plasma cells, even though the patient otherwise meets the criteria for myeloma; because bone marrow involvement in myeloma may be focal rather than diffuse, repeated bone marrow examinations or biopsy of a discrete bone or extramedullary lesion may be required. In most cases, the plasma cells in myeloma are cytoplasmic Ig^+, $CD38^+$, and $CD138^+$; only a minority express CD10 and human leukocyte antigen (HLA)-DR, and 20% express CD20. The clonality of the plasma cells is established using the κ/λ ratio, which is abnormal in myeloma (either >4 : 1, indicating a clonal κ population, or <1 : 2, indicating a clonal λ population). This is helpful for differentiating monoclonal plasma cell proliferation in multiple myeloma from reactive plasmacytosis related to connective tissue disease, metastatic carcinoma, liver disease, and infection.

Radiologic Findings

Conventional radiographs reveal abnormalities consisting of punched-out lytic lesions (Fig. 193-5), osteoporosis, or fractures in nearly 80% of patients. The vertebrae, skull, thoracic cage, pelvis, and proximal ends of the humerus and femur are the most frequent sites of involvement. Technetium-99m bone scanning is inferior to conventional radiography and should not be used. Positron emission tomography (PET; Fig. 193-6) and magnetic resonance imaging (MRI) are helpful in patients who have skeletal pain but no abnormality on radiographs and for monitoring the response to therapy.

Organ Involvement

Renal

At diagnosis, the serum creatinine value is increased initially in almost half of patients and is greater than 2 mg/dL in 20%.

The two major causes of renal insufficiency are light chain cast nephropathy *(myeloma kidney)* and hypercalcemia. Light chain cast nephropathy is characterized by the presence of large, waxy, laminated casts in the distal and collecting tubules. The casts are composed mainly of precipitated monoclonal light chains. The extent of cast formation correlates directly with the amount of free urinary light chain and with the severity of renal insufficiency. Dehydration may precipitate acute renal failure.

Hypercalcemia (Chapters 186 and 253), which is present in 15 to 20% of patients initially, is a major and treatable cause of renal insufficiency. It results from destruction of bone. Hyperuricemia may contribute to renal failure. Besides light chain cast nephropathy and hypercalcemia, there are other mechanisms by which renal dysfunction can occur in myeloma. For example, light chain amyloidosis occurs in nearly 10% of patients and may produce nephrotic syndrome, renal insufficiency, or both. Acquired Fanconi's syndrome (Chapter 124), characterized by proximal tubular dysfunction, results in glycosuria, phosphaturia, and aminoaciduria. Deposition of monoclonal light chains in the renal glomerulus (light chain deposition disease) may also produce renal insufficiency and nephrotic syndrome.

Neurologic

Radiculopathy (Chapter 407), the single most frequent neurologic complication, usually occurs in the thoracic or lumbosacral area and results from compression of the nerve by the vertebral lesion or by the collapsed bone itself. Compression of the spinal cord occurs in up to 10% of patients. Peripheral neuropathy (Chapter 428) is uncommon in multiple myeloma and, when present, is generally caused by amyloidosis. Rarely, myeloma cells diffusely infiltrate the meninges. Intracranial plasmacytomas almost always represent extensions of myelomatous lesions of the skull.

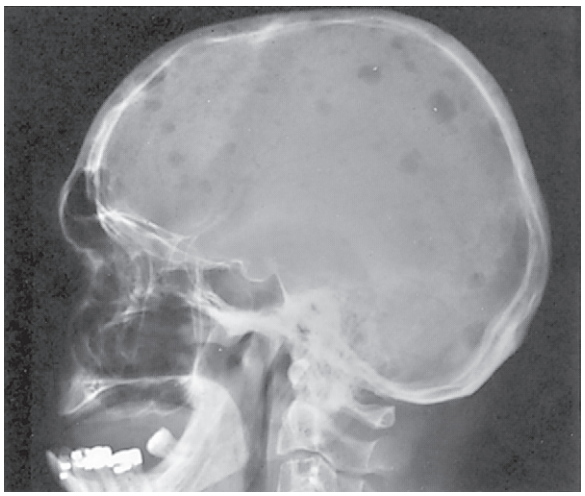

FIGURE 193-5. Skull radiograph showing multiple lytic lesions.

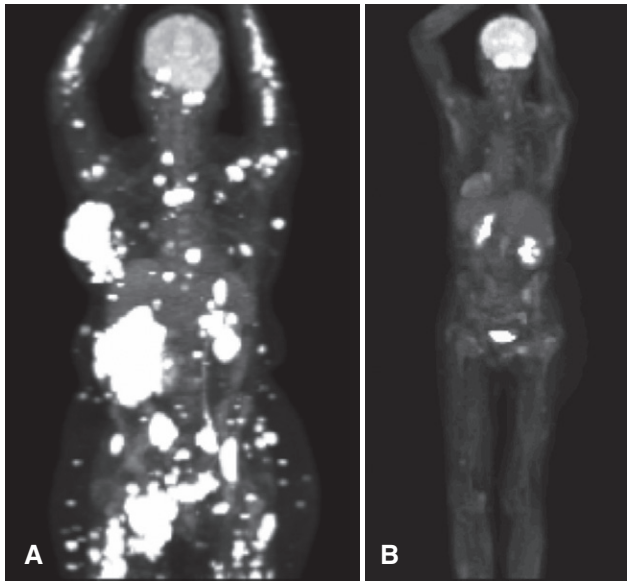

FIGURE 193-6. Positron emission tomography in multiple myeloma. A, Extensive bony and extramedullary disease. **B,** Significant improvement after systemic chemotherapy for myeloma.

Other Systemic Involvement

Hepatomegaly from plasma cell infiltration is uncommon. Plasmacytomas of the ribs are common and arise either as expanding bone lesions or as soft tissue masses. The incidence of infections is increased in patients with multiple myeloma. Historically, *Streptococcus pneumoniae* and *Staphylococcus aureus* have been the most frequent pathogens, but gram-negative organisms now account for more than half of all infections. The propensity for infection results from impairment of the antibody response, deficiency of normal immunoglobulins, and neutropenia. Bleeding from coating of the platelets by M protein may occur. Myeloma patients have an increased risk of deep vein thrombosis.

PREVENTION AND TREATMENT

Rx

Patients with MGUS or smoldering multiple myeloma should not be treated until evidence of multiple myeloma develops. The approach to treatment of multiple myeloma is illustrated in Figure 193-7.

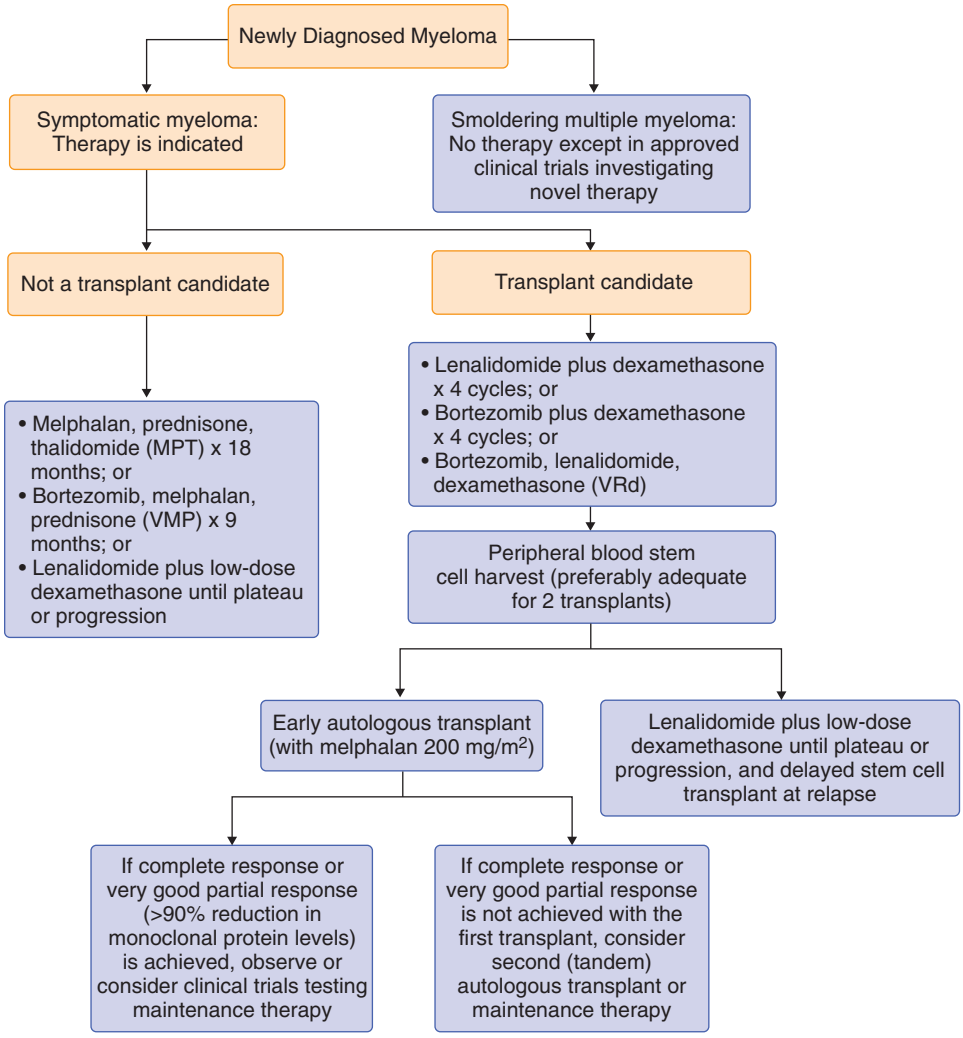

FIGURE 193-7. Approach to newly diagnosed multiple myeloma.

Initial Therapy of Patients Who Are Candidates for Stem Cell Transplantation

In the approximately 50% of patients with newly diagnosed multiple myeloma who are considered candidates for autologous stem cell transplantation based on good performance status, no or limited comorbid conditions, and younger physiologic age (<65 to 70 years), autologous peripheral blood stem cell transplantation (Chapter 181) with high-dose chemotherapy improves overall survival in comparison to conventional chemotherapy.■ Currently, it is not possible to eradicate myeloma cells completely with conditioning regimens, and reinfused autologous stem cells are usually contaminated by myeloma cells or their precursors. As a result, autologous transplantation is not curative, but it prolongs event-free and overall survival.

Initial therapy typically consists of low-dose dexamethasone (40 mg once a week) plus lenalidomide (25 mg/day on days 1 to 21, every 28 days) and/or bortezomib (1.3 mg/m^2 on days 1, 4, 8, and 11, every 21 days) for approximately 4 months to reduce the number of tumor cells in the bone marrow and peripheral blood. As induction before stem cell transplantation in previously untreated myeloma, bortezomib plus dexamethasone has been found to be superior to vincristine plus doxorubicin plus dexamethasone (VAD).■ Lenalidomide plus high-dose dexamethasone, compared with high-dose dexamethasone only, produced superior 1-year progression-free survival, overall and partial response rates, but not 1-year overall survival.■ In a randomized trial, lenalidomide plus low-dose dexamethasone (40 mg once a week) was associated with superior overall survival compared with lenalidomide and high-dose dexamethasone (40 mg on days 1 to 4, 9 to 12, and 17 to 20).■ As a result, high-dose pulse dexamethasone is no longer recommended in the context of initial therapy. Reducing the dose of bortezomib to once a week instead of days 1, 4, 8, and 11 decreases the risk of serious neuropathy and should be considered after the first 1 to 2 months if a bortezomib-based regimen is used.■ Toxicities of lenalidomide plus dexamethasone include deep vein thrombosis, and all patients must be treated with prophylactic aspirin or an anticoagulant. After induction therapy, peripheral blood stem cells adequate for two stem cell transplants are collected with the use of granulocyte colony-stimulating factor with or without cyclophosphamide to aid in mobilization. Autologous stem cell transplantation (Chapter 181) is performed with melphalan 200 mg/m^2 as the conditioning regimen, followed by infusion of the peripheral blood stem cells. Patients who do not achieve a complete or very good partial response with the first autologous transplant are considered for a second autologous transplant.■

An alternative approach in patients with newly diagnosed disease is to cryopreserve stem cells for future use after initial therapy. Patients then continue initial therapy, such as lenalidomide plus low-dose dexamethasone, until progression or achievement of a plateau phase, reserving stem cell transplantation for the first relapse. Data from randomized trials comparing early versus delayed transplantation indicate no significant difference in survival between the two strategies. The choice is based on the patient's preferences and other clinical conditions, but early transplantation is often preferred because its mortality is low (<1%) and it avoids the inconvenience, cost, and potential side effects of prolonged chemotherapy.

Role of Allogeneic Bone Marrow Transplantation

Ninety to 95% of patients with multiple myeloma cannot undergo allogeneic bone marrow transplantation because of their age, lack of an HLA-matched sibling donor, or inadequate renal, pulmonary, or cardiac function (Chapter 181). Although a complete response occurs in 40% of patients, most have a relapse; in long-term follow-up there is no apparent survival plateau. The mortality rate from the procedure is approximately 25%, and conventional allogeneic bone marrow transplantation is rarely used in myeloma. An alternative is autologous stem cell transplantation followed by nonmyeloablative ("mini") allogeneic transplantation, but treatment-related mortality is still approximately 20%. Nonmyeloablative allogeneic transplantation for myeloma is best performed only in the context of clinical trials.

Initial Therapy of Patients Who Are Not Candidates for Transplantation

Approximately 50% of newly diagnosed patients are not considered candidates for stem cell transplantation. For decades, the oral administration of melphalan (8 to 10 mg/day for 7 days) and prednisone (20 mg three times a day for the same 7 days) repeated every 6 weeks has been the standard of care. When using melphalan, the leukocyte and platelet levels should be

measured every 3 weeks, and the dosage of melphalan must be adjusted until midcycle cytopenia occurs. The addition of thalidomide to the standard regimen of melphalan plus prednisone improves event-free and overall survival compared with melphalan plus prednisone alone in patients with newly diagnosed myeloma who are not candidates for transplantation.[7-9] Similarly, in a randomized trial, the addition of bortezomib to melphalan plus prednisone prolonged event-free and overall survival compared with melphalan plus prednisone alone by 39% among patients not eligible for high-dose chemotherapy and stem cell transplantation.[10] Based on these data, melphalan and prednisone plus either thalidomide (MPT) or bortezomib (VMP) are two recommended treatments for this patient population. Lenalidomide plus low-dose dexamethasone is a third option based on its high efficacy and low toxicity in elderly patients.

MPT is typically administered for 18 months, whereas VMP is given for 9 months. Lenalidomide plus low-dose dexamethasone can be given for 1 year or until progression, based on tolerability. Maintenance therapy is not generally recommended following MPT or VMP. If relapse occurs during the plateau state 6 to 12 or more months after cessation of therapy, the initial chemotherapeutic regimen can be reinstituted. Most patients respond, but the duration and quality of the response are usually inferior to those of the initial response.

Treatment of Relapsed Refractory Myeloma

Almost all patients with multiple myeloma eventually relapse. Single-agent dexamethasone, alkylating agents, thalidomide, lenalidomide, and bortezomib, administered alone or in combination, are all options for the treatment of relapsed refractory myeloma. Methylprednisolone 2 g three times a week intravenously for a minimum of 4 weeks, then reduced to once or twice a week if there is a response, is helpful for patients with pancytopenia and may be associated with fewer side effects than dexamethasone.

Thalidomide (50 to 200 mg/day orally) produces an objective response, with a median duration of about 1 year, in about a third of patients with refractory myeloma. Side effects are sedation, constipation, peripheral neuropathy, rash, bradycardia, and thrombotic events. The addition of dexamethasone to thalidomide increases the response rate to approximately 50%, and combinations of thalidomide, dexamethasone, and alkylating agents produce response rates exceeding 70% in patients with relapsed refractory disease.

The thalidomide analogue lenalidomide is better tolerated and produces objective benefits in approximately 40% of patients with relapsed refractory myeloma as a single agent; in combination with dexamethasone, 60% of patients benefit. Lenalidomide plus dexamethasone significantly prolongs time to progression and overall survival compared with dexamethasone alone.[11,12] The starting dose of lenalidomide is 25 mg orally on days 1 to 21, every 28 days. Lenalidomide has significantly fewer nonhematologic toxicities than thalidomide does; myelosuppression is the most common adverse event.

Bortezomib, an inhibitor of the ubiquitin-proteasome pathway, acts through multiple mechanisms to arrest tumor growth, tumor spread, and angiogenesis. It produces objective responses in about a third of patients with refractory myeloma and is superior to single-agent dexamethasone.[13] Like thalidomide and lenalidomide, bortezomib can also be combined with dexamethasone and other active agents to increase response rates.[14] The starting dose is 1.3 mg/m^2 administered intravenously on days 1, 4, 8, and 11, every 21 days. The most common adverse events are gastrointestinal side effects, fatigue, and neuropathy.

Other novel agents that have shown promise but are not commercially available at this time include pomalidomide (a new analogue of thalidomide) and carfilzomib (a new proteasome inhibitor). Several other novel agents are in clinical trials.

Role of Radiation Therapy

Palliative radiation in a dose of 20 to 30 Gy should be limited to patients who have multiple myeloma with disabling pain and a well-defined focal process that has not responded to chemotherapy and to patients with spinal cord compression from a plasmacytoma. Analgesics in combination with chemotherapy can usually control the pain (Chapter 29).

Management of Complications

Hypercalcemia

Hypercalcemia, present in 15 to 20% of patients at diagnosis, should be suspected in those with anorexia, nausea, vomiting, polyuria, polydipsia, constipation, weakness, confusion, or stupor. If hypercalcemia is untreated, renal insufficiency may develop. Hydration, preferably with isotonic saline plus prednisone (25 mg four times/day), usually relieves the hypercalcemia. Bisphosphonates such as zoledronic acid or pamidronate are recommended and will correct hypercalcemia in almost all patients (Chapter 251).

Renal Insufficiency

The most common cause of acute renal failure is light chain cast nephropathy in patients who have excess excretion of monoclonal protein in urine (myeloma kidney). Aggressive treatment of acute renal failure due to light chain cast nephropathy is critical for long-term overall survival. If the patient is not oliguric, intravenous fluids and furosemide are needed to maintain a high urine flow rate (100 mL/hour). If the underlying cause is thought to be light chain cast nephropathy based on clinical findings (e.g., serum free light chains >150 mg/dL) or renal biopsy, plasmapheresis is recommended daily for 5 days to reduce the levels of circulating light chains. Hemodialysis is necessary for symptomatic azotemia. The mainstay of therapy is aggressive treatment of myeloma with a regimen such as bortezomib, thalidomide, and dexamethasone (VTD). Allopurinol is necessary if hyperuricemia is present.

Infection

Prompt, appropriate therapy for bacterial infections is necessary. Prophylactic antibiotics such as trimethoprim-sulfamethoxazole should be considered in patients taking high-dose corticosteroids, but trimethoprim-sulfamethoxazole should be avoided in patients receiving thalidomide or lenalidomide to minimize the risk of serious skin reactions. Intravenously administered gamma globulin is reserved for patients with hypogammaglobulinemia and recurrent severe infections. Pneumococcal and influenza immunizations (Chapter 17) should be given to all patients.

Skeletal Lesions

Patients should be encouraged to be as active as possible but to avoid trauma. Pamidronate (90 mg infused intravenously over a 4-hour period every 4 weeks) or zoledronic acid (4 mg intravenously over at least 15 minutes every 4 weeks) reduces the incidence of bone pain, pathologic fractures, and spinal cord compression; such prophylaxis is now routinely recommended for all patients with myeloma bone disease and may improve overall survival.[15] After 1 to 2 years the dosing can be reduced to once every 3 months in patients who are stable, to minimize the risk of osteonecrosis of the jaw, which is a complication of long-term bisphosphonate therapy.

Spinal cord compression from an extramedullary plasmacytoma (Chapter 407) should be suspected in patients who have severe back pain, weakness or paresthesias of the lower extremities, or bladder or bowel dysfunction. Initial treatment is with dexamethasone-based therapy and/or radiation therapy. If the neurologic deficit increases, surgical decompression is necessary.

Miscellaneous Complications

Symptomatic hyperviscosity (see later) is less common than in Waldenström's macroglobulinemia. Anemia that persists despite adequate treatment of underlying myeloma often responds to erythropoietin.

PROGNOSIS

Multiple myeloma is considered incurable at present, but survival has improved significantly in recent years following the arrival of new agents such as lenalidomide and bortezomib. The median survival is approximately 4 years, but it varies widely according to clinical stage and risk stratification factors (Table 193-5). In some patients an acute or aggressive terminal phase is characterized by rapid tumor growth, pancytopenia, soft tissue subcutaneous masses, decreased M protein levels, and fever; survival in this subset is generally only a few months.

FUTURE DIRECTIONS

Future efforts must be directed toward identifying new active agents and developing effective combinations of active drugs. Studies are under way to improve the conditioning regimen used in autologous stem cell transplantation and to better integrate novel therapies with stem cell transplantation.

TABLE 193-5 STAGING AND PROGNOSTIC FACTORS IN MULTIPLE MYELOMA

STAGE/RISK FACTOR	MEDIAN SURVIVAL (MO)
INTERNATIONAL STAGING SYSTEM	
Stage I (serum β_2-microglobulin <3.5 mg/L and serum albumin ≥3.5 g/dL)	62
Stage II (neither stage I nor stage III)	44
Stage III (serum β_2-microglobulin ≥5.5 mg/L)	29
RISK STRATIFICATION	
High-risk myeloma (any one of the following): Fluorescence in situ hybridization: t14;16, t14;20, deletion 17p	24-36

VARIANT FORMS OF MULTIPLE MYELOMA

Smoldering Multiple Myeloma

Smoldering (asymptomatic) multiple myeloma is defined by the presence of an M protein level greater than 3 g/dL in serum or 10% or more plasma cells in bone marrow in the absence of anemia, renal insufficiency, hypercalcemia, or skeletal lesions. Biologically, patients with smoldering multiple myeloma are similar to those with MGUS but carry a much higher risk for progression to myeloma or related malignancy: 10% per year for the first 5 years, 5% per year for the next 5 years, and 1 to 2% per year thereafter. As a result, patients must be observed more closely (every 3 to 4 months), but they should not be treated unless progression to symptomatic multiple myeloma occurs.

Plasma Cell Leukemia

Patients with plasma cell leukemia have more than 20% plasma cells in the peripheral blood and an absolute plasma cell count of 2000/μL or greater. Plasma cell leukemia is classified as primary when it is diagnosed in the leukemic phase (60%) or as secondary when there is leukemic transformation of a previously recognized multiple myeloma (40%). Patients with primary plasma cell leukemia are younger and have a greater incidence of hepatosplenomegaly and lymphadenopathy, a higher platelet count, fewer bone lesions, a smaller serum M protein component, and longer survival (median, 6.8 vs. 1.3 months) than do patients with secondary plasma cell leukemia. Treatment of plasma cell leukemia is unsatisfactory. An aggressive initial treatment regimen that contains bortezomib, dexamethasone, and either thalidomide or lenalidomide for two or three cycles, followed by autologous stem cell transplantation and subsequent maintenance therapy with lenalidomide, is a reasonable strategy if the patient's clinical condition permits such an approach. Secondary plasma cell leukemia rarely responds to chemotherapy because the patients have already received chemotherapy and are resistant.

Nonsecretory Myeloma

Patients with nonsecretory myeloma have no M protein in either serum or urine and account for only 3% of cases of myeloma. To make the diagnosis, the clonal nature of bone marrow plasma cells should be established by immunoperoxidase, immunofluorescence, or flow cytometric methods. Treatment and survival are similar to those in patients with typical myeloma. The serum free light chain assay is abnormal in more than 60% of patients and can be used to monitor the response to therapy.

Osteosclerotic Myeloma (POEMS Syndrome)

This syndrome is characterized by polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes (POEMS). The diagnosis of POEMS syndrome requires the presence of a monoclonal plasma cell disorder, peripheral neuropathy, plus at least one of the following seven features: osteosclerotic bone lesions, Castleman's disease, organomegaly, endocrinopathy (excluding diabetes mellitus or hypothyroidism), edema, typical skin changes, and papilledema. However, not every patient meeting these criteria has POEMS syndrome; the features should have a temporal relationship to one another, with no other attributable cause. The absence of osteosclerotic lesions makes the diagnosis suspect. Elevations in plasma or serum levels of vascular endothelial growth factor and thrombocytosis are common features of the syndrome and are helpful when the diagnosis is difficult. The major clinical features are a chronic inflammatory-demyelinating polyneuropathy with predominantly motor disability and sclerotic skeletal lesions. The bone marrow usually contains less than 5% plasma cells, and hypercalcemia and renal insufficiency rarely occur. Almost all patients have a λ-type M protein. The diagnosis is confirmed by identification of monoclonal plasma cells obtained at biopsy of an osteosclerotic lesion.

If the lesions are in a limited area, radiation therapy substantially improves the neuropathy in more than 50% of patients. If the patient has widespread osteosclerotic lesions, treatment is with autologous stem cell transplantation or other systemic therapy similar to that used for myeloma.

Solitary Plasmacytoma (Solitary Myeloma) of Bone

The diagnosis of solitary bone plasmacytoma is based on histologic evidence of a solitary tumor consisting of monoclonal plasma cells identical to those in multiple myeloma. In addition, complete skeletal radiographs and MRI of the spine and pelvis must show no other lesions of myeloma, and the bone marrow aspirate must contain no evidence of clonal plasma cells. An M protein may be present in serum or urine at diagnosis, but persistence of the M protein after radiation therapy is associated with an increased risk for progression to multiple myeloma. Treatment consists of radiation in the range of 40 to 50 Gy. Almost 50% of patients who have a solitary plasmacytoma are alive at 10 years, and disease-free survival rates at 10 years range from 15 to 25%. Progression to myeloma, when it occurs, usually takes place within 3 years, but patients must be monitored indefinitely. There is no convincing evidence that adjuvant chemotherapy decreases the rate of conversion to multiple myeloma.

Extramedullary Plasmacytoma

Extramedullary plasmacytomas outside the bone marrow are most commonly found in the upper respiratory tract (80% of cases), especially in the nasal cavity and sinuses, nasopharynx, and larynx. Extramedullary plasmacytomas may also occur in the gastrointestinal tract, central nervous system, urinary bladder, thyroid, breast, testes, parotid gland, or lymph nodes. Extramedullary plasmacytomas may be solitary, or they may occur in the context of existing myeloma. The diagnosis of solitary extramedullary plasmacytoma is based on detection of a plasma cell tumor in an extramedullary site, absence of clonal plasma cells on bone marrow examination, and absence of other bony or extramedullary lesions on radiographic studies. Treatment of solitary extramedullary plasmacytoma consists of either complete surgical resection or tumoricidal irradiation. The plasmacytoma may recur locally, metastasize to regional nodes, or, rarely, develop into multiple myeloma.

WALDENSTRÖM'S MACROGLOBULINEMIA (PRIMARY MACROGLOBULINEMIA)

DEFINITION

Waldenström's macroglobulinemia is the result of the uncontrolled proliferation of lymphocytes and plasma cells in which an IgM M protein is produced. The cause is unknown; familial clusters have been reported. The median age of patients at the time of diagnosis is about 65 years, and approximately 60% are male. The diagnostic criteria are IgM monoclonal gammopathy (regardless of the size of the M protein), 10% or greater bone marrow infiltration (usually intertrabecular) by clonal lymphocytes that exhibit plasmacytoid or plasma cell differentiation, and a typical immunophenotype (e.g., surface IgM^+, $CD5^{+/-}$, $CD10^-$, $CD19^+$, $CD20^+$, $CD23^-$) that would satisfactorily exclude other lymphoproliferative disorders, including CLL (Chapter 190) and mantle cell lymphoma (Chapter 191).

CLINICAL MANIFESTATIONS

Weakness, fatigue, and bleeding (especially oozing from the oronasal area) are common initial symptoms. Blurred or impaired vision, dyspnea, weight loss, neurologic symptoms, recurrent infections, and heart failure may occur. In contrast to multiple myeloma, lytic bone lesions, renal insufficiency, and amyloidosis are rare. Physical findings include pallor, hepatosplenomegaly, and lymphadenopathy. Retinal hemorrhages, exudates, and venous congestion with vascular segmentation ("sausage" formation) may occur. Sensorimotor peripheral neuropathy is common. Pulmonary involvement is manifested by diffuse pulmonary infiltrates and isolated masses.

Laboratory Evaluation

Almost all patients have moderate to severe normocytic, normochromic anemia. The serum electrophoretic pattern is characterized by a tall, narrow peak or dense band that is of the IgM type on immunofixation. Quantitative IgM levels are high. A monoclonal light chain is detected in the urine of 80% of patients, but the amount of urinary protein is generally modest.

The bone marrow aspirate is often hypocellular, but the biopsy is hypercellular and extensively infiltrated with lymphoid cells and plasma cells. The number of mast cells is frequently increased. Rouleau formation is prominent (Chapter 160), and the sedimentation rate is markedly increased. About 10% of cases may have an associated type I cryoglobulinemia (see later).

DIAGNOSIS

Diagnosis requires the combination of typical symptoms and physical findings, the presence of an IgM M protein, and 10% or greater lymphoplasmacytic infiltration of the bone marrow. The lymphoplasmacytic cells express CD19, CD20, and CD22, whereas expression of CD5 and CD10 occurs in a minority. Asymptomatic patients with 10% or greater lymphoplasmacytic infiltration of the bone marrow are considered to have smoldering Waldenström's macroglobulinemia. Multiple myeloma, CLL, and MGUS of the IgM type must be excluded.

Patients meeting the diagnostic criteria for Waldenström's macroglobulinemia but who have less than 3 g/dL IgM protein at diagnosis have sometimes been classified as having "lymphoplasmacytic lymphoma with an IgM M protein" (Chapter 191). However, except for hyperviscosity, the clinical picture, therapy, and prognosis for these patients do not differ from those of patients with an IgM level of 3 g/dL or greater; thus, these patients are also considered to have Waldenström's macroglobulinemia by the current definition.

PREVENTION AND TREATMENT Rx

Patients should not be treated unless they have anemia; constitutional symptoms such as weakness, fatigue, night sweats, or weight loss; hyperviscosity; or significant hepatosplenomegaly or lymphadenopathy. Rituximab, a chimeric anti-CD20 monoclonal antibody (Chapter 35), produces a response in at least 50% of untreated patients. Alkylating agents such as cyclophosphamide and chlorambucil with or without corticosteroids are also effective. Another choice for therapy is a purine nucleoside analogue, either fludarabine or 2-chlorodeoxyadenosine. In general, for minimally symptomatic patients, rituximab as a single agent is an excellent choice for initial therapy. For patients with more advanced symptoms, including severe anemia or hyperviscosity, combination approaches are preferred. The combination of rituximab, cyclophosphamide, and dexamethasone is highly active and also preserves the ability to mobilize stem cells for transplantation, if necessary. An alternative is cladribine with or without rituximab.

For relapse, the agents used as initial therapy can be given alone or in combination. Autologous stem cell transplantation can be considered for eligible patients with relapsed disease.

Spuriously low hemoglobin and hematocrit levels may occur because of the increased plasma volume from the large amount of intravascular M protein. Consequently, transfusions should not be given solely on the basis of the hemoglobin or hematocrit value. Symptomatic hyperviscosity should be treated by plasmapheresis. The median survival of patients with macroglobulinemia is 5 years.

HYPERVISCOSITY SYNDROME

Hyperviscosity syndrome occurs in patients with Waldenström's macroglobulinemia who have high levels of serum IgM M protein (>5 g/dL) and occasionally in those with myeloma, especially of the IgA type. Hyperviscosity is disproportionately more common relative to the same serum concentration of IgM and IgA M proteins compared with IgG M proteins, owing to the inherent tendency of IgM and IgA molecules to polymerize. Typically, IgM forms pentamers, whereas IgA forms dimers or sometimes trimers, resulting in high-molecular-weight complexes. Chronic nasal bleeding and oozing from the gums are the most frequent symptoms of hyperviscosity, but postsurgical or gastrointestinal bleeding may also occur. Retinal hemorrhages are common, and venous congestion with sausage-like segmentation and papilledema may be seen (Fig. 193-8). The patient occasionally complains of blurring or loss of vision. Dizziness, headache, vertigo, nystagmus, decreased hearing, ataxia, paresthesias, diplopia, somnolence, and coma may occur. Hyperviscosity can precipitate or exacerbate heart failure. Most patients have symptoms when the relative viscosity is greater than 4 cP, but the relationship between serum viscosity and clinical manifestations is not precise. Patients with symptomatic hyperviscosity should be treated with plasmapheresis and with chemotherapy to treat the underlying malignancy. Plasma exchange of 3 to 4 L with albumin should be performed daily until the patient is asymptomatic. Plasma exchange is rapidly effective (two to three exchanges) in the case of IgM M proteins, which are primarily intravascular; with IgG M proteins, multiple attempts may be needed because a significant amount of IgG can exist in the extravascular space.

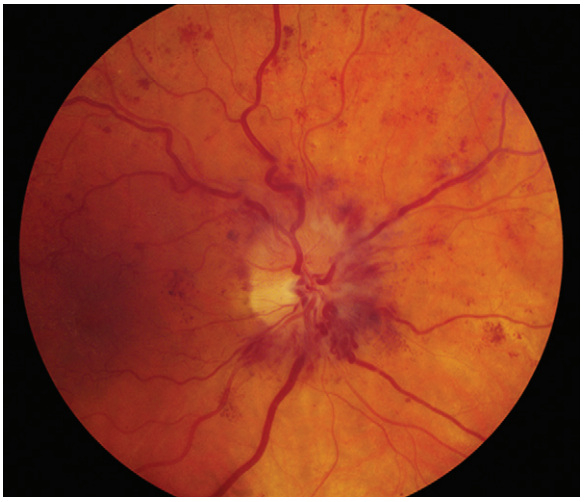

FIGURE 193-8. Hyperviscosity syndrome. Right eye retinal image in a patient with Waldenström's macroglobulinemia and hyperviscosity syndrome showing sausaging (focal venular dilations), intraretinal hemorrhages, microaneurysms, and peripapillary cotton-wool spots and disc swelling (papilledema).

HEAVY CHAIN DISEASES

The HCDs are characterized by the presence of an M protein consisting of a portion of the immunoglobulin heavy chain in serum, urine, or both. These heavy chains are devoid of light chains and represent a lymphoplasma cell proliferative process. There are three major types: γ-HCD, α-HCD, and μ-HCD.

γ-HCD

Patients with γ-HCD often initially have a lymphoma-like illness, but the clinical findings are diverse and range from an aggressive lymphoproliferative process (Chapter 191) to an asymptomatic state. Hepatosplenomegaly and lymphadenopathy occur in about 60% of patients. Anemia is found in approximately 80% initially and in nearly all eventually. The electrophoretic pattern often shows a broad-based band more suggestive of a polyclonal increase than an M protein. The diagnosis depends on the identification of an isolated monoclonal γ heavy chain on serum immunofixation, without evidence of either monoclonal κ or λ light chain expression.

Treatment is indicated only for symptomatic patients and consists of chemotherapy with melphalan plus prednisone or regimens used to treat non-Hodgkin's lymphoma (Chapter 191), such as cyclophosphamide, vincristine, and prednisone. The prognosis of γ-HCD is variable and ranges from a rapidly progressive downhill course of a few weeks' duration to the asymptomatic presence of a stable monoclonal heavy chain in serum or urine.

α-HCD

α-HCD is the most common form of HCD and occurs in patients from the Mediterranean region or the Middle East, generally in the second or third decade of life. About 60% are men. Most commonly the gastrointestinal tract is involved, and severe malabsorption with diarrhea, steatorrhea, and weight loss is noted (Chapter 142). Plasma cell infiltration of the jejunal mucosa is the most frequent pathologic feature. Immunoproliferative small intestinal disease is restricted to patients with small intestinal lesions who have the pathologic features of α-HCD but do not synthesize α heavy chains.

The serum protein electrophoretic pattern is normal in half the cases; in the remainder an unimpressive broad band may appear in the α2 or β region. The diagnosis depends on identification of an isolated monoclonal α heavy chain on serum immunofixation, without evidence of either monoclonal κ or λ light chain expression. The amount of α heavy chain in urine is small.

In the absence of therapy, α-HCD is typically progressive and fatal. The usual treatment consists of antibiotics, such as tetracyclines, and the eradication of any concurrent parasitic infection. Patients who do not respond adequately to antibiotics are given chemotherapy similar to that used to treat non-Hodgkin's lymphoma, for example, the cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone (CHOP) regimen (Chapter 191).

μ-HCD

This disease is characterized by the demonstration of an isolated monoclonal μ chain fragment on serum immunofixation, without evidence of either monoclonal κ or λ light chain expression.

The serum protein electrophoretic pattern is usually normal, except for hypogammaglobulinemia. Bence Jones proteinuria has been found in two thirds of cases. Lymphocytes, plasma cells, and lymphoplasmacytoid cells are increased in the bone marrow. Vacuolization of the plasma cells is common and should suggest the possibility of HCD. The course of μ-HCD is variable, and survival ranges from a few months to many years. Treatment is with corticosteroids and alkylating agents.

CRYOGLOBULINEMIA

Cryoglobulins are plasma proteins that precipitate when cooled and dissolve when heated. They are designated as idiopathic or essential when they are not associated with any recognizable disease. Cryoglobulins are classified into

FIGURE 193-9. Skin infarction in cryoglobulinemia. The skin has a reticulated pattern as a result of leakage of red blood cells from damaged skin capillaries. Necrosis and ulceration have occurred in peripheral sites because of vessel blockage. This patient eventually required plastic surgery. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine,* 3rd ed. London: Mosby; 2003.)

three types: type I (monoclonal), type II (mixed monoclonal plus polyclonal), and type III (polyclonal).

Type I Cryoglobulinemia

Type I (monoclonal) cryoglobulinemia is most commonly of the IgM or IgG class, but IgA and Bence Jones cryoglobulins have been reported. Most patients, even with large amounts of type I cryoglobulin, are completely asymptomatic from this source. Others with monoclonal cryoglobulins in the range of 1 to 2 g/dL may have evidence of vasculitis with pain, purpura, Raynaud's phenomenon, cyanosis, and even ulceration and sloughing of skin and subcutaneous tissue (Fig. 193-9) on exposure to cold because their cryoglobulins precipitate at relatively high temperatures. Type I cryoglobulins are associated with macroglobulinemia, multiple myeloma, or MGUS. Therapy for patients with symptomatic type I cryoglobulinemia and significant symptoms is similar to that for Waldenström's macroglobulinemia for the IgM type and multiple myeloma for the non-IgM type.

Type II Cryoglobulinemia

Type II (mixed) cryoglobulinemia typically consists of an immune complex of IgM M protein and polyclonal IgG, although monoclonal IgG or monoclonal IgA may also be seen with polyclonal IgM. Serum protein electrophoresis generally shows a normal pattern or a diffuse, polyclonal hypergammaglobulinemic pattern. The quantity of mixed cryoglobulin is usually less than 0.2 g/dL. Despite the monoclonal component, most patients do not have a clonal plasma cell disorder; rather, they have serologic evidence of infection with hepatitis C virus (Chapter 151). At present, hepatitis C is thought to be the cause of most cases of type II cryoglobulinemia.

Most clinical manifestations are related to the development of vasculitis and include palpable purpura, livedo reticularis, polyarthralgias, and neuropathy. Involvement of the joints is symmetrical, but joint deformities rarely develop. Raynaud's phenomenon, necrosis of the skin, and neurologic involvement may be present. In almost 80% of renal biopsy specimens, glomerular damage can be identified. Nephrotic syndrome may result, but severe renal insufficiency is uncommon.

Early administration of corticosteroids is the most frequent therapy. Treatment should also target underlying hepatitis C infection with interferon-α2 or ribavirin (Chapter 151). Agents to treat the monoclonal component, such as cyclophosphamide, chlorambucil, azathioprine, or rituximab, are used if there is no response. Plasmapheresis (with a warmed circuit) is helpful in the acute management of symptoms by removing circulating immune complexes.

Type III Cryoglobulinemia

Type III (polyclonal) cryoglobulinemia does not have a monoclonal component and is not associated with a clonal plasma cell proliferative disorder. Type III cryoglobulins are found in many patients with chronic infections or inflammatory diseases and are usually of no clinical significance unless associated with hepatitis C infection.

AMYLOIDOSIS

MORIE A. GERTZ

DEFINITION

Immunoglobulin light chain amyloidosis is characterized by a clonal population of bone marrow plasma cells that produces a monoclonal light chain of the κ or λ type, as either an intact molecule or a fragment. The light chain protein, instead of conforming to the α-helical configuration of most proteins, misfolds and forms a β-pleated sheet. This insoluble protein deposits in tissues and interferes with organ function. The β-pleated sheet configuration is responsible for the tinctorial properties; when the protein is stained with Congo red and viewed under polarized light, apple-green birefringence is demonstrated and is required for the diagnosis. Systemic light chain amyloidosis (AL) must be distinguished from the much less common amyloidosis associated with chronic infection and inflammatory arthropathies (secondary or AA) or with inherited amyloid cardiomyopathies and neuropathies (familial or AF).

CLINICAL MANIFESTATIONS

Amyloidosis is particularly difficult to diagnose and is a challenge for internists. The presenting symptoms can be very broad and are mimicked by far more common disorders (Table 194-1). The signs include tongue enlargement with dental indentations and "pinch" or periorbital purpura, a result of vascular fragility. The signs are specific but lack sensitivity, in that they are present in no more than 20% of patients. No single imaging procedure or

TABLE 194-1 SYMPTOMS, SIGNS, AND SYNDROMES IN AMYLOIDOSIS

SYMPTOMS AND SIGNS
Common symptoms: fatigue, edema, dyspnea, anorexia, paresthesias
Rare symptoms: claudication, joint pain and stiffness, sicca syndrome
Common signs: periorbital purpura, glossomegaly, hepatomegaly
Rare signs: waxy infiltration of eyelids, shoulder pad sign
SYNDROMES
Nondiabetic nephrotic syndrome
Nonischemic cardiomyopathy with an echocardiogram showing "hypertrophy"
Hepatomegaly or increased alkaline phosphatase with no imaging abnormality
Peripheral neuropathy with monoclonal gammopathy of undetermined significance or chronic inflammatory demyelinating polyneuropathy with autonomic features
Atypical myeloma with monoclonal light chains and modest marrow plasmacytosis

laboratory study is diagnostic for the disease. The clinician must therefore be aware of the possibility of amyloidosis, or it may be overlooked. The kidney is commonly involved in amyloidosis. The diagnosis should be suspected in any patient who presents with nondiabetic nephrotic-range proteinuria (Chapter 123). One third of patients with amyloidosis have nephrotic syndrome that presents with dramatic increases in the blood cholesterol level (median, 270 mg/dL), and urinalysis for proteinuria should be done in patients with a sudden increase in the serum cholesterol level. A patient with nondiabetic proteinuria may receive an empirical course of corticosteroids for possible minimal-change glomerulopathy. This treatment delays the diagnosis of amyloidosis and allows other organs to become involved. Ten percent of renal biopsy specimens in nondiabetic nephrotic syndrome are subsequently shown to be involved by amyloidosis. The incidence of bleeding after percutaneous renal biopsy is not increased in AL.

The heart is involved in approximately 50% of patients with amyloidosis, and the presentation is subtle because fatigue is often the only manifestation. Because amyloid heart disease (Chapter 60) is a disorder of diastolic failure, the typical findings of cardiomyopathy (enlarged cardiac silhouette on chest radiography, depressed ejection fraction by echocardiography, and pulmonary vascular redistribution) are absent. The effect of amyloidosis on the heart is poor filling during diastole. Patients have low end-diastolic volume and, as a consequence, poor stroke volume despite a completely normal ejection fraction. Electrocardiography frequently shows a pseudoinfarct pattern, which can be interpreted as demonstrating silent ischemic infarction; this finding leads to coronary angiography, which is invariably negative (unless there is coincidental coronary artery disease). Echocardiography, which shows thickening of the heart walls due to amyloid infiltration, is frequently interpreted as showing left ventricular hypertrophy, and the cause of heart failure can be ascribed to silent hypertension or, alternatively, hypertrophic cardiomyopathy. Echocardiography frequently shows valvular insufficiency of the mitral and tricuspid valves. Restrictive cardiomyopathy has been confused with pericardial disease, and patients have undergone unnecessary pericardiectomy, without clinical benefit. The classic granular sparkling appearance of the echocardiogram is not a useful diagnostic finding. Patients with amyloidosis rarely have symptoms of ischemic heart disease. Enhancement on magnetic resonance imaging with gadolinium is delayed in 69% of patients with cardiac amyloidosis. Myocardial enhancement is associated with increased ventricular mass and impaired left ventricular systolic function.

The liver is involved in 13% of patients (Chapter 153). The typical presentation is hepatomegaly and an increased serum alkaline phosphatase value. An increased transaminase value and hyperbilirubinemia are late signs. Imaging is not helpful, and liver uptake is homogeneous. Many patients undergo an evaluation for metastatic malignancy. Liver biopsy is not associated with an increased rate of bleeding and is not contraindicated in the presence of hepatic amyloidosis. Rare patients present with spontaneous splenic rupture. Acquired deficiency of coagulation factor X is specific to AL and can be associated with clinically severe hemorrhage. Levels improve with effective therapy because the cause is binding of the factor to the fibrils of amyloid.

The peripheral neuropathy (Chapter 428) associated with amyloidosis begins in the lower extremities, is symmetrical, and is generally sensory or mixed sensorimotor. When a monoclonal protein is recognized, frequent diagnoses are chronic inflammatory demyelinating polyneuropathy or neuropathy associated with monoclonal gammopathy of undetermined significance, because amyloidosis has not been considered in the differential diagnosis. Associated autonomic neuropathy occurs in approximately 4% of patients and can be characterized by orthostatic hypotension, which may be misattributed to the cardiac failure. Autonomic dysmotility of the bowel is a common associated finding (Chapter 138). It can be upper intestinal, leading to pseudo-obstruction and recurrent emesis, or lower intestinal, which is characterized by alternating obstipation and fecal incontinence. Diarrhea caused by autonomic failure has been misdiagnosed as collagenous colitis when eosinophilic deposits are found in the bowel mucosa on hematoxylin-eosin staining in the absence of Congo red staining. Carpal tunnel syndrome (Chapter 428) occurs in approximately 13% of patients; it is not clinically distinguishable from the syndrome associated with repetitive stress injury but frequently fails to improve after surgical release. Rarely, interstitial lung disease, pseudoclaudication, periarticular deposits, and unexplained weight loss are presenting symptoms.

Systemic amyloidosis can be confused with early multiple myeloma (Chapter 193). Patients who present with vague symptoms of fatigue and edema are found to have a monoclonal protein in the urine, and a bone marrow biopsy shows a clonal plasmacytosis with a median of 5% plasma cells in the bone marrow; however, a quarter of patients have more than 10% plasma cells in the bone marrow, a finding that qualifies as a diagnosis of multiple myeloma. These patients are often considered to have atypical multiple myeloma when the underlying amyloid syndrome goes undetected. In these patients, a misdiagnosis of myeloma kidney or demyelinating neuropathy is made when an adequate diagnostic evaluation to exclude amyloidosis has not been performed.

DIAGNOSIS

Screening for Amyloidosis

In a patient with nondiabetic proteinuria, cardiomyopathy without ischemic risk factors, unexplained hepatomegaly, peripheral or autonomic neuropathy, or carpal tunnel syndrome, amyloidosis is not the most likely cause. The disorder occurs in only 8 per million persons per year, and routine biopsy is not appropriate whenever consistent symptoms are found. The classic physical finding of periorbital purpura occurs in only 10% of patients, is often limited to petechial eruptions over the eyelids, and is easily overlooked. Enlargement of the tongue occurs in 10 to 15% of patients; therefore, although it is specific, it is not sensitive for the diagnosis. Patients with enlarged tongues may be unrecognized, or they may be evaluated for acromegaly or undergo unnecessary tongue biopsies because of the suspicion of squamous cell cancer. If biopsy is not an appropriate screening technique, what algorithm should be used to recognize light chain amyloidosis?

By definition, amyloidosis is a plasma cell dyscrasia (Chapter 193); therefore, virtually all patients have a detectable immunoglobulin abnormality by immunofixation of the serum or urine, or they have abnormal results on a serum immunoglobulin free light chain assay. When a patient presents with a compatible clinical syndrome, these diagnostic studies should be completed before performing invasive diagnostic studies (Fig. 194-1). Simple electrophoresis without immunofixation is inadequate because the monoclonal proteins are very small in most patients and will not cause a detectable peak on serum protein electrophoresis. When these three diagnostic studies are used in combination, the sensitivity is 100%. If a monoclonal protein is detected, further investigations for amyloid should proceed, as described later. If a monoclonal protein is not found, three possibilities exist: (1) the patient does not have amyloidosis; (2) if the patient is known to have amyloidosis, it may be localized rather than systemic; (3) if the patient is known to have systemic amyloidosis, it may be the senile systemic or familial type rather than the light chain type.

Confirming the Diagnosis of Amyloidosis

In view of the grave prognosis associated with light chain amyloidosis, the diagnosis must be confirmed by biopsy (with Congo red staining) in all cases. Although it is reasonable to biopsy the kidney when proteinuria is the presenting symptom, the heart when cardiomyopathy is recognized, the liver when there is hepatomegaly and increased alkaline phosphatase, or the nerve when there is a sensorimotor functional loss, these invasive and occasionally risky procedures are not required. Subcutaneous fat aspiration is an outpatient procedure that has a 24-hour turnaround time and recognizes amyloid deposits in 70% of patients. Bone marrow is a second convenient biopsy site, and this test is often required to exclude the possibility of associated multiple myeloma. Bone marrow biopsy is positive in 50% of patients. When both

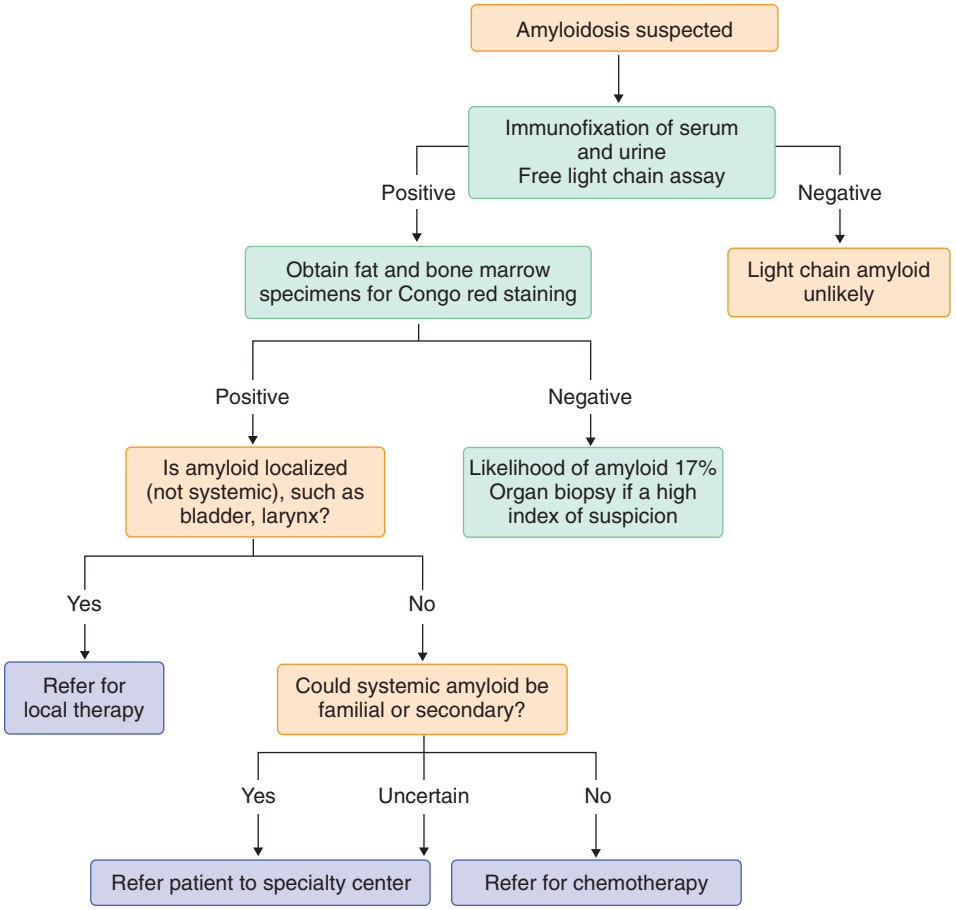

FIGURE 194-1. Algorithm for the cost-effective pursuit of a diagnosis of systemic light chain amyloidosis.

subcutaneous fat aspiration and bone marrow biopsy are done, amyloid is detected in 87% of patients. The remaining patients should have biopsy of the appropriate organ.

Once amyloid deposits are detected in tissues, further diagnostic evaluation is required. The presence of a monoclonal protein in the serum or urine and the presence of congophilic deposits in tissue do not verify that amyloidosis is light chain in origin. Further diagnostic studies are essential to classify the type of amyloid before therapy is initiated. Immunohistochemical studies on the tissue may be useful, but misfolding of the amyloid light chain often prevents epitopes from being recognized by commercial antisera; thus false-negative results are common. Mass spectroscopic analysis of the amyloid deposit can be done on paraffin-embedded tissue and validates the type of amyloid by direct amino acid sequencing, leaving no question about the origin of the amyloid protein as an immunoglobulin light chain. The incidence of monoclonal gammopathies in the elderly ranges from 3 to 5%. Therefore, that fraction of patients with senile systemic, localized, and familial amyloidosis could be expected to have an associated monoclonal gammopathy, which would be misleading. Mass spectroscopic analysis is feasible on subcutaneous fat tissue.

TREATMENT

Rx

Previously, amyloidosis was thought to be untreatable and invariably fatal. With current therapy, response rates of about 70% regularly occur, and the median duration of survival is reportedly upward of 5 years. Agents to reverse the misfolding of the protein and render it soluble would be ideal, but they are not available. The source of the immunoglobulin light chain is the clonal plasma cell population in the bone marrow. All known therapies are directed at destruction of the plasma cell clone. The two choices are generally traditional-dose chemotherapy or high-dose chemotherapy with autologous stem cell transplantation. Most patients are not candidates for high-dose therapy because of age, advanced cardiac dysfunction, or renal insufficiency. Current therapies include combinations of melphalan, dexamethasone, bortezomib, and lenalidomide. The role of high-dose therapy with stem cell transplantation in the management of amyloidosis remains controversial. Effective therapy has been associated with resolution of nephrotic syndrome, cardiac failure, and hepatomegaly. Imaging has shown amyloid deposits to regress after the suppression of light chain synthesis.

Assessing the Effect of Therapy

The serum immunoglobulin free light chain assay has been cited as a useful screening test for patients with a compatible clinical syndrome. This assay is also used to measure the therapeutic effect of intervention because the light chain level is quantifiable and reproducible. Based on current hematologic response criteria, successful therapy is characterized by a 50% reduction in the abnormal free light chain level. Because the tissue toxicity associated with amyloid is related to the deposition of small amounts of light chain, it is unclear whether a successful outcome requires complete eradication of the light chain product. Studies have shown that patients achieving complete normalization of the free light chain have a better outcome, but it is uncertain whether patients who do not achieve this level of response should be subjected to more intensive treatment in an effort to remove this pathogenic amyloid serum precursor.

PROGNOSIS

The outcome of patients with light chain amyloidosis depends on the extent of cardiac involvement (Chapter 60). With the advent of routine hemodialysis for this population, death due to renal failure is uncommon. The greater the involvement of the heart, the shorter a patient's survival. Echocardiography provides useful information about the ejection fraction, the thickness of the ventricular septum and left ventricular free wall, and the strain percentage (the rate at which wall shortening occurs). Doppler echocardiography allows quantitative measurements of diastolic function and reflects the slowing of blood flow into the ventricular chamber as the noncompliant left ventricle fills. This "stiffness" measured by the deceleration time provides useful information and correlates well with survival.

Cardiac biomarkers are extremely sensitive measures of myocardial function, are reproducible, and can be used not only for prognosis but also to follow cardiac response after effective therapy. The serum troponin value is a powerful predictor of survival in patients with amyloidosis, and the N-terminal pro-brain natriuretic peptide value predicts survival after a diagnosis

of amyloidosis. A staging system has been developed using these two cardiac biomarkers to accurately predict survival. In clinical trials of amyloidosis, half the patients with extreme increases in these markers have been incapable of completing 3 months of therapy.

Other Forms of Amyloidosis

Localized amyloidosis can be confused with systemic amyloidosis, but it has a much better prognosis. Patients with localized amyloidosis generally do not require systemic therapy; management can be supportive or localized to the deposition. The location of the amyloid deposits can be a clue to the localized nature. Typical sites for localized amyloid deposition include the ureter, bladder, urethra, and prostate. Therapy entails cystoscopic resection or intravesical instillation of dimethyl sulfoxide. Most forms of cutaneous amyloidosis are localized, although nodular cutaneous amyloidosis has occurred in systemic light chain AL. Tracheobronchial and laryngeal amyloidosis and nodular pulmonary amyloidosis are localized, are not associated with a plasma cell dyscrasia, and generally require only local therapy. Nodular pulmonary amyloidosis is often diagnosed after thoracotomy for a presumed malignant pulmonary nodule. Most cases of laryngeal amyloidosis are found when the patient presents to an otorhinolaryngologist with hoarseness and amyloid deposits are found on endoscopic biopsy. Patients with localized amyloidosis do not have a demonstrable monoclonal protein in the serum or urine and have a normal free light chain ratio. The localized amyloidosis found in Alzheimer's disease is chemically unrelated to light chain amyloidosis, and patients with light chain amyloidosis have no increased risk of dementia.

Senile systemic amyloidosis results from the deposition of a normal serum protein, transthyretin, in the myocardium. It has a much better prognosis than cardiac AL and generally necessitates endomyocardial biopsy for diagnosis; most patients are older than 70 years. When a monoclonal protein is present, it is incidental, and confirmation generally requires analysis of the amyloid-laden tissues. Therapy is supportive. The clinical presentation of senile systemic amyloidosis is not distinguishable from that of cardiac AL.

Familial amyloidosis is uncommon in the United States and represents only 3% of the cases of systemic amyloidosis. Patients present with the full clinical spectrum associated with amyloidosis, including cardiomyopathy, peripheral neuropathy, and proteinuria. Patients do not have a monoclonal protein because the deposited precursor is a mutant form of transthyretin, fibrinogen, lysozyme, or apolipoprotein A. Selected patients with familial amyloidosis have benefited from liver transplantation. One very important form of familial amyloidosis in the United States is associated with an allele of the normal serum protein transthyretin in which isoleucine is substituted for valine at position 122 (TTR Val-122-Ile). The prevalence of this mutation in blacks in the United States is as high as 3.9%. Heterozygous inheritance of this mutant TTR is associated with late-onset cardiomyopathy in this population. Wall thickening is found on echocardiography. The heart failure is often mild at onset. The prognosis is far better than that of cardiac AL, and its recognition has important implications for genetic counseling.

Secondary Amyloidosis

Secondary systemic amyloidosis is the rarest form in Western nations. Previously, it was a consequence of uncontrolled sustained inflammation, usually infectious, and causes included tuberculosis and osteomyelitis. Today it occurs primarily in patients with difficult-to-control inflammatory rheumatic syndromes, including juvenile arthritis and ankylosing spondylitis. These patients present with nephrotic syndrome, diarrhea related to intestinal involvement, and thyromegaly. Suppression of the inflammatory process results in regression of tissue amyloid deposits. There are familial forms of secondary amyloidosis associated with familial periodic fever syndromes, the most common being familial Mediterranean fever (Chapter 269) due to mutations in the tumor necrosis factor receptor.

195 TUMORS OF THE CENTRAL NERVOUS SYSTEM AND INTRACRANIAL HYPERTENSION AND HYPOTENSION

LISA M. DEANGELIS

INTRACRANIAL TUMORS

General Approach to Brain Tumors

EPIDEMIOLOGY

About 17,000 new primary brain tumors and nervous system cancers are diagnosed annually in the United States, making central nervous system (CNS) tumors more than twice as common as Hodgkin's disease and approximately one third as common as melanoma. In contrast, intracranial metastases are five times more common than primary brain tumors. More than 120 types of primary brain tumors arise from the different cells that make up the CNS (Table 195-1). In addition to classifying tumors by their cell of origin, in clinical practice it is often useful to classify a tumor by its intracranial site as well, such as pineal region tumors or pituitary and suprasellar tumors.

PATHOBIOLOGY

In contrast to tumors arising elsewhere in the body, there is little distinction between benign and malignant tumors when they occur in the brain. The growth of brain tumors is restricted to the CNS; they rarely, if ever, metastasize to other organs. In the CNS, a malignant tumor is characterized by aggressive pathologic features, including local tissue invasion, neovascularity, regional necrosis, and cytologic atypia. These features confer a growth advantage to malignant cells and lead to rapid expansion and, frequently, to early regrowth after treatment. Tumors lacking these aggressive histologic features are preferably classified as low-grade rather than benign. Many low-grade tumors continue to grow within the CNS, causing progressive neurologic disability, and some may acquire a more malignant phenotype over time. The low-grade tumors that transform into high-grade neoplasms are primarily the intra-axial tumors that cannot be cured by resection because of their diffuse infiltration of brain. Almost all truly benign CNS tumors are extra-axial tumors, such as meningiomas and acoustic neuromas that can be cured with complete surgical resection.

CLINICAL MANIFESTATIONS

A patient with a brain tumor can present with one or both of two types of symptoms and signs. *Generalized symptoms,* which typically reflect the increased intracranial pressure (ICP) that often accompanies cerebral tumors, include headache, lethargy, personality change, nausea, and vomiting. *Lateralizing symptoms,* which reflect the specific location of the tumor, include hemiparesis, hemisensory deficits, aphasia, visual field impairment, and seizures (Table 195-2).

Most patients have symptoms that progress over a week to a few months. A sudden intensification of symptoms may precipitate the patient's initial visit to the physician; however, a careful history usually reveals symptoms that predated the acute deterioration and slowly worsened over time. Two exceptions are the new appearance of a seizure in a previously asymptomatic individual (Chapter 410) and sudden hemorrhage into a tumor.

Facial weakness (ipsilateral)
Ataxia
Cerebellum
Ataxia (ipsilateral)
Nystagmus

Symptoms of brain tumors can be produced by tumor invading brain parenchyma, tumor and edema compressing brain tissue, cerebrospinal fluid (CSF) obstruction caused directly by the tumor or by a shift of brain tissue, and herniation. Invasion and compression typically produce focal symptoms, many of which can be relieved if the compression is reduced. Obstruction of CSF flow and herniation are frequently a consequence of elevated ICP and typically produce generalized symptoms of headache, nausea, and vomiting, but they can also cause false localizing signs, such as an abducens nerve palsy, as a result of diffuse increased ICP.

Headache (Chapter 405) is a presenting symptom of approximately 35% of brain tumors. It is more common in younger than older patients and more common in patients who have rapidly growing tumors than in those whose tumors have evolved slowly (Fig. 195-1). Mental and cognitive abnormalities may be a reflection of local tumor (e.g., aphasia, alexia, agnosia) or of general impairment (e.g., lethargy, confusion, word finding difficulty, apathy). Seizures affect approximately one third of patients with brain tumors, and they are especially common as the presenting and only symptom of a low-grade tumor. The seizures, which are focal because they originate at the site of the tumor, may remain restricted (e.g., focal motor seizures), or they may generalize secondarily, producing loss of consciousness (Chapter 410), sometimes so quickly that the focal signature is missed by the patient or even an observant witness.

FIGURE 195-1. Meningioma. Computed tomography scan with contrast of a meningioma in a patient who presented with mild cognitive deficits, illustrative of the size a slow-growing tumor can attain in the brain. The tumor was completely resected.

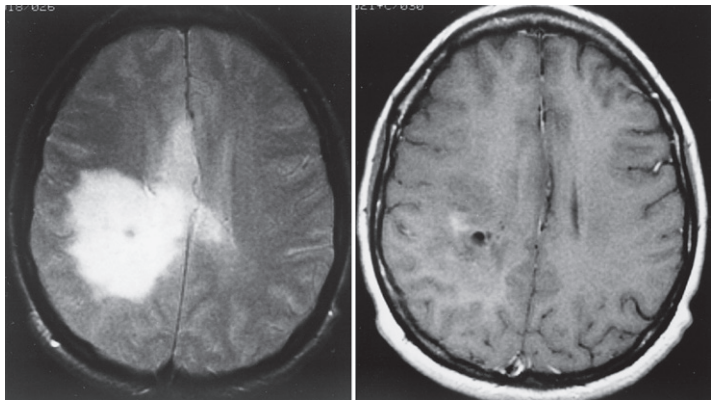

FIGURE 195-2. Glioma. Magnetic resonance imaging (MRI) view of a low-grade glioma. **Left,** T2-weighted image; **right,** T1-weighted image, gadolinium contrast with minimum enhancement. The images are typical of this tumor, which is being detected with increasing frequency by MRI in seizure patients. Many are invisible on computed tomographic scans.

TABLE 195-3 MAGNETIC RESONANCE IMAGING OF COMMON BRAIN TUMORS

TUMOR TYPE	NONCONTRAST T1	CONTRAST T1	T2
Malignant glioma	↓ density	+	↑ density
Low-grade glioma	↓ density	–	↑ density
Primary central nervous system lymphoma	↑ density	+	↑ density
Meningioma	Iso to ↑	+	Iso to ↓
Acoustic neuroma	↓ to Iso	+	Iso to ↑
Metastases	↑ to ↓	+	Variable, ↑ to ↓

DIAGNOSIS

Imaging

Magnetic resonance imaging (MRI) is far superior to computed tomography (CT) and should be used in all cases of suspected intracranial tumor. MRI should be performed both without and with intravenous gadolinium. A well-performed MRI scan identifies any intracranial tumor, and normal MRI results effectively exclude a neoplasm. The MRI of some extra-axial tumors (e.g., acoustic neuromas, meningiomas) is so characteristic that histologic confirmation is not required (Table 195-3). A non-contrast-enhancing infiltrative lesion that is visible primarily on T2 or fluid-attenuated inversion recovery (FLAIR) images is most consistent with a low-grade glioma (Fig. 195-2), whereas a contrast-enhancing lesion with an area of central necrosis and surrounding edema is most likely to be a glioblastoma or possibly a brain metastasis. Although these diagnoses must be confirmed histologically, the preoperative diagnostic possibilities affect the choice of surgical procedure and the surgical approach to the lesion.

Perfusion MRI after rapid infusion of gadolinium can measure the relative cerebral blood volume and neovascularity associated with a tumor; high perfusion is associated with higher grade of malignancy. This technique can help estimate the tumor grade preoperatively and guide the planning of treatment.

Magnetic resonance spectroscopy (MRS) noninvasively assesses tissue composition. High-grade primary brain tumors are associated with a decrease in *N*-acetylaspartate (NAA) and an increase in choline (Cho). More malignant tumors are associated with a greater Cho/NAA ratio and frequently contain areas with elevation of lactate and lipid.

Surgical resection is a major objective in the treatment of almost every kind of brain tumor, but resection must be balanced against possible damage to adjacent normal brain. The development of functional MRI (fMRI), which measures cerebral blood flow when areas of cortex are activated, has greatly enhanced the ability to localize critical neurologic functions and their relationship to the tumor preoperatively. When the fMRI is fused with the anatomic MRI, critical functions can be identified in relationship to the patient's tumor, and a safer and more complete resection may be planned.

On positron emission tomography (PET), high-grade tumors are usually hypermetabolic, whereas low-grade tumors are hypometabolic. New technologies using ^{11}C-methionine PET may differentiate low- from high-grade gliomas much more efficiently than deoxyglucose PET.

CT, without and with intravenous contrast, should be used only for patients who cannot undergo MRI. A CT scan, even with contrast, may miss low-grade tumors and tumors in the posterior fossa.

Currently, angiography has no role in the diagnosis of intracranial tumors. However, angiographic embolization is occasionally useful preoperatively to reduce the vascularity of some meningiomas, thereby making a complete resection safer and more feasible.

Other Tests

Electroencephalography (EEG) is rarely needed in the diagnosis or management of brain tumors. An EEG can occasionally be useful in a patient who has prolonged or unexplained stupor and in whom nonconvulsive status epilepticus is a consideration. Intraoperative monitoring is also frequently used to help guide resection of epileptogenic cortex adjacent to or within brain tumor tissue.

CSF analysis has little role in the diagnosis of most intracranial neoplasms. In primary CNS lymphoma (PCNSL), the diagnosis may be established on CSF cytologic examination in about 15% of patients. Rarely, a lumbar puncture is required to exclude inflammatory conditions or other processes that may be confused with a primary brain tumor. Lumbar puncture must be avoided in patients with cerebellar tumors because the release of pressure through the spinal needle may result in herniation of the cerebellar tonsils through the foramen magnum.

Differential Diagnosis

Patients who present with symptoms of raised ICP or the new onset of central neurologic symptoms such as hemiparesis or seizure should be hospitalized and evaluated rapidly. Prompt neuroimaging discloses a mass, and the radiographic features narrow the differential diagnosis (Table 195-4). Extra-axial tumors, such as a meningioma or acoustic neuroma, can be confused with a dural metastasis. Low-grade intra-axial tumors, which are nonenhancing on MRI, have been confused with infections such as herpes encephalitis when they involve the temporal lobe. Contrast-enhancing intra-axial tumors can be confused with a stroke, brain abscess, or focal plaque of demyelination. Subacute infarction can show brisk contrast enhancement, usually in a gyral pattern, unlike brain tumors, in which enhancement is primarily in the white matter; occasionally, however, the two are indistinguishable radiographically. Brain abscesses typically have a thinner enhancing wall than a malignant tumor, but they sometimes appear similar on MRI. Despite careful evaluation, patients thought to have a malignant glioma occasionally are found at surgery to have a brain abscess. A single large plaque of demyelination can

TABLE 195-4 DIFFERENTIAL DIAGNOSIS OF INTRACRANIAL TUMORS

- Infection

  - Cavernous angiomas
  - Venous angiomas
- Congenital abnormalities
  - Cortical dysplasia
  - Heterotopia

also be confused radiographically with a brain tumor, and sometimes the diagnosis can be established only by biopsy.

When MRI suggests a primary brain tumor, there is no need for an extensive systemic search for a possible source of metastasis. Brain metastases are more common than primary brain tumors, but most occur in patients with known cancer, typically with active systemic disease. If an obvious systemic cancer is not revealed by a thorough general examination, chest radiograph, routine blood tests, and urinalysis, then the patient should proceed to craniotomy. Even if a brain metastasis is found at surgery, resection of a single brain metastasis is the appropriate treatment, and the pathology of the lesion guides the subsequent search for the primary tumor.

TREATMENT

Rx

The treatment for all brain tumors can be divided into two main categories: symptomatic and definitive (Table 195-5). Symptomatic treatment addresses the associated problems, such as cerebral edema, seizures, and thromboembolic disease, which can contribute substantially to clinical symptoms. Definitive treatment addresses the tumor itself.

Symptomatic Treatment

Symptomatic management includes the use of corticosteroids, anticonvulsants, and prophylaxis for deep vein thrombosis (DVT) (Chapter 37). Corticosteroids decrease the vasogenic edema that surrounds primary and metastatic brain tumors. Blood vessels associated with tumor formation are leaky and do not share the normal morphologic and physiologic features that form the blood-brain barrier; corticosteroids effectively reconstitute the blood-brain barrier by decreasing the abnormal permeability of these neovessels. Clinical improvement may begin within minutes, and frequently patients are dramatically improved within 24 to 48 hours.

Dexamethasone is the most commonly used glucocorticoid because it has the least mineralocorticoid activity. The usual starting dose is 12 to 16 mg/day, but this can be adjusted to find the lowest possible dose that alleviates neurologic symptoms. After definitive treatment is instituted, many patients can be tapered off their corticosteroid completely. Chronic high-dose corticosteroid therapy is associated with substantial side effects (Chapter 34). Patients who will be taking glucocorticoids for 6 weeks or longer should receive prophylaxis against *Pneumocystis jiroveci* (formerly *Pneumocystis carinii;* Chapter 349).

Anticonvulsants are administered to any patient who has had a seizure, but prophylactic anticonvulsants should not be prescribed for patients who have never had a seizure, except they may be useful in the perioperative period.[1,2]

DVT, which occurs in about 25% of patients with brain tumors, can occur early in the illness or at any time during treatment. All patients undergoing neurosurgery should have pneumatic compression boots in the postoperative period to reduce the incidence of DVT. Prophylactic anticoagulants have also been used successfully in the immediate postoperative period without increasing postoperative hemorrhage. Appropriately regulated anticoagulation (Chapter 37) is the optimal therapy for DVT and is not associated with an increased risk of intracerebral hemorrhage in patients with intracranial tumors. Inferior vena cava filters can be used for patients who have DVTs or pulmonary emboli and who cannot be fully anticoagulated.

TABLE 195-5 TREATMENT FOR BRAIN TUMORS

SYMPTOMATIC

- Glucocorticoids
- Anticonvulsants
- Deep vein thrombosis prophylaxis and treatment

DEFINITIVE

- Surgery
  - Goal is gross total excision
- Radiotherapy
  - Standard external beam
    - Fractionated
    - Usually focal
  - Stereotactic radiosurgery
- Chemotherapy
  - Limited by intrinsic drug resistance and blood-brain barrier

Definitive Treatment

Surgery

Complete excision is the goal for a primary brain tumor. Surgical excision can often be accomplished for primary extra-axial tumors, such as meningiomas and acoustic neuromas. However, meningiomas often occur in intracranial locations that make resection impossible. Tumors of the skull base are particularly difficult to remove, and partial resection for decompression is often performed to preserve neurologic function. The safe boundaries for resecting cortical lesions while preserving function can often be elucidated by preoperative fMRI and intraoperative cortical mapping. However, lesions involving many critical structures, such as the brain stem or thalamus, cannot be excised safely.

Lesions that cannot be resected are still amenable to biopsy for diagnostic purposes. In particular, the use of stereotactic biopsy has made it feasible to reach lesions in almost any area of the brain with minimal morbidity. The risks of stereotactic biopsy include (1) inadequate tissue sample to make a diagnosis, (2) a tissue sample that does not accurately reflect the most malignant grade of the tumor, and (3) a procedure-related complication, such as hemorrhage. Hemorrhage that causes neurologic impairment occurs in only 2% of stereotactic biopsies, typically in patients with glioblastoma multiforme.

Complete excision can cure extra-axial primary brain tumor and is associated with prolonged survival and better neurologic outcome even in patients with primary intra-axial tumors. Gross total excision, as measured by postoperative neuroimaging, is associated with prolonged survival in patients with malignant gliomas and probably in those with low-grade gliomas as well. However, most low-grade gliomas are not amenable to gross total excision, and usually only partial excision is feasible. Macroscopic tumor can frequently be removed completely in patients with high-grade gliomas, but there is always remaining microscopic disease that infiltrates surrounding brain.

Some tumors, such as brain stem gliomas, are in such critical locations that biopsy is not attempted. Their characteristic radiographic appearance permits diagnosis and initiation of medical treatment.

Radiation Therapy

A course of external beam radiation therapy is delivered in small daily fractions to a total cumulative dose usually between 45 and 60 Gy. Dividing the treatment into small daily fractions permits sublethal repair in normal tissues and markedly reduces neurologic toxicity associated with cerebral radiation. External beam irradiation, which is the most effective nonsurgical treatment for brain tumors, doubles median survival time of patients with malignant primary brain tumors or metastatic lesions. It can also be useful for recurrent meningiomas and acoustic neuromas. However, it only rarely cures any of these lesions, and most patients develop recurrent disease despite maximal radiation therapy.

Stereotactic radiosurgery has been developed to deliver high fractions of focused radiation therapy that spare normal surrounding tissue. The technique is limited to tumors that are 3 cm in diameter or smaller and is less useful for malignant gliomas because of their infiltrative nature.

The neurologic complications of radiation therapy, which are usually observed in patients months to years after completion of treatment, include radionecrosis, dementia, and leukoencephalopathy. The incidence is reported as less than 5%, and most patients die of their brain tumor before the delayed consequences of treatment can be observed. However, in long-term survivors (e.g., patients with low-grade glioma or children with medulloblastoma), the late consequences of radiation therapy are important. Dementia accompanying radiation-induced leukoencephalopathy can progress and result in severe neurologic impairment. Radionecrosis can mimic recurrent tumor with a large contrast-enhancing lesion on MRI. Corticosteroids can reduce the edema and sometimes are sufficient to treat small areas of radionecrosis. However, if the lesion is sufficiently large, resection may be required to decompress the mass and reduce the steroid requirements.

Chemotherapy

Chemotherapy for brain tumors has usually been disappointing because of the intrinsic resistance of these tumors to most conventional agents. Carboplatin and cisplatin are active agents against medulloblastoma, even when the tumor is disseminated in the CSF. Temozolomide (150 to 200 mg/m^2 for 5 days every 4 weeks) is active in all gliomas, and high-dose methotrexate (3 to 8 g/m^2 for 3 to 12 months) is effective for PCNSL. For patients with glioblastoma, polymers impregnated with carmustine (BCNU) and placed in a resection cavity offer modest benefit when compared with no chemotherapy, but they are associated with local tissue injury and edema.

SPECIFIC TYPES OF BRAIN TUMORS

Primary Extra-axial Tumors

The most common primary extra-axial tumors are meningiomas, pituitary adenomas, and acoustic neuromas. These tumors arise within the intracranial cavity but are not tumors of brain tissue. Almost all are benign; because the brain is rarely invaded, complete excision often enables cure with full recovery of neurologic function. These tumors produce neurologic symptoms and signs by compressing the underlying brain; however, edema of the underlying brain is infrequent, so glucocorticoids have a limited role.

MENINGIOMAS

EPIDEMIOLOGY

Meningiomas are usually benign. Between 5 and 10% of meningiomas are atypical or malignant variants with a more aggressive course. Meningiomas are more common in women, may be multiple in about 10% of patients with sporadic meningioma, and are occasionally part of a familial syndrome. They occur with increased frequency in patients with neurofibromatosis type 2 (Chapter 426).

DIAGNOSIS

Meningiomas grow slowly and produce symptoms that are insidious in onset and typically slowly progressive. Tumors can reach a considerable size, but they grow so slowly that the brain accommodates to the progressive compression. Meningiomas typically occur in specific locations: over the convexity, along the falx and parasagittal area, the olfactory groove, base of the skull near the sphenoid bone, cavernous sinus, cerebellopontine angle, and foramen magnum. Cortical and parasagittal tumors typically manifest with seizures or progressive hemiparesis. Tumors in the anterior cranial fossa can cause slowly progressive changes in personality and cognition. Meningiomas at the base of the skull manifest with cranial neuropathies and gait difficulties when there is brain stem compression. Frequently, tumors are completely asymptomatic and are identified on neuroimaging done for another purpose, such as head trauma.

On MRI, meningiomas have a characteristic appearance consisting of a diffusely enhancing, dural-based lesion that is associated with a thin enhancing dural tail extending from the tumor. Often the radiographic features are so characteristic that surgery is performed for therapeutic purposes only. The radiographic differential diagnosis includes the less common hemangiopericytoma and dural metastasis. Most meningiomas are not accompanied by significant edema, but marked edema is seen with high-grade malignant lesions or the secretory variant.

If small meningiomas are discovered in the absence of clinical symptoms or the symptoms are minor, lesions may be monitored with serial images because growth can be so slow.

TREATMENT

Rx

If treatment is indicated, complete resection is often curative, but even completely resected benign tumors may recur (as many as 20% in some series), so radiologic follow-up is essential. Tumors at the base of the skull often cannot be resected completely and tend to recur despite successive attempts at surgical resection. Radiation therapy can sometimes slow progression and is essential for the treatment of malignant meningiomas. No effective chemotherapy has yet been identified.

Acoustic Neuromas

Acoustic neuromas (Chapter 436), better called vestibular schwannomas, are benign tumors that arise from the eighth cranial nerve. Acoustic neuromas are twice as common in women as in men; the peak age is between 40 and 60 years. Sporadic vestibular schwannomas are unilateral; bilateral acoustic neuromas are pathognomonic of neurofibromatosis type 2 (Chapter 426).

Acoustic neuromas usually arise from the vestibular portion of the nerve and typically manifest with unilateral hearing loss, sometimes preceded or accompanied by tinnitus and a sensation of dizziness or unsteadiness but not true vertigo. The slow, progressive enlargement of the tumor produces ipsilateral facial numbness or weakness by compressing the fifth or seventh cranial nerve, respectively. Tumors originate within the internal auditory meatus but grow out of the acoustic canal and into the cerebellopontine angle, where they can compress the brain stem and cause ataxia and ipsilateral cerebellar signs. Cranial MRI with gadolinium delineates even small acoustic neuromas with ease.

Treatment is often surgical; stereotactic radiosurgery may be an alternative for lesions smaller than 3 cm. It is preferable to treat the tumors when they are small, to preserve facial nerve function and hearing.

Pituitary Adenomas

Pituitary adenomas (Chapter 231) can be classified according to their size as microadenomas (<1 cm in diameter) or macroadenomas; by the presence or absence of endocrine function; and by the endocrinologic syndromes or neurologic syndromes caused by tumor compression. Microadenomas typically manifest with endocrine symptoms as described in Chapter 231. As pituitary tumors enlarge and become macroadenomas, they compress the surrounding neural structures, including the optic chiasm and optic nerves, typically causing bitemporal hemianopia and occasionally causing unilateral visual loss. Macroadenomas are frequently nonsecreting but destroy pituitary tissue, causing panhypopituitarism. Rarely, pituitary tumors manifest with the abrupt onset of headache, ophthalmoplegia, unilateral blindness, and even a depressed level of alertness or coma—a syndrome of *pituitary apoplexy* caused by hemorrhage or infarction.

Cranial MRI, particularly with coronal images and gadolinium administration, can completely outline the pituitary tumor and surrounding neural structures. All macroadenomas and some microadenomas can be treated with transsphenoidal pituitary surgery, which is associated with minimal morbidity. Occasionally, residual or recurrent tumor necessitates radiation therapy. Some hormone-secreting tumors, particularly prolactinomas or growth hormone–secreting tumors, can be treated medically with cabergoline or octreotide, respectively (Chapter 231). These medications not only correct the hormonal excess but also shrink the tumor; they must be taken for life.

Other tumors in the pituitary and suprasellar region include craniopharyngiomas, suprasellar epidermoid cysts, Rathke cleft cysts, germinomas (discussed later), and lymphocytic hypophysitis, which is a benign inflammatory condition that usually manifests with diabetes insipidus (Chapter 232). MRI frequently differentiates these conditions, which are usually suprasellar and erode into the pituitary fossa only secondarily. Some of these lesions also have characteristic radiographic features. These lesions are benign. Except for hypophysitis, which resolves completely with corticosteroid treatment (e.g., methylprednisolone, 120 mg daily for 2 weeks and then tapered for 1 additional week), complete surgical excision is the curative therapy.

Other Extra-axial Tumors

Pineal region tumors all have a characteristic clinical presentation that includes Parinaud's syndrome, which consists of paresis of upward gaze, poor pupillary reaction to light with brisk reaction on accommodation, impairment of convergence, and convergence-retraction nystagmus. Some of these lesions may also cause hydrocephalus and symptoms of increased ICP. Pineal region tumors include pineal parenchymal tumors, such as pineocytomas and the more aggressive pineoblastomas, and germ cell tumors, including germinomas and nongerminomatous germ cell tumors. Germinomas can be completely cured with focal radiation therapy, whereas nongerminomatous germ cell tumors are more aggressive and frequently relapse despite chemotherapy plus cranial irradiation.

Chordomas are rare tumors of residual notochordal tissue. They usually occur at the base of the skull, are locally invasive, and are characterized by multiple recurrences despite surgery and radiation therapy.

Lipomas are benign tumors that can occur in midline structures, particularly near the corpus callosum. They can be cured by complete removal.

Arachnoid cysts are not tumors per se but can manifest with headaches, seizures, or focal neurologic symptoms if they become large enough to compress underlying brain tissue. Many are completely asymptomatic and

are found incidentally on neuroimaging. Only symptomatic cysts require removal.

Primary Intra-axial Tumors

Most primary intra-axial brain tumors are gliomas, including the astrocytomas, oligodendrogliomas, and ependymomas. Less common are medulloblastomas, other rare neuroectodermal tumors, and PCNSLs. All of these tumors have a tendency to invade brain tissue, and none can be completely excised surgically.

GLIOMAS

DEFINITION

Astrocytomas, which are the most common glioma, are classified into one of four World Health Organization (WHO) categories: grade I is the pilocytic astrocytoma, grade II is the fibrillary astrocytoma, grade III is the anaplastic astrocytoma, and grade IV is the glioblastoma multiforme. Pilocytic astrocytomas (grade I) are extremely low-grade focal tumors that are more common in children and may be associated with neurofibromatosis type 1; they are often cured by complete surgical excision. Astrocytomas, anaplastic astrocytomas, and glioblastomas are diffuse tumors that tend to infiltrate widely into brain; even grade II tumors progress over time, and most acquire the histologic features and growth patterns of grade III and IV tumors.

EPIDEMIOLOGY

Gliomas occur at any age, but the peak age is 20 to 30 years for an astrocytoma, 40 years for anaplastic astrocytoma, and 55 to 60 years for glioblastoma. Age is the single most important prognostic factor: younger patients live substantially longer than older patients. Histology is also critical: patients with glioblastoma do significantly worse than patients with lower-grade lesions. Performance status, duration of symptoms, and whether a complete resection has been achieved are also strong predictors of improved outcome and prolonged survival. For all grades of glioma, men are more frequently affected than women, and whites significantly more frequently than blacks. Gliomas are typically single lesions, but multifocal disease is seen in approximately 5% of patients with high-grade tumors. A variant of gliomas, called *gliomatosis cerebri,* causes widespread infiltration of the entire brain; most patients have relatively low-grade pathology on biopsy, but focal regions of high-grade transformation can exist.

PATHOBIOLOGY

At least 95% of gliomas are sporadic, and only 5% occur in patients with a family history of brain tumor. Furthermore, patients with a familial history of glioma usually do not fall into a well-recognized hereditary syndrome. However, neurofibromatosis 1 (von Recklinghausen's disease; Chapter 426) is associated with an increased incidence of gliomas, particularly in the optic pathway, hypothalamus, and brain stem. Gliomas also occur with increased frequency in Turcot's syndrome, in which colorectal neoplasms are seen in association with a variety of CNS tumors. Somatic mutations of the isocitrate dehydrogenase 1 and 2 genes (*IDH1* and *IDH2*) have been identified in most low-grade gliomas and secondary glioblastomas: these patients had a better outcome than those with wild-type *IDH* genes.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with gliomas often present with seizures, headache, and lateralizing signs such as hemiparesis, aphasia, or a visual field deficit. On MRI, low-grade gliomas typically appear as diffuse, nonenhancing lesions with a propensity to occur in the frontal lobe and insular cortex. High-grade gliomas, which typically enhance with contrast, occur in the cortical white matter and are accompanied by significant surrounding edema. Glioblastomas frequently have regions of central necrosis (Fig. 195-3), and hemorrhage can occur in 5 to 8% of patients.

TREATMENT

Rx

For all gliomas, treatment frequently involves surgery, radiation therapy, and chemotherapy. The surgical goal of complete removal of all visible disease is often impossible. The adequacy of resection is best assessed on a postoperative MRI study, without and with gadolinium, performed within 72 to 96 hours after surgery. Surgical removal usually improves neurologic function and reduces dependency on corticosteroids.

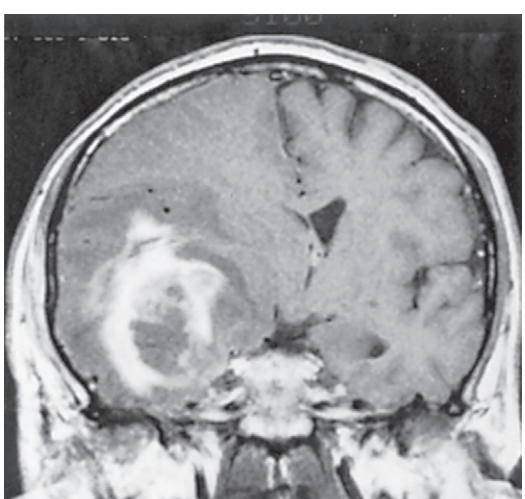

FIGURE 195-3. Temporal lobe glioblastoma. This T1-weighted gadolinium-enhanced magnetic resonance imaging view shows a typical ring configuration of contrast with central necrosis and marked mass effect.

ANAPLASTIC ASTROCYTOMAS AND GLIOBLASTOMAS

All anaplastic astrocytomas and glioblastomas should be treated with postoperative radiation therapy to a dose of approximately 60 Gy. In a randomized trial of patients with glioblastoma, the alkylating agent temozolomide (75 mg/m^2 daily), administered concurrently with radiation therapy and followed by adjuvant temozolomide (150 to 200 mg/m^2 for 5 consecutive days every 4 weeks for 6 cycles), significantly improved survival (median, 14.6 months) compared with radiation therapy alone (median, 12.1 months; $P < .001$), and the 2-year survival rate more than doubled to 26.5%.■ Patients whose tumors contained a methylated promoter of the O6-methylguanine-DNA methyltransferase *(MGMT)* DNA repair gene benefited most from the addition of temozolomide. Based on these data, combined treatment is the current standard of care for patients with glioblastoma. Chemotherapy is generally well tolerated and associated with minimal toxicity. Elderly patients often do poorly, but a randomized trial showed that radiotherapy (compared with supportive care only) results in a modest improvement in survival, without reducing quality of life or cognition, in elderly patients with glioblastoma.■ Recurrences can be treated with re-resection, additional chemotherapy, or, occasionally, stereotactic radiosurgery, or a combination of these. Despite aggressive treatment, disease recurs in almost all patients, and the median survival time is 14 to 15 months for glioblastoma. Patients with anaplastic gliomas (including anaplastic oligodendrogliomas) had identical median survivals of about 7 years whether the initial treatment was radiotherapy or chemotherapy.■ However, some young patients with anaplastic astrocytoma can survive many years before the tumor recurs.

OPTIC AND BRAIN STEM GLIOMAS

Optic gliomas, which can involve the optic nerve or optic chiasm, are usually associated with neurofibromatosis type 1. These gliomas are typically pilocytic tumors that can have an indolent course, including rare spontaneous regression. Often they are not amenable to surgical resection, and they can have a stuttering clinical course, with periods of visual loss punctuated by prolonged periods of visual stability. When necessary, radiation or even chemotherapy may be useful, but often no treatment is required. Brain stem gliomas usually involve the pons, less often the medulla or midbrain. Brain stem gliomas are most commonly seen in children in the first decade of life but can be found even in elderly people; they can have a low-grade or a high-grade histology, but outcome is primarily determined by the location of the tumor. In general, most brain stem gliomas have a dismal outcome with survival of 1 year or less, but relatively benign variants occasionally occur.

LOW-GRADE ASTROCYTOMAS

Low-grade astrocytomas have a variable course. In patients who present with isolated seizures that can be easily controlled with anticonvulsants, treatment with radiation therapy or chemotherapy immediately after surgery does not prolong survival, and patients can be monitored until there is clinical or

radiographic evidence of tumor progression. Patients with progressive neurologic symptoms or cognitive impairment require immediate treatment after diagnosis, and focal radiation therapy to a total of about 54 Gy is the optimal choice. An astrocytoma can progress as a low-grade tumor or transform to a higher-grade malignancy, a change that typically is associated with the appearance of contrast enhancement on MRI. Resection or a biopsy may be necessary in these patients, followed by radiation therapy if they have not received it previously; chemotherapy with temozolomide (150 to 200 mg/m^2 for 5 days every 4 weeks for anywhere from 6 to 24 cycles) is also used. Patients with astrocytomas have a median survival of about 5 years.

OLIGODENDROGLIOMAS

Oligodendrogliomas occur as low-grade tumors and, less commonly, as anaplastic lesions. Treatment of these tumors differs from that of their astrocytic counterparts because oligodendrogliomas are uniquely chemosensitive, owing to their characteristic loss of chromosomes 1p and 19q. As with the low-grade astrocytomas, treatment should be withheld in patients with low-grade oligodendrogliomas who have no symptoms other than well-controlled seizures. Patients with progressive neurologic symptoms require treatment, and initial therapy is often chemotherapy, usually with single-agent temozolomide (150 to 200 mg/m^2 for 5 days every 4 weeks for 6 to 24 cycles) or the combination of procarbazine, lomustine, and vincristine. Radiation therapy is withheld until chemotherapy fails.

By comparison, all anaplastic oligodendrogliomas require immediate treatment. The standard approach includes focal radiation therapy. Adjuvant chemotherapy significantly prolongs disease-free survival but not overall survival time. However, there is a growing movement toward treating high-grade tumors with chemotherapy alone and, in some cases, using high-dose chemotherapy with autologous stem cell rescue (Chapter 181). Some success has been reported with this approach, but it should still be considered experimental. Tumor progression should be treated with re-resection, radiation therapy if not previously administered, and additional chemotherapy. Patients with low-grade oligodendrogliomas have a median survival time in excess of 15 years, and those who have anaplastic oligodendrogliomas survive a median of 4 to 5 years.

MEDULLOBLASTOMAS

Medulloblastomas usually occur in the vermis of the cerebellum and principally affect children and young adults. Boys outnumber girls by about 2 : 1, and peak onset is at age 7 years; medulloblastoma in adulthood is rare and usually affects the cerebellar hemisphere.

The most common chromosomal abnormality associated with medulloblastoma is isochromosome 17q, which is found in as many as 60% of tumors. Tumors with an identical histology but different genetics may arise in the cerebral hemispheres and are called *primitive neuroectodermal tumors* (PNETs). PNETs usually have an aggressive course, leading to rapid death despite vigorous treatment.

Medulloblastomas have a characteristic clinical presentation, with ataxia (due to cerebellar and brain stem involvement) and headache, nausea, and vomiting (due to increased ICP from obstructive hydrocephalus). Aggressive surgery with complete excision is strongly associated with improved outcome. Surgery is always followed by neuraxis radiation therapy. Chemotherapy with vincristine, etoposide, carboplatin, and cyclophosphamide significantly improves 5-year event-free survival from 60 to 74% but has not significantly prolonged overall survival, which is about 70 to 80% at 5 years. This vigorous therapy often results in significant delayed complications in survivors, including intellectual deficits, growth impairment, and endocrinologic dysfunction. Late relapses as well as secondary neoplasms compromise long-term outcome.

GANGLIOGLIOMAS

Gangliogliomas, as the name implies, possess both a glial component and a neoplastic neural component (ganglion cell). Some low-grade gangliogliomas are indolent and do not require additional treatment after surgical extirpation. Patients with anaplastic tumors may fare better than patients with malignant gliomas, but recurrence is the rule despite surgery and radiation therapy.

PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMAS

PCNSLs are associated with immunodeficiency states, particularly acquired immunodeficiency syndrome and organ transplantation, and are seen with increased frequency among the apparently immunocompetent population as well. Men are more frequently affected than women, and the median age at diagnosis is about 60 years. These tumors are usually large cell, B-cell non-Hodgkin's lymphomas identical to systemic lymphoma (Chapter 191). The tumor can involve the CSF, the eye, and the brain, where it is multifocal in about 40% of patients at presentation. In contrast to all other brain tumors, surgical resection is not associated with improved survival and can cause significant neurologic morbidity; therefore, biopsy, not resection, is the better surgical approach. Chemotherapy is the primary treatment, and high-dose methotrexate (3 to 8 g/m^2 on alternate weeks for 3 to 12 months) is the most important chemotherapeutic agent. In older patients, radiation therapy is avoided because the necessary whole brain irradiation causes significant cognitive impairment when combined with chemotherapy. Furthermore, radiation therapy alone produces a response but is followed by relapse within 1 year. Corticosteroids (e.g., dexamethasone 8 to 16 mg/day), which are frequently used as part of the chemotherapeutic regimen, not only help manage the associated cerebral edema but also can cause tumor regression. With the use of multiagent chemotherapy, with or without cranial irradiation, median survival times are now in the 3- to 5-year range.

OTHER INTRA-AXIAL TUMORS

Rare, intra-axial cerebral tumors include the *ependymoma,* which is optimally treated with surgical excision followed by radiation therapy. *Choroid plexus papillomas* and carcinomas may manifest with hydrocephalus or lateralizing signs. Resection may be sufficient for the benign papilloma, but carcinomas rapidly recur even when postoperative radiation therapy is also used. *Colloid cysts* of the third ventricle are benign tumors that can cause obstructive hydrocephalus; they may be treated with a ventricular peritoneal shunt or with resection using an intraventricular endoscope. *Hemangioblastomas* occur primarily in the cerebellum but can also occur in the spinal cord and the hemispheres. About 15% of patients with a hemangioblastoma have the autosomal dominant disorder, von Hippel-Lindau disease (Chapter 426), which is characterized by hemangioblastomas in the CNS and retina, renal cell carcinoma, pheochromocytoma, endolymphatic sac tumors, and cysts in a variety of visceral organs. Hemangioblastomas are treated by surgical excision and require radiation therapy only for recurrence. Complete removal usually results in cure.

Metastatic Tumors

BRAIN METASTASES

DEFINITION AND EPIDEMIOLOGY

Every systemic cancer is capable of metastasizing to the brain. Melanoma (Chapter 210) has the greatest propensity to spread to the CNS, but the most common causes of CNS metastases are cancers of the breast (Chapter 204) and lung (Chapter 197), followed by cancers of the colon (Chapter 199) and kidney (Chapter 203). CNS metastases are being seen with greater frequency as patients with systemic cancers have prolonged survival with better treatments. In most patients with brain metastases, CNS disease develops late in the course of their illness, but a brain metastasis may be the initial presentation of a systemic cancer. In most of the latter patients, lung cancer is the primary site; in some, however, a primary site is never identified (Chapter 211).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with brain metastases present with progressive neurologic symptoms and signs that typically include headache, seizures, and lateralizing signs. Metastases are best diagnosed by a cranial MRI with gadolinium enhancement (Fig. 195-4). All lesions can be clearly seen by MRI, which is better than CT for visualizing the posterior fossa. Metastases, which are usually well-circumscribed lesions at the gray matter–white matter junction, are often associated with extensive edema. Hemorrhage into a metastasis occurs most frequently with metastases from melanoma, renal cancer, and thyroid cancer; however, because brain metastases from lung cancer are so common, they are the type most commonly associated with hemorrhage. Sometimes, hemorrhage into a brain metastasis is best visualized by noncontrast head CT.

TREATMENT

Rx

Because brain metastases do not widely infiltrate into brain tissue and tend to have a pseudocapsule around them, they can be completely excised surgically. In randomized controlled studies, complete removal of a single brain metastasis substantially prolonged life and maintained neurologic function for

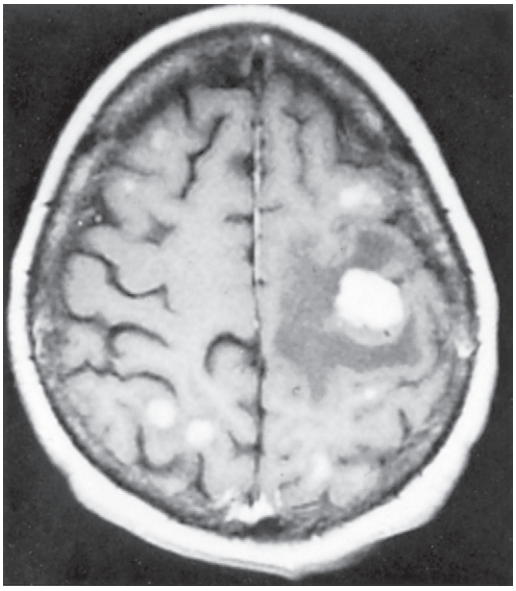

FIGURE 195-4. Brain metastasis. Multiple metastases from breast carcinoma are seen on this T1-weighted gadolinium-enhanced magnetic resonance imaging view. The multiple smaller tumors were not visible on computed tomography, even after a contrast agent was given.

FIGURE 195-5. Leptomeningeal metastases. Gadolinium-enhanced magnetic resonance imaging of the lumbosacral spine in a patient with leptomeningeal metastases from melanoma. Multiple enhancing nodules are seen on the cauda equina, and the conus medullaris and lower spinal cord are encased by tumor.

a longer period. Postoperative whole brain radiation therapy significantly improves control of CNS disease after resection of a single brain metastasis, but it does not prolong survival because patients die of progressive systemic tumor. Consequently, the use of postoperative whole brain radiation therapy is frequently decided on an individual basis. If multiple lesions can be completely resected, these patients do as well as those with a single lesion that has been removed.

Most patients with multiple brain metastases are best treated with a course of whole brain radiation therapy, most commonly 3 Gy in 10 fractions for a total of 30 Gy. Some patients with single brain metastasis are also treated with whole brain irradiation if they are in poor general condition, have uncontrolled systemic disease, or are not good candidates for surgical treatment.

Stereotactic radiosurgery, using either a gamma knife that delivers gamma radiation from multiple cobalt sources or a linear accelerator that delivers x-rays to a highly focused area involving the tumor, has been quite effective for the treatment of one or a few brain metastases. Most patients tolerate radiosurgery without difficulty, but occasionally the procedure is complicated by seizures or acute swelling that causes more neurologic dysfunction. Approximately 20 to 30% of patients develop radionecrosis, which may be indistinguishable clinically and on MRI from recurrent tumor. One advantage of stereotactic radiosurgery is that most of the normal brain is not exposed to the radiation.

Chemotherapy is used to treat brain metastases from only a few chemosensitive primary cancers such as choriocarcinoma, small cell lung cancer, and, to a lesser extent, breast cancer. Because few patients have a significant response to chemotherapy, it is usually used as a last resort. The oral agent temozolomide (150 to 200 mg/m^2 for 5 days every 4 weeks) has shown some activity against brain metastases from lung cancer and is very well tolerated.

LEPTOMENINGEAL METASTASES

The brain is the most common intracranial site of metastases, but systemic cancer can spread to the dura and the leptomeninges as well. Dural metastases most commonly arise from breast or prostate cancer, frequently from a metastasis in the overlying calvaria. Metastasis to the leptomeninges often manifests as multifocal neurologic symptoms and signs. These metastases involve the cranial nerves to cause diplopia or bulbar palsy; the cervical and lumbar roots to cause limb pain or weakness; and the intracranial space to cause headache, nausea, vomiting, and elevated ICP. The diagnosis is established by the presence of tumor cells in the CSF or by neuroimaging that definitively outlines tumor in the subarachnoid space (Fig. 195-5). Treatment frequently involves radiation therapy to symptomatic sites; intrathecal chemotherapy, usually through an intraventricular cannula (Ommaya reservoir); or systemic chemotherapy with agents at doses that penetrate into the CSF.

Spinal Tumors

Tumors involving the spine can be classified according to the anatomic area they involve: extradural, intradural extramedullary, and intramedullary tumors (Table 195-6). Extradural tumors typically arise from the bony elements of the spine and cause neurologic symptoms and signs by spinal cord compression. Intradural but extramedullary tumors arise from the pachymeninges or nerve roots (meningiomas or schwannomas) and can cause either radicular symptoms or spinal cord compression. Intramedullary spinal cord tumors arise from the spinal cord parenchyma and have a biology similar to brain tumors. Intramedullary tumors are rare.

EXTRADURAL TUMORS

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Most extradural tumors originate from a metastasis to the bony elements of the spine, typically the vertebral body and occasionally the vertebral lamina or spinous process. Less common are primary tumors of the spine, including chordoma, osteogenic sarcoma, plasmacytoma, and chondrosarcoma. Expansile growth of the bone tumor impinges on the spinal canal and, if untreated, compresses the spinal cord or the nerve roots as they exit the intervertebral foramina. Whereas most of these lesions arise from bony metastases, extradural tumors can also arise from paravertebral metastases that can grow through the intervertebral foramina and into the epidural

space; very rarely, a direct metastasis to the epidural space is also seen. The most common primary cancers that cause extradural metastases are prostate (Chapter 207), breast (Chapter 204), and lung cancer (Chapter 197), as well as the lymphomas (Chapter 191). Hematologic malignancies may also be associated with paravertebral disease that grows through the intervertebral foramina.

Whether the mass is a primary bone tumor or a metastasis from a distant source, 98% of patients present with pain that is usually local at the site of the tumor. Because there are more thoracic than cervical or lumbar vertebrae, the tumor and pain are likely to be in the middle or high back, a less common site for benign pain (Chapter 407). Motor impairment and sensory symptoms are present in about 50% of patients, whereas sphincter disturbances are found in only about 25% of patients. Back pain often precedes the development of any other neurologic symptom or sign, frequently by weeks and occasionally by months.

DIAGNOSIS

Severe back pain in a patient with cancer should be evaluated by MRI, which does not require intravenous contrast. Plain films of the spine, bone scans, or even CT scans may show bony disease, but epidural tumor can be seen only on MRI. Furthermore, MRI is the only technique that can reveal paravertebral or direct epidural metastasis. Patients who cannot have an MRI should be imaged by CT myelography.

Differential Diagnosis

The differential diagnosis of extradural tumors includes epidural abscess (Chapter 421), acute or subacute epidural hematomas (Chapter 407), herniated intervertebral discs (Chapter 407), spondylosis (Chapter 407), epidural lipomatosis, and, rarely, extramedullary hematopoiesis. Occasionally, a percutaneous needle biopsy or decompressive laminectomy is required to make a definitive diagnosis.

TREATMENT Rx

Extradural metastases require immediate treatment because patients can develop acute and unpredictable neurologic deterioration resulting in paraplegia. Patients should be started on high-dose corticosteroids, usually 100 mg IV dexamethasone, which rapidly relieve pain and may contribute to neurologic recovery. Surgery followed by postoperative radiation therapy is superior to radiotherapy alone in preserving the ability to walk[9] and may prolong survival in a wide population of patients with metastatic spinal cord compression. It is much easier to preserve neurologic function than to reverse impairment, so clinically silent areas of extradural tumor that are detected on MRI should be treated before neurologic compromise develops. Patients whose primary tumor arises in the spine, such as an osteogenic sarcoma (Chapter 208), should undergo definitive surgery; the need for postoperative radiation therapy is determined on the basis of the tumor's histology. Patients with extradural metastases can have a good neurologic outcome if treated before the onset of severe neurologic compromise, but their overall survival is usually short because of the presence of widespread metastatic disease.

INTRADURAL EXTRAMEDULLARY TUMORS

Meningiomas

Most intradural extramedullary tumors are benign. Meningiomas are benign, slow-growing tumors that occur primarily in middle-aged women and are predominantly located in the thoracic region. Back pain is a common symptom, but about 25% of patients have no pain and present with slowly progressive neurologic dysfunction, typically a gait disorder that has been slowly progressing, frequently for years. Spinal MRI with gadolinium clearly delineates the lesion. Surgical resection is curative, and a complete resection can usually be accomplished easily.

Nerve Sheath Tumors

Nerve sheath tumors include schwannomas and neurofibromas. Both typically arise from the dorsal root, and the first symptom is often radicular pain that precedes symptoms of spinal cord compression by months or even years. Some patients with spinal neurofibroma or schwannoma have neurofibromatosis type 1 (Chapter 426), but most do not. The diagnosis is clearly established by gadolinium-enhanced MRI of the spine. The treatment is surgical, and complete removal results in cure.

Metastases

Metastasis to the spinal leptomeninges can manifest as an intradural extramedullary lesion. A single large tumor nodule can cause focal symptoms and signs referable to that spinal level, but in most patients, multiple levels of the neuraxis are involved, causing multifocal neurologic symptoms and signs. Cervical and lumbosacral radicular pain, as well as sensory and motor loss, is seen in more than half of patients. The diagnosis is established by gadolinium-enhanced MRI showing multifocal nodules or sometimes a layer of cells coating the spinal cord or nerve roots (see Fig. 195-5). If imaging is negative, the diagnosis can be established by demonstrating tumor cells in the CSF. Treatment is complicated and frequently requires radiation therapy to symptomatic sites of disease, intrathecal chemotherapy best administered through an intraventricular cannula (Ommaya device), and occasionally systemic chemotherapy. Radiation therapy can ameliorate neurologic symptoms, particularly pain, but the disease often has a relentless progressive course, resulting in death in 3 to 6 months despite aggressive therapy. Because of the diffuse nature of the disease, surgery is not an option.

INTRAMEDULLARY TUMORS

Intramedullary spinal cord tumors are similar to neoplasms that arise in brain parenchyma. The most common spinal cord tumors are ependymomas and astrocytomas; hemangioblastomas (particularly in association with von Hippel-Lindau disease; Chapter 426), lipomas, and, rarely, intramedullary metastases are also seen.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

All intramedullary tumors have a similar clinical presentation, and pain is a common initial symptom. Signs of spinal cord dysfunction subsequently ensue and reflect the location of the lesion. In addition, some intramedullary tumors are accompanied by a syrinx (Chapter 426), which can contribute to symptoms. The classic signs of intramedullary spinal cord lesions, such as dissociated sensory loss, sacral sparing, and early sphincter problems, are not sufficiently reliable to distinguish intramedullary from extramedullary lesions on the basis of clinical findings. The diagnosis is established by gadolinium-enhanced MRI.

TREATMENT Rx

Surgery is the first therapeutic intervention, both to obtain a definitive diagnosis and to resect the lesion. Complete resection of spinal cord tumors is possible, particularly in the case of ependymomas and hemangioblastomas. However, spinal cord tumors are rare, and only neurosurgeons experienced in removal of this type of lesion should perform the procedure. High-grade gliomas and residual ependymomas should be treated with postoperative radiation therapy. Low-grade astrocytomas of the spinal cord can be treated with radiation therapy when the patient develops symptomatic neurologic impairment, but presymptomatic treatment does not prevent the development of impairment nor necessarily delay it. Intramedullary metastases do not require surgery because the diagnosis is usually straightforward; radiation therapy provides limited benefit because these patients typically have other CNS metastases.

INTRACRANIAL HYPERTENSION AND HYPOTENSION

CSF is made, in part, by the choroid plexus in the ventricular system; newly formed fluid circulates out the foramina of Luschka and Magendie, at the bottom of the fourth ventricle, to surround the entire spinal cord and cerebrum. It is reabsorbed back into the circulation through the arachnoid granulations over the convexities. Balance between CSF production and reabsorption keeps the volume relatively constant at about 150 mL in the normal healthy adult. CSF is produced at a rate of roughly 20 mL/hour, implying that the entire volume of CSF is replaced three to four times each day. CSF circulates nutrients to the nervous system and removes waste products from the only organ in the body that lacks a lymphatic system. In addition, CSF performs an important mechanical function by absorbing shock to the brain and spinal cord, cushioning them from the bony surroundings of the skull and spine.

A lumbar puncture provides the opportunity not only for sampling the CSF composition to detect disease processes but also for measuring ICP. CSF

pressure is normally maintained between 70 and 195 mm H_2O. ICP is maintained within this narrow window because significant fluctuations, either up or down, can cause marked neurologic dysfunction.

Intracranial Hypertension

Elevated ICP causes symptoms by compressing neural tissue, a process that causes ischemia and sometimes hemorrhage due to associated arterial and venous compression. ICP is partially maintained through the autoregulatory mechanisms of the cerebral blood vessels. Low ICP is caused by diminished CSF volume, and symptoms result from the loss of buoyancy of the brain as it floats within the CSF liquid. Pulling or stretching of the dura and cortical veins, which are the pain-sensitive structures in the cranial vault, causes headache; compensatory vasodilation may also contribute to headache.

The principal symptoms and signs associated with increased ICP are headache, nausea, vomiting, and lethargy; other symptoms are less frequent (Table 195-7). Focal mass lesions that cause a herniation syndrome may produce lateralizing signs such as hemiparesis; by comparison, diffuse elevation of ICP, as in communicating hydrocephalus, rarely does. Three main herniation syndromes are (1) herniation of the medial frontal gyrus under the falx; (2) transtentorial herniation of the uncus, pushing the diencephalon and the brain stem downward and laterally; and (3) herniation of the cerebellar tonsils through the foramen magnum. Generalized increased ICP may be due to obstruction of CSF, which may be caused by blockage of the ventricular system (obstructive or noncommunicating hydrocephalus) or by impairment of CSF reabsorption (nonobstructive or communicating hydrocephalus).

Increased ICP of any cause may produce pressure or plateau waves (episodic increases in ICP), leading to transient symptoms such as headache, vertigo, or diminished consciousness. Plateau waves occur normally and are associated with symptoms only when the baseline ICP is elevated. Plateau waves may be precipitated by a change in body position.

Hydrocephalus

Hydrocephalus refers to ventricular dilation caused by accumulated CSF. Hydrocephalus can be acute, resulting from sudden blockage of CSF outflow, or chronic, developing slowly over many months to years (Table 195-8). Patients with chronic hydrocephalus sometimes have normal CSF pressures, whereas those with acute hydrocephalus always have elevated CSF pressure.

CLINICAL MANIFESTATIONS

Acute hydrocephalus usually manifests with severe headache, lethargy, nausea, vomiting, papilledema, and diplopia from abducens palsy as well as signs from the causative lesion. Diffuse hyperreflexia and bilateral Babinski signs are common. Patients with chronic communicating hydrocephalus often have normal CSF pressure, so-called normal pressure hydrocephalus (NPH), and may present with progressive dementia characterized by memory loss and psychomotor retardation, an unsteady gait, and urgency incontinence (Chapter 409). Some patients have features of parkinsonism (Chapter 416) because of the bradykinesia and psychomotor retardation associated with hydrocephalus, but resting tremor is absent.

DIAGNOSIS

Ventriculomegaly is readily diagnosed by MRI or CT. In older patients, cerebral atrophy and the associated compensating increase in ventricular volume that accompanies normal aging (hydrocephalus ex vacuo) must be considered. Periventricular hyperintensity on T2-weighted or FLAIR MRI may help separate patients with NPH from those with hydrocephalus ex vacuo. MRI is the best test to identify a cause of hydrocephalus.

TREATMENT

Rx

If the ICP approaches or exceeds the systolic blood pressure, the cerebral perfusion pressure decreases, and ischemia develops. Marked elevation of ICP is a neurologic emergency that requires immediate intervention (Table 195-9) to reduce the volume of the intracranial contents and to prevent permanent brain damage. Hyperventilation to lower the arterial partial pressure of carbon dioxide ($PaCO_2$) to 25 to 30 mm Hg causes immediate vasoconstriction, which reduces cerebral blood volume. Intravenous mannitol or hypertonic saline can cause a rapid diuresis, which reduces intravascular plasma volume and helps to withdraw water from the extracellular space in the brain. Glucocorticoids, typically as dexamethasone 50 to 100 mg by IV bolus, will require hours to reduce underlying edema; vasogenic edema from brain tumor or brain abscess responds rapidly to corticosteroids, but cytotoxic edema accompanying an acute ischemic stroke or hematoma seldom responds to corticosteroids.

Ultimately, however, definitive treatment of the specific cause is necessary. If such treatment is not immediately feasible, hydrocephalus often responds promptly to ventricular drainage. If temporary drainage is necessary, an external ventricular drain can be placed until the underlying obstruction is relieved. A ventriculoperitoneal shunt is the definitive treatment for chronic hydrocephalus, but it is not reliably effective for "idiopathic" NPH. The clinical response to several days of external lumbar CSF drainage has a high predictive value for determining which patients with NPH are likely to benefit from a shunt. Complications of shunting include subdural hematomas and infection.

Idiopathic Intracranial Hypertension

DEFINITION AND EPIDEMIOLOGY

Idiopathic intracranial hypertension, also called benign intracranial hypertension or pseudotumor cerebri, refers to elevated ICP that develops in an otherwise healthy individual without evidence of a structural CNS

TABLE 195-9 EMERGENCY TREATMENT OF ELEVATED INTRACRANIAL PRESSURE IN ACUTELY DECOMPENSATING PATIENTS

THERAPY	TREATMENT	ONSET (DURATION OF ACTION)	OTHER
Hyperventilation	Lower $Paco_2$ to 25-30 mm Hg	Seconds (minutes)	Usually requires intubation and mechanical ventilation
Osmotherapy	Mannitol 0.5-2 g/kg IV, repeat as necessary	Minutes (hours)	Brisk diuresis Requires Foley catheter Strict attention to electrolytes
Corticosteroids	Dexamethasone 50-100 mg IV, followed by 50-100 mg/day in divided doses	Hours (days)	Most effective on vasogenic edema (tumors, abscesses) Less effective on cytotoxic edema (stroke)

$Paco_2$ = arterial partial pressure of carbon dioxide.

TABLE 195-10 SYSTEMIC AND IATROGENIC CONDITIONS ASSOCIATED WITH BENIGN INTRACRANIAL HYPERTENSION

COMMONLY PRESCRIBED DRUGS
Nalidixic acid
Nitrofurantoin
Phenytoin
Sulfonamides
Tetracycline
Vitamin A
Retinoic acid (*cis* or *trans*)
ENDOCRINE AND METABOLIC DISORDERS
Addison's disease
Cushing's syndrome
Hypoparathyroidism
Menarche, pregnancy, oral contraceptives
Obesity (often associated with irregular menses)
Corticosteroid therapy or withdrawal
HEMATOLOGIC DISORDERS
Cryoglobulinemia
Iron deficiency anemia
MISCELLANEOUS DISORDERS
Dural venous sinus obstruction or thrombosis
Head trauma
Internal jugular vein ligation
Systemic lupus erythematosus
Middle ear disease

abnormality. Most patients are obese young women, but the disorder can also occur in men, thin patients, older adults, and children. Idiopathic intracranial hypertension can be associated with a variety of systemic disorders and medications (Table 195-10), but the direct cause of ICP elevation is usually unknown. Chronic elevations of ICP can lead to the "empty sella syndrome" (Chapter 231), which refers to enlargement of the sella turcica due to an incompetent diaphragma sellae, leading to CT or MRI evidence of CSF in the sella; the result is a compressed but functioning pituitary gland.

CLINICAL MANIFESTATIONS

Patients usually present with headache that may be accompanied by visual disturbances, including visual loss, nausea, vomiting, diplopia, tinnitus, and vertigo. Examination is notable for bilateral papilledema in an otherwise healthy patient. Loss of vision, which is the most feared complication, is uncommon. Visual fields typically reveal an enlarged blind spot owing to the papilledema, but no other visual impairment. Diplopia can occur from an abducens palsy as a false localizing sign.

DIAGNOSIS

The diagnosis is established by excluding any structural cause of elevated ICP by MRI. Magnetic resonance venography (MRV) also should be performed to exclude dural venous sinus thrombosis or stenosis. Lumbar puncture is performed after neuroimaging and is required to confirm the diagnosis by establishing an elevated opening pressure, frequently greater than 300 mm H_2O; however, the composition of the fluid is normal, and the protein concentration is typically in the low-normal range (<20 mg/dL).

TABLE 195-11 CAUSES OF INTRACRANIAL HYPOTENSION

Postlumbar puncture
CSF leak following CNS surgery or trauma
CSF fistula
Post-thoracotomy leak into pleural space
Spontaneous/idiopathic dural tear

CNS = central nervous system; CSF = cerebrospinal fluid.

TREATMENT

Rx

The need to treat chronic intractable elevation of ICP is based on the patient's symptoms and serial visual field testing. Headache or new or progressive visual loss on eye examination or perimetry testing should trigger one or more of five treatments: (1) weight reduction (e.g., 20 lb) or correction of underlying endocrinologic or hematologic disorders, or both; (2) repeated lumbar punctures; (3) acute pharmacologic treatments, including corticosteroids, loop diuretics, and acetazolamide, although corticosteroids can contribute to weight gain and their tapering may exacerbate the syndrome; (4) ventriculoperitoneal or lumboperitoneal shunt; and (5) fenestration of the optic nerve sheath, especially for patients with persistently elevated ICP and deteriorating vision.

PROGNOSIS

Outcome is variable: spontaneous remissions may occur; clinical improvement is not always accompanied by a reduction in CSF pressure; and the CSF pressure may remain persistently elevated despite intervention. Furthermore, patients with chronically elevated ICP from idiopathic intracranial hypertension never develop hydrocephalus, so CSF pressure and ventriculomegaly are not linked.

Intracranial Hypotension

Intracranial hypotension occurs most commonly after lumbar puncture or after an idiopathic tear of the spinal dura. Evidence suggests that new "atraumatic" needles, as well as smaller-bore needles and few passes of the needle to perform the lumbar puncture, are associated with a lower incidence of postspinal headache.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Low CSF pressure (Table 195-11) can cause clinical symptoms that are usually mild but occasionally severe and debilitating. Postural headaches occur within 30 seconds after assuming the erect posture and subside completely when the patient lies flat (Chapter 405). The headaches, which are usually bifrontal or occipital, are typically severe, generalized, and throbbing. Headaches may be accompanied by nausea, dizziness, photophobia, neck stiffness, and, rarely, an abducens nerve palsy. All symptoms are relieved when the patient lies down.

TREATMENT AND PROGNOSIS

Rx

In most patients, symptoms resolve spontaneously and can be treated with simple analgesics. Some patients develop persistent, symptomatic intracranial hypotension that does not respond to simple measures.

In patients whose symptoms are persistent or disabling, an epidural blood patch is performed by injecting approximately 10 mL of the patient's own blood into the epidural space to seal the presumed dural leak. Occasionally, CSF radioisotope studies must be performed to identify the site of the leak so that surgical repair of the dura can be performed.

HEAD AND NECK CANCER

MARSHALL R. POSNER

DEFINITION

The principal cancers of the head and neck include squamous cell cancers arising from the mucosal surfaces of the upper aerodigestive tract and a diverse group of salivary gland neoplasms. Unique cancers of the region include nasopharyngeal carcinoma, thyroid malignancies (Chapter 233), esthesioneuroblastoma, and sinonasal undifferentiated carcinoma. A variety of other cancers arise from structures and tissues in the head and neck, including the more common skin cancers (Chapter 210), lymphomas (Chapters 191 and 192), and sarcomas (Chapter 209).

EPIDEMIOLOGY

Squamous cell carcinomas account for 95% of all malignancies of the head and neck, whereas salivary gland cancers represent nearly all of the remaining 5%. They represent 4% of all malignancies in the United States. Squamous cell cancers of the head and neck can be divided into two distinct groups based on pathogenesis, biology, and prognosis. Environmentally related cancers, caused principally by tobacco and alcohol, have been declining in incidence; however, they remain common. There has been an increasing incidence of human papillomavirus (HPV)-related oropharynx cancer (HPVOC). HPVOC now represents about 65% of oropharynx cancers seen in the United States and Europe. HPVOC affects a younger population (50 to 60 years) than environmental cancers (55 to 65 years). HPVOC patients are also generally healthier.

The mucosal surfaces of the head and neck are divided into six anatomic regions: the oral cavity, oropharynx, hypopharynx, larynx, nasopharynx, and paranasal sinuses. The site of anatomic origin for a squamous cell carcinoma of the head and neck has important, albeit imperfect implications for diagnosis, pathogenesis, spread, prognosis, and treatment because of intrinsic differences in the biology of the mucosal cells and subsequent cancers at the sites of origin, as well as differences in lymphatic drainage patterns and proximity to other structures in this compact region.

Oral Cavity

The oral cavity includes the floor of the mouth, anterior or oral aspect of the tongue, lips, buccal surfaces, hard palate, retromolar trigone, and gums. This region is easily appreciable by physical examination, and thus tumors in this area can frequently be detected early in their course. Tumors of the oral cavity, which are strongly related to the use of smokeless tobacco and other oral tobacco products (Chapter 31), appear on the buccal and gingival surfaces in the sites where tobacco products are held in contact with the mucosa for long periods. Anterior tongue cancers are more common in smokers. Lip cancers are particularly prevalent in transplant recipients and can be caused by DNA damage from solar ultraviolet light.

Oropharynx

The oropharynx consists of the tongue from the circumvallate papillae, posteriorly to the epiglottis, the tonsils, the associated pharyngeal walls, and the soft palate. The oropharynx has become the most common location for head and neck tumors in the United States and is a common site of origin in Europe. This is due to a high rate of HPVOC, which continues to increase in incidence. HPVOC is caused almost exclusively by HPV-16, a high-risk HPV type associated with cervical, anal, and vulvar cancers. HPVOC presents with lower primary T stage (T1 and T2) and higher nodal stage (N2 and N3) than environmental cancers and is frequently a cause of unknown primary cancer because of small and hard to identify primary tumors.

Hypopharynx

The hypopharynx comprises the piriform sinuses, the lateral and posterior pharyngeal walls, and the posterior surfaces of the larynx. These structures surround the larynx posteriorly and laterally. Tumors in this region can be difficult to detect because of the recesses and spaces surrounding the larynx. As a result, primary hypopharyngeal tumors may be asymptomatic and, like oropharyngeal tumors, may initially be recognized in an advanced state or diagnosed as an "unknown primary" (Chapter 211). These tumors are associated with tobacco (Chapter 31) and alcohol (Chapter 32) use.

Larynx

The larynx includes the vocal cords, the subglottis, and the supraglottic larynx, as well as the thyroid, cricoid, and arytenoid cartilages. Tumors arising in the true vocal cords are frequently symptomatic early and rarely spread beyond the confines of the larynx, whereas subglottic and supraglottic cancers can be relatively asymptomatic and have a much higher and earlier risk of spread to the lymphatics and regional sites. Laryngeal cancers are strongly associated with smoking (Chapter 31).

Nasopharynx

The nasopharynx includes the mucosal surfaces and structures of the cavity behind the nasal passages. Nasopharyngeal cancers are common in the Pacific Rim, northern Africa, and the Middle East. In some areas of China and Southeast Asia, nasopharyngeal cancers occur with a frequency that rivals lung cancer. In North America, there are about 2000 cases each year, but numbers are increasing as high-risk ethnic populations settle in North America. Nasopharyngeal cancers are frequently associated with the presence of latent infection of the epithelial tumor cells by Epstein-Barr virus (EBV), the etiologic agent of infectious mononucleosis (Chapter 385). Nasopharyngeal cancers are also associated with both environmental and genetic factors in susceptible populations that have migrated to North America and remain at high risk for this disease. Unlike other squamous cell carcinomas of the head and neck, nasopharyngeal cancers can occur at an early age, with a distinct peak in adolescence and young adulthood. Nasopharyngeal cancers are categorized into three histologic subtypes by the World Health Organization (WHO): the undifferentiated (WHO III) and nonkeratinizing forms (WHO II) are latently infected with EBV in 95% of cases and represent the majority of cases in North America and worldwide; the well-differentiated (WHO I) form is rarer and represents about 5% worldwide but about 15 to 25% of all nasopharyngeal cancers in North America, and it is usually associated with traditional risk factors such as smoking. Nasopharyngeal cancers have a high risk of early regional lymph node

involvement, a prolonged natural history, and a very high risk of spread to distant sites.

Paranasal Sinuses

The paranasal sinuses comprise the maxillary, ethmoid, sphenoid, and frontal sinuses as well as the nasal cavity. These are relatively rare locations for tumors of the head and neck in North America, but there is an unexplained higher rate of malignant sinus disease among the Japanese. Squamous maxillary sinus cancers are more common in smokers. Up to 50% of cancers of the sinuses may be of salivary gland origin, often related to exposure to dust from woodworking, tanning, or leather working (Chapter 18). Occasionally, neuroendocrine tumors and the rare sinonasal undifferentiated carcinoma are found. Sinus cancers are frequently diagnosed late in their course at the time of symptomatic invasion of surrounding structures, including the orbit, nasal cavity, base of the skull, and cranial nerves.

Salivary Glands

Salivary glands occur in all the regions described, as well as in the trachea and esophagus. Tumors can develop in all of the major and minor salivary glands with an incidence that is roughly proportional to the quantity of glandular tissue. The most common single site is the parotid. Although tumors can develop at any age, including childhood, the peak incidence is between 55 and 65 years of age. Salivary gland cancers have diverse histologic findings and manifest different behavior based on their histologic classification. A substantial fraction of parotid salivary tumors can be benign. Risk factors for salivary gland cancers are poorly understood, but previous radiation therapy in adjacent areas increases the risk (Chapter 19).

PATHOBIOLOGY

Tobacco products and alcohol are major etiologic and risk factors for squamous cell carcinoma of the head and neck. Both show a clear dose response. Any irritating smoked product increases the risk for local cancer, but nicotine in tobacco, as well as in other tobacco leaf components, directly affects the oral mucosa and increases the risk for squamous cancer (Chapter 31). Alcohol is also a carcinogen, and alcohol consumption (Chapter 32), as well as its direct application in mouthwashes, is associated with an increased risk. Moreover, alcohol affects local and systemic detoxification enzymes and may increase the carcinogenic potential of other environmental carcinogens. Other environmental risk factors include radiation exposure and solar radiation; welding, metal refining, diesel exhaust, wood stove, and asbestos exposure; chronic irritants; vitamin A deficiency; and immunosuppression.

Carcinogenic viruses are responsible for the increasing incidence of head and neck cancer in the United States and Europe. Pathogenic HPV subtypes, specifically HPV-16, independently account for approximately 65% of oropharyngeal cancer cases. HPV is transmitted by epithelial contact, and there is increased risk of HPVOC associated with increasing numbers of individual sexual partners. HPV-16 DNA can be found in the tumor cells, and the oncogenic viral proteins E6 and E7 are responsible and necessary for the growth and survival of the cancer cells by effecting critical signaling pathways. HPVOC patients have a three-fold better prognosis than patients with environmentally related cancers. Nasopharyngeal cancer is predominantly associated with keratinocyte infection with EBV (Chapter 385). The classic nasopharyngeal cancer, which is also called *lymphoepithelioma,* is associated with a brisk lymphoid infiltrate that can be confused with a lymphoma. Careful examination reveals the malignant epithelial cells in the tumor. EBV is also rarely associated with epithelial tumors of the oropharynx, tonsil, and salivary gland.

Several inherited diseases and genetic abnormalities are associated with the development of head and neck cancer. Fanconi's anemia (Chapter 168), a rare disorder of a family of related gene products, has been linked to the development of tongue cancer, as has Cowden's syndrome (Chapter 184), which is associated with mutation of the *PTEN* gene. Finally, common inherited allelic variants of the alcohol dehydrogenase and P-450 genes may be associated with increased susceptibility to alcohol and other environmental carcinogens.

The development of squamous cell carcinoma of the head and neck is a multistep process in which early genetic changes evolve into frank malignancy. In environmentally related cancers, an abnormal premalignant clone of mucosal cells may be localized to a single site within the head and neck, or clones may occur independently in many sites. The pathogenesis of HPVOC is less well understood. Second cancers are rare with HPVOC in the short term, and long-term risk is unknown. In contrast, about 20% of patients with environmentally caused cancers will develop a second primary cancer, most commonly in the head and neck, lung, and esophagus; 5% of patients are initially seen with a synchronous second primary. In environmentally related cancers, the cell cycle is dysregulated by the early loss of p16, an inhibitor of cyclin D1, or by upregulation of cyclin D1; p53 is disabled through a number of mechanisms preventing programmed cell death; mitogenic signaling is enhanced by upregulation of epidermal growth factor (EGF) receptor function; cyclooxygenase-2 is overexpressed, thereby inhibiting apoptosis and promoting angiogenesis; and chromosomal instability with aneuploidy develops. Many of these early molecular and functional changes occur without obvious alteration in the physical appearance of the oral mucosa, although leukoplakia can occur. In HPVOC, the RB and p53 pathways are inactivated by the HPV oncogenic proteins E6 and E7. As a result, the p16 protein is upregulated as a biomarker of HPV tumor origin. As a consequence of RB and p53 inactivation, these patients have dysregulation of cell growth and DNA damage control/programmed cell death, respectively. The differences between the genetic and molecular determinants of cancer in HPVOC and environmentally related cancers can be differentially targeted for therapy.

In environmentally related cancers, high-risk early lesions can occasionally be identified as leukoplakia and erythroplakia. Leukoplakia (Fig. 196-1A) is diagnosed clinically as a white patch of mucosal tissue in the oral mucosa or larynx. It can unpredictably progresses to cancer over a period of several years in approximately 30% of patients. Erythroplakia (see Fig. 196-1B), a red hyperkeratotic change in the mucosa, is a more advanced premalignant lesion with an approximately 60% rate of progression to oral cancer. Surgical resection of leukoplakia or erythroplakia has no effect on the subsequent development of invasive cancer. There is no proven chemopreventive therapy for persons with oral premalignant lesions. Because continued smoking or alcohol consumption increases the risk for recurrence and second primaries dramatically, patients with prior cancers should stop alcohol and tobacco use.

CLINICAL MANIFESTATIONS

The symptoms and clinical manifestations of tumors in the head and neck can vary broadly and are related to the structures at the site of the primary tumor, as well as regional lymph node drainage. Small tumors of the oral cavity and larynx can be easily appreciated because of physical self-discovery

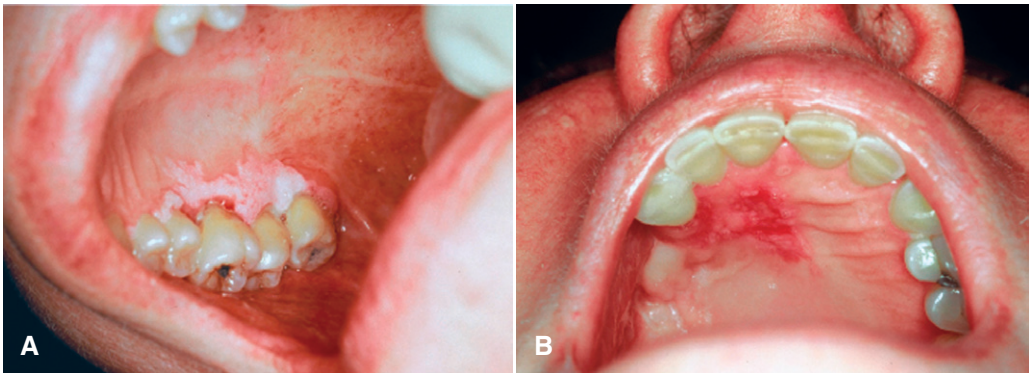

FIGURE 196-1. High-risk early mouth lesions. **A,** Oral leukoplakia. **B,** Oral erythroplakia.

or early compromise of the function of a critical structure. As a result of the propensity for squamous cell carcinoma of the head and neck to remain a local and regional disease, it is unusual for this cancer to be associated with abnormalities outside the head and neck. Salivary gland malignancies are less constrained and frequently spread distantly; however, because the primary tumors are also frequently accessible to direct physical examination and discovery, it is still uncommon to identify these tumors as a result of metastatic spread outside the region.

Clinical manifestations of *tumors in the oral cavity* include a painless lump, a painful mass or ulcer, or simple thickening of the mucosa. Small lesions in the lateral aspect of the tongue and the floor of the mouth can cause pain referred to the mandible, gums, and ear because of the shared sensory nerves supplying these areas. Antibiotics can relieve symptoms and even reduce the size of a tumor or lymph nodes when superficial infection and inflammation are contributing to the pain; however, recurrent or continued pain in an adult should trigger suspicion about more ominous disease. Speech may be affected late if the tumor causes restricted tongue motion or cranial nerve XII dysfunction. Gingival tumors can loosen teeth and invade the mandible along tooth sockets.

In true vocal cord cancer, hoarseness and other forms of voice change are common and expected early symptoms, but they may be later manifestations of *supraglottic and subglottic laryngeal tumors,* which become relatively large without affecting the voice. Tumors of the piriform sinus can affect the voice when they become large and impair the recurrent laryngeal nerve, or they are associated with deep local invasion; pain in the ear or pain on swallowing referred to the ear is also a common and important feature of these tumors. Adults with ear pain or persistent hoarseness should be referred to an otolaryngologist for evaluation. Because this posterior area is difficult to assess, primary tumors are frequently missed in routine office examinations. *Tumors of the supraglottic region, subglottic cancers, and cancers of the piriform sinus* can also be manifested as acute, emergency airway obstruction. Frequently, patients have a history of wheezing and mild upper airway distress in the period leading up to the emergency situation. Occasionally, such findings are confused with adult-onset asthma.

A middle ear infection or effusion in an adult should also prompt an ear, nose, and throat (ENT) evaluation. Nasopharyngeal cancer may be manifested as an ear infection in young adults. Hemoptysis or epistaxis may be the only clue to a nasopharyngeal cancer or a *paranasal sinus tumor.* Cranial nerve findings from deep invasion of the base of skull are late events and include lateral gaze abnormalities, diplopia, facial pain, or facial nerve paralysis. *Sinus tumors* can also be associated with these later findings, although nasal stuffiness occurs frequently and can be confused with sinusitis. New and persistent symptoms of sinusitis or facial pain should raise suspicion of sinus cancer and prompt an evaluation.

Tumors in the tonsil or base of the tongue can cause local pain and referred ear pain; however, they are frequently asymptomatic and can attain a large size before becoming evident as a result of changes in speech ("hot potato voice"), a sense of globus, or restriction of tongue movement. Manifestation as a painless lump in the neck is increasingly common with the increased incidence of HPVOC. Tumors of the tonsil or base of the tongue may also lose their mucosal component, not be seen or felt on direct inspection, and occur as a solid or cystic neck mass. Isolated neck masses can wax and wane with antibiotics. A mass, especially a cystic mass, in the neck in an adult is cancer and specifically HPVOC until proved otherwise and should prompt an ENT evaluation, before fine-needle aspiration (FNA) or excisional biopsy.

The staging of squamous cell carcinoma of the head and neck is based on the TNM (tumor, node, metastasis) staging system, and prognosis is related primarily to the N and T stages (Table 196-1). The risk of the cancer spreading to lymph nodes is directly related to the location of the primary and secondarily to the size of the primary. Tumors of the oropharynx have a high risk for nodal metastases, followed in risk by the supraglottic larynx and piriform sinus (hypopharynx), oral portion of the tongue, soft palate, oral cavity and floor of the mouth, and larynx. Nasopharyngeal cancer is highly associated with extensive nodal spread, whereas paranasal sinus cancers rarely spread to the lymph nodes. The location of lymph node spread is determined in part by site. Nasopharyngeal cancer spreads to the posterior cervical lymph nodes, as well as the high cervical nodes. Oropharynx, larynx, and piriform sinus tumors spread to the high cervical nodes. Nodal metastases from these locations can be bilateral. Oral cavity tumors spread to the submental nodes and submandibular nodes. Spread tends to be orderly from the submandibular nodes to the midcervical nodes. Oral cavity cancers can have as high as a 20% risk of clinically unappreciated contralateral spread.

DIAGNOSIS

The relative accessibility of the head and neck to direct inspection makes physical examination critical for diagnosis and staging. Patients with localized symptoms or a sign such as an ulcer or a small mass should have a thorough head and neck office examination performed by their primary physician and by a specialist, including inspection of the visible structures and palpation of the base of the tongue and tonsil areas, as well as the neck. Specialized office examination with fiberoptics should be included in the preliminary assessment. Regardless of whether cancer is suspected, excisional biopsies should be discouraged because margins are frequently violated and inadequate, thereby leading to larger re-excisions. A simple punch biopsy is sufficient for diagnosis, particularly in the oral portion of the tongue where tumors can spread readily though lymphatics.

When cancer is highly suspected and before definitive surgical intervention, a computed tomography (CT) scan from the base of the skull to the clavicles, preferably with the spiral technique, and a chest radiograph should be obtained. Magnetic resonance imaging (MRI) provides added information in evaluating soft tissue involvement, especially in the base of the tongue and the parapharyngeal spaces and for sinus tumors. MRI can distinguish between soft tissue masses and retained secretions, whereas CT is more helpful in assessing nodal spread in the neck and bone invasion. Positron emission tomography (PET) provides an adjunct to CT scanning and can identify occult disease. PET scanning should be performed when cancer is suspected and when the patient has an "unknown primary tumor," before biopsy, in order to guide the evaluation and reduce the risk of inadequate diagnostic and premature therapeutic procedures (Fig. 196-2).

When a biopsy indicates cancer or cancer is highly suspected, an examination under anesthesia with endoscopy should be performed to stage the primary tumor before definitive therapy is undertaken. This procedure, which provides information regarding the extent of disease, the appropriateness of the planned definitive procedure, and the presence of second primaries, is an absolute requirement before definitive therapy can be discussed with a patient. Endoscopy and palpation under anesthesia can identify unexpected local spread or a synchronous second primary (found in about 5% of patients with environmentally related cancers).

Approach to the Patient with an Unknown Primary Site

Patients frequently seek care from their primary physician because of an enlarged lymph node, a cystic mass, or a collection of lymph nodes in the

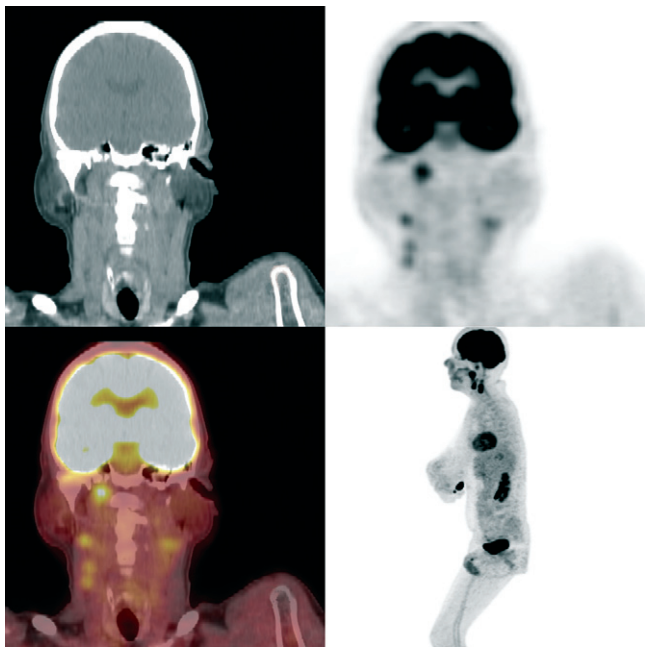

FIGURE 196-2. Positron emission tomography and computed tomography fused images. A primary human papillomavirus–positive base of tongue cancer and neck adenopathy is shown.

T1 T1a T1b	*Supraglottis:* Tumor limited to one subsite of supraglottis with normal vocal cord ability *Glottis:* Tumor limited to the vocal cord(s) (may involve anterior or posterior commissure) with normal mobility Tumor limited to one vocal cord Tumor involves both vocal cords *Subglottis:* Tumor limited to the subglottis	Tumor 2 cm or less in greatest dimension	Tumor 2 cm or less in greatest dimension	Tumor limited to one subsite of hypopharynx and/or 2 cm or less in greatest dimension
T2	*Supraglottis:* Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside the supraglottis (e.g., mucosa of base of tongue, vallecula, medial wall of pyriform sinus) without fixation of the larynx *Glottis:* Tumor extends to supraglottis and/or subglottis, and/or with impaired vocal cord mobility *Subglottis:* Tumor extends to vocal cord(s) with normal or impaired mobility	Tumor more than 2 cm but not more than 4 cm in greatest dimension	Tumor more than 2 cm but not more than 4 cm in greatest dimension	Tumor invades more than one subsite of hypopharynx or an adjacent site, or measures more than 2 cm but not more than 4 cm in greatest dimension without fixation of hemilarynx
T3	*Supraglottis:* Tumor limited to larynx with vocal cord fixation and/or invades any of the following: postcricoid area, pre-epiglottic space, paraglottic space, and/or inner cortex of thyroid cartilage *Glottis:* Tumor limited to the larynx with vocal cord fixation and/or invasion of paraglottic space, and/or inner cortex of the thyroid cartilage	Tumor more than 4 cm in greatest dimension	Tumor more than 4 cm in greatest dimension or extension to lingual surface of epiglottis	Tumor more than 4 cm in greatest dimension or with fixation of hemilarynx or extension to esophagus
T4a	Moderately advanced local disease Tumor invades through the thyroid cartilage and/or invades tissues beyond the larynx (e.g., trachea, soft tissues of neck including deep extrinsic muscle of the tongue, strap muscles, thyroid, or esophagus)	Moderately advanced local disease Lip: Tumor invades through cortical bone, inferior alveolar nerve, floor of mouth, or skin of face, i.e., chin or nose Oral cavity: Tumor invades adjacent structures only (e.g., through cortical bone [mandible or maxilla] into deep [extrinsic] muscle of tongue [genioglossus, hyoglossus, palatoglossus, and styloglossus], maxillary sinus, skin of face)	Moderately advanced local disease Tumor invades the larynx, extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible (Note: Mucosal extension to lingual surface of epiglottis from primary tumors of the base of the tongue and vallecula does not constitute invasion of larynx)	Moderately advanced local disease Tumor invades thyroid/cricoid cartilage, hyoid bone, thyroid gland, or central compartment soft tissue (Note: Central compartment soft tissue includes prelaryngeal strap muscles and subcutaneous fat).
T4b	Very advanced local disease Tumor invades prevertebral space, encases carotid artery, or invades mediastinal structures	Very advanced local disease Tumor invades masticator space, pterygoid plates, or skull base and/or encases internal carotid artery	Very advanced local disease Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery	Very advanced local disease Tumor invades prevertebral fascia, encases carotid artery, or involves mediastinal structures

NODE	DEFINITION
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1*	Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2*	Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a*	Metastasis in single ipsilateral lymph node more than 3 cm but not more than 6 cm in greatest dimension
N2b*	Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c*	Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3*	Metastasis in lymph node more than 6 cm in greatest dimension
METASTASIS	**DEFINITION**
M0	No distant metastasis
M1	Distant metastasis present

*Distribution and prognostic impact of regional lymph node spread from nasopharynx cancer are different from those of other head and neck mucosal cancers and justify the use of a different N classification scheme.
From *AJCC Cancer Staging Manual*. 7th ed. New York: Springer-Verlag; 2010.

upper part of the neck (Fig. 196-3). Such masses in an adult should be considered cancer until proved otherwise. Unless there is an obvious symptom or sign that leads the clinician to the identification of a primary site in the head and neck, such patients are considered to have an unknown primary. Masses in the supraclavicular areas represent primary tumors below the clavicles, and masses in the midneck and cervical regions are almost always from the head and neck. Identification of a primary site is critical to focus therapy, reduce morbidity, and determine prognosis.

The most common primary sites for painless lumps are the oropharynx (base of the tongue and tonsil) and piriform sinus. Oropharynx cancers are frequently due to HPV and a positive HPV-16 polymerase chain reaction test of the biopsy or FNA is presumptive evidence of oropharynx origin. Salivary gland cancers, lymphomas, melanomas, and skin cancers can also be manifested in this manner. Bilateral nodal disease or nodal disease with systemic symptoms may suggest lymphoma. By comparison, pain, warmth, and erythema may suggest an infectious etiology. Intraparotid nodes most likely represent metastases from skin malignancies. Physical examination should include a careful investigation for primary skin cancers. CT, PET, and MRI should be part of the initial evaluation. FNA should be performed and repeated if initially negative. CT-guided biopsy may be indicated if the mass is difficult to approach. If squamous cells are identified, the tumor is most likely a squamous cell carcinoma of the head and neck. Next, endoscopy under anesthesia should be performed with bilateral tonsillectomy and directed biopsies of any abnormalities, areas of firmness, and the base of the tongue, nasopharynx, and ipsilateral piriform sinus, even if they appear normal. Core or excisional (single node <3 cm) biopsy of the lymph node should be performed if the pathology is equivocal and a primary site is not confirmed. Neck dissection can be accomplished if a primary site is not identified and the patient has an N1 or small N2a/b manifestation. Some unknown primaries with squamous histology are never identified. Currently, HPV-16 and EBV are the only molecular markers to distinguish head and neck cancer from skin or salivary gland squamous cancer. EBV positivity indicates a nasopharyngeal cancer, and HPV-16 is an oropharyngeal primary.

In contrast to squamous cell carcinoma of the head and neck, salivary gland cancers are heterogeneous in their natural history and treatment. The three most common histologic types are adenoid cystic carcinoma, mucoepidermoid cancer, and adenocarcinoma. Other histologic types include the aggressive salivary duct cancer and squamous cell cancers, whereas less aggressive histologic varieties include adenocarcinoma ex pleomorphic adenoma and acinic cell carcinoma. Because adenoid cystic carcinoma travels along nerves and can spread hematogenously, careful assessment of the cranial nerves and the chest by CT is indicated before major surgery is undertaken. Patients should also be evaluated for bone and liver metastases. Formal lymph node dissection is not indicated. Ethmoid and sphenoid sinus adenoid cystic carcinomas are locally and regionally aggressive and require specialized surgery and radiation therapy techniques for local and regional control. The behavior of mucoepidermoid carcinoma is determined by histology. Low- and intermediate-grade lesions rarely metastasize. Isolated high-grade tumors spread to local lymph nodes and by hematogenous routes and carry a high risk for the development of lung metastases. The work-up for high-grade lesions should be similar to that for adenoid cystic carcinoma. Local therapy should be directed at local and regional control with lymph node dissection. Radiation therapy is indicated for close microscopic margins or lymph node involvement. Adenocarcinoma, salivary duct cancers, and squamous cell carcinoma are also poor-prognosis lesions with aggressive local and distant behavior. These tumors should be evaluated in the same fashion as aggressive mucoepidermoid carcinomas. Acinic cell carcinoma and carcinoma ex pleomorphic adenoma are relatively rare. They have a propensity for local and regional recurrence if they are not removed in toto. Metastases are rare and tend to be slow growing.

Other Tumors of the Head and Neck

Lymphomas in the head and neck frequently manifest either as nodal disease in the neck or as tumor involving the lymphoid tissues of Waldeyer's ring (Chapters 191 and 192). A primary head and neck cancer may later develop in patients with lymphoma as a consequence of past exposure to tobacco, radiation therapy, or immunosuppression. The tonsil is a preferred site for mantle cell and undifferentiated lymphomas. Mucosa-associated lymphoid tissue (MALT) lymphomas can affect the salivary glands.

In the context of an isolated neck mass, a systematic evaluation (see Fig. 196-3) should be undertaken, even in young adults without a smoking history. The sinonasal T-cell and natural killer cell lymphomas, also known as *lethal midline granulomas*, represent a unique family of lymphomas of the head and neck. These lymphomas are associated with EBV infection (Chapter 385). Solitary, extramedullary plasmacytoma can also occur in the nasopharynx or paranasal sinuses (Chapter 193).

Sarcomas that arise in the head and neck include osteogenic sarcomas (Chapters 208 and 209) and nerve sheath tumors. Paragangliomas, which are rare malignant tumors of the chief cells of nerve paraganglia, can be extensive, multicentric, and vascular. Rhabdomyosarcomas, which have a predilection for the orbit and sinuses, occur in younger persons; the prognosis tends to be better for tumors of the head and neck than for other locations. Olfactory

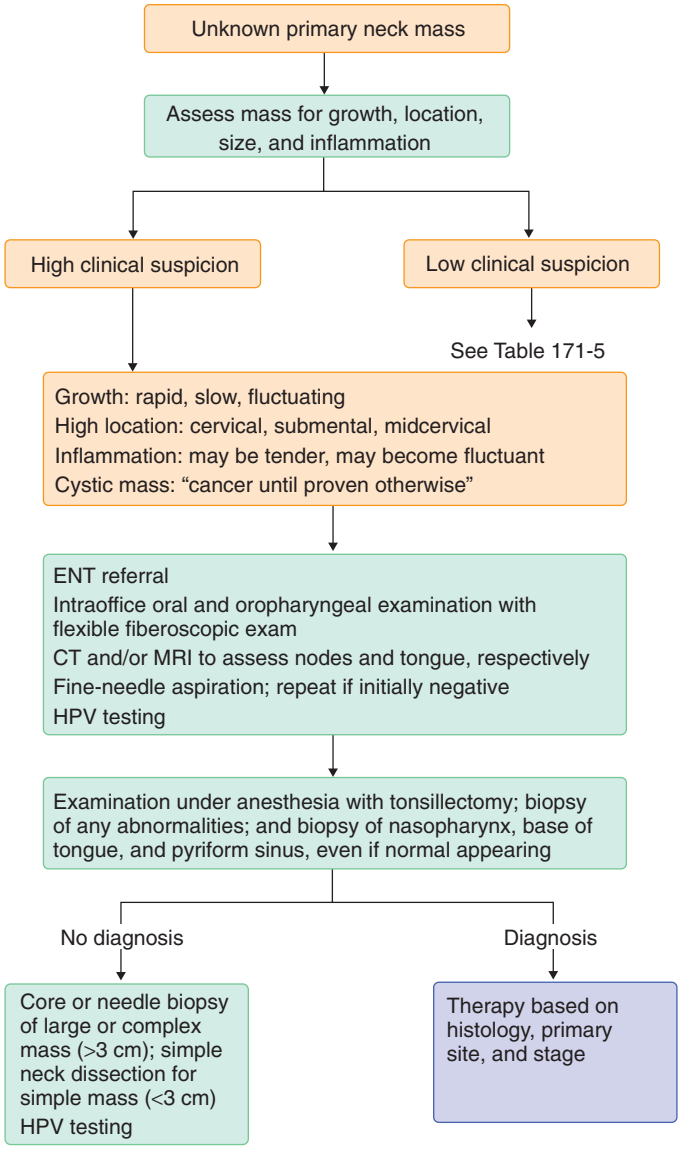

FIGURE 196-3. Evaluation of an unknown primary neck mass. CT = computed tomography; ENT = ear, nose, and throat; HPV = human papillomavirus; MRI = magnetic resonance imaging.

neuroblastomas or esthesioneuroblastomas invade the nasal cavity and base of the skull.

Many skin tumors, including melanoma and squamous cell cancer, can be accompanied by adenopathy of the neck or parotid area (Chapter 210). An unusual skin appendage tumor, Merkel cell cancer, can be confused with other neuroendocrine epithelial tumors.

PREVENTION AND TREATMENT

Rx

Selection of a treatment program for an individual patient is based on three factors: the primary site and stage of the tumor, the patient's comorbid conditions and preferences, and the biology of the tumor (Table 196-2). Early-stage lesions, T1N0 and T2N0, are defined by their size, and their prognosis is site specific. For example, early *larynx cancer* involving the true vocal cords has an excellent prognosis and can be treated by local excision. Voice-preserving larynx conservation surgery is effective for selected patients. Radiation therapy is equally effective for early cancer. When there is a risk of lymph node spread, radiation therapy must be given postoperatively, and the primary value of surgery is diminished. Intensity-modulated radiation therapy (IMRT) allows radiation to be delivered in a more conformal manner to the tumor and areas at risk while sparing critical structures such as the spinal cord and noncritical but important structures such as the salivary glands. IMRT is now a standard of care for patients with head and neck cancer.

Oral tongue, piriform sinus, and environmentally related oropharynx tumors have a worse prognosis and are difficult to stage accurately because of submucosal spread or lymphatic involvement. Stage I and II cancers are cured with local and regional surgery or radiation therapy in 70% to 90% of cases. Surgery may be preferred for oral cavity and anterior lesions. In surgically treated patients, those with a positive margin, two or more positive lymph nodes, or extracapsular spread have a poorer survival rate (<30%) at 5 years. Perineural invasion and lymphovascular invasion may also be associated with a poor prognosis. Postoperative cisplatin-based chemoradiotherapy improves local and regional control, as well as survival, and should be given to poor-prognosis patients if their condition permits.[1] At present, aside from HPV status and p16 immunohistochemistry, no molecular or immunohistochemical finding definitively adds to the information gleaned from pathology, staging, and performance status.

When organ preservation and function are issues for stage III or IV cancers or when radiation therapy is required regardless of surgical outcome, primary chemoradiotherapy or sequential therapy should be considered.[2,3] The curative treatment of intermediate (stage III, T1-3N1, T3N0) and locally advanced (stage IV, T1-3N2-3, T4) disease remains controversial. Long-term (3 years) survival rates in patients with stage III disease are generally between 50 and 75%, whereas only 15 to 50% of stage IV patients survive for 3 years. Intermediate-stage tumors are usually resectable, but organ preservation may be an important consideration. In many of these cases, a combined-modality approach that includes chemotherapy is the standard of care.

Patients with anterior lesions may do better with initial surgical treatment. The oral cavity is easy to assess and is relatively forgiving for surgery and reconstruction; postoperative radiation therapy or chemoradiotherapy can be moderated in the absence of bad prognostic features. For intermediate and advanced tumors, radiation therapy or chemoradiotherapy is a necessary adjunct to prevent recurrence. For example, a T3 or N1 lesion of the oropharyngeal tongue or hypopharynx is almost always more extensive than clinically appreciated and may be more suited to a nonsurgical regional and systemic approach. In addition, patients with rapidly growing tumors are more suitable for a combined-modality approach. Patients with extensive N2 or N3 nodal disease (stage IV) should be considered relatively unresectable because of a poor prognosis from regional recurrence and distant metastases. Certain locations such as the nasopharynx and posterior pharynx should also be considered for definitive radiation therapy, sequential therapy, or chemoradiotherapy.

Radiation therapy has been proved by randomized trials to yield better local control and disease-free survival if given in twice-daily fractionated treatments rather than as daily therapy. However, the absolute benefit of hyperfractionated radiation therapy at 5 years is only 3 to 4%, and it is unclear whether a twice-daily schedule is advantageous with chemotherapy.[4]

Induction chemotherapy is the delivery of chemotherapy before definitive local-regional treatment. Sequential therapy adds chemoradiotherapy (see later) to induction chemotherapy. Induction chemotherapy with docetaxel (75 mg/m^2), cisplatin (75 to 100 mg/m^2 by intravenous bolus), plus 5-fluorouracil (750 to 1000 mg/m^2/day for 4 to 5 days by intravenous infusion), repeated every 3 or 4 weeks (TPF) are effective, standard regimens. For patients with advanced oropharynx, larynx, and hypopharynx tumors, sequential chemotherapy with chemoradiotherapy using concomitant carboplatin and once-daily radiotherapy improves survival and preserves function compared with radiation, surgery, or cisplatin and 5-fluorouracil chemotherapy (PF).[5,6]

Chemoradiotherapy integrates chemotherapy and radiation therapy together and has led to significant improvements in overall survival in patients with advanced disease compared with radiation therapy alone. For example, patients with unresectable disease who received cisplatin (100 mg/m^2 by intravenous bolus) every 3 weeks during radiation therapy have significantly better survival than do those treated with radiation therapy alone.[7] In a trial of patients with oropharyngeal carcinoma, those treated with carboplatin and 5-fluorouracil plus simultaneous radiation therapy had significantly better survival than did those treated by radiation therapy alone.[8] Cetuximab plus radiotherapy has also proved effective in improving survival in patients with locally advanced head and neck cancer compared with radiotherapy alone.[9]

Patients with locally advanced or unresectable disease (or both) should receive chemotherapy as part of a combined-modality approach. Sequential therapy, induction chemotherapy, and chemoradiotherapy all prolong survival compared with surgery or radiotherapy, or both, and support an organ preservation approach. Organ preservation should be offered to patients who can tolerate the treatment and participate in the post-treatment rehabilitation.

Treatment of *tumors of the paranasal sinuses* is a special case. They rarely metastasize, and treatment should focus on surgical resection with postoperative radiation therapy for resectable stage III and IV disease and on chemoradiotherapy for local and regional control of unresectable disease. Proton beam irradiation may be more suited for tumors in and around the base of the skull and brain.

Follow-up

Patients need lifelong follow-up. A chest radiograph should be performed at least yearly, and surveillance examinations for second primaries and

TABLE 196-2 GENERAL APPROACH TO SQUAMOUS CELL HEAD AND NECK CANCER

STAGE	TNM	DISEASE-SPECIFIC SURVIVAL	TREATMENT APPROACH	SPECIAL CONDITIONS
I	T1N0	85-95%	Surgery or radiation therapy	Consider organ function and long-term toxicity
II	T2N0	75-90%	Surgery, radiation therapy, or chemoradiotherapy	Consider organ function Combined-modality treatment for high-volume tumor Postoperative chemoradiotherapy for poor prognostic findings on pathologic staging
III	T3N0 T1-3N1	50-75%	Combined-modality treatment	Primary chemoradiotherapy or TPF induction therapy or sequential therapy for organ function Postoperative chemoradiotherapy More aggressive approach (sequential therapy) for high-volume disease or hypopharynx tumors
IV	T1-3N2-3 T4N0-3 Any M1	20-60%	Combined-modality treatment	Combined-modality therapy Limited surgery Postoperative chemoradiotherapy Palliative therapy for M1 (curative therapy for isolated lung metastases)

recurrences should be performed monthly to bimonthly in the first year and then less frequently over time. Treatment failure after 3 years is uncommon, but second primaries may continue to be identified in environmentally related cancers. It is important to counsel these patients to avoid tobacco products and any exposure to alcohol.

During therapy and immediately after therapy, patients benefit from pain medications, local anesthetics, mucolytics, and saline mouthwash. Patients must avoid alcohol-containing preparations or irritants. Long-acting agents such as fentanyl or time-release narcotics should be added when needed (Chapter 29). A percutaneous endoscopic gastrostomy feeding tube is effective for maintaining weight, improving healing, and managing nutrition during radiation therapy. Because depression is a major problem, psychiatric support and antidepressants may be very helpful. Salivary function improves over more than 4 years after radiation therapy, but most improvement occurs in the first 2 years. Pilocarpine and cevimeline (Evoxac) are effective stimulants of salivary flow in about 20% of patients.

Long-term sequelae of radiation therapy include dependence on a feeding tube in patients treated with aggressive chemoradiotherapy or radiation therapy alone. Attention should be paid to preserving swallowing function by means of training in speech and swallowing, as well as dilation in selected patients. Hypothyroidism occurs in up to 50% of patients and as early as 3 months after treatment. Patients should be monitored by determining serum thyroid-stimulating hormone levels at regular intervals and then be treated as appropriate (Chapter 233). Dental failure is a common problem. Patients must be counseled to see their dentists regularly for cleanings and to obtain fluoride therapy daily for dental preservation. Patients are at substantial lifelong risk for complications from dental manipulations after radiation therapy. Bone necrosis is painful, can be confused with recurrent tumor, and requires vigorous antibiotic therapy, débridement, and possibly hyperbaric oxygen to promote healing.

Patients with recurrent disease, a second primary, or metastatic disease must be evaluated for potential curability. If patients have a recurrence or second primary, curative treatment options are defined by their current stage, their previous therapy, and the interval from their original therapy. Patients who have previously been treated with surgery but not radiation therapy can undergo surgery, radiation therapy, and chemotherapy as part of a curative treatment plan. Patients with a surgically treatable recurrence in an irradiated field should undergo surgery as appropriate. It is important to recognize that the surgery must encompass the entire recurrence. Symptomatically, persistent pain may be the most important indicator of a recurrence, and repeat biopsy should be considered when a suspicious lesion is observed. Surgical salvage may cure as many as 30% of patients with recurrent oral cavity, larynx, or hypopharyngeal tumors. A repeat course of radiation therapy is also acceptable in selected patients.

Patients who are incurable can be managed effectively with palliative therapy to improve quality of life and survival (e.g., tracheostomy for airway control, laryngectomy for pain and aspiration, percutaneous endoscopic gastrostomy tube for feeding). These maneuvers can improve comfort and care in appropriate patients.

Palliative chemotherapy can provide meaningful benefit to some patients. Response rates with single agents are generally poor, and combination therapy offers higher response rates (30 to 50%). The combination of a platinum (cisplatin or carboplatin) plus 5-fluorouracil with an anti-EGF receptor antibody, cetuximab, significantly improves survival, response rate, and progression-free survival compared with the same chemotherapy without cetuximab.

Salivary Gland Tumors

In contrast to squamous cell carcinoma of the head and neck, salivary gland cancers are heterogeneous in their natural history and treatment; however, the mainstays of therapy for these tumors are surgery and radiotherapy. Early symptoms of local-regional recurrence include cranial nerve dysfunction and progressive pain. A PET scan may be useful in distinguishing recurrence from the neuropathy that may result from radiation therapy.

There are no highly active agents or combinations for treatment of metastatic salivary gland tumors. Local therapy can include surgical removal of isolated metastases, radio frequency ablation, and radiation therapy. Response rates are generally in the 20 to 35% range, but prolonged responses are occasionally seen.

Future Directions

Antibodies that target the EGF receptor and other molecular targets may improve local and regional control, as well as survival, when delivered with radiation therapy. Vaccines against EBV and HPV may prevent malignancy in high-risk populations.

PROGNOSIS

The prognosis for patients with squamous cell carcinoma of the head and neck (see Table 196-2) is directly related to the presence of HPV, stage, and performance status. The risk for recurrence declines dramatically at 2 years after definitive treatment, and survival and possible cure can be defined after 3 years. HPV status and then N (nodal) stage are the most important prognostic indicators of potential recurrence, with T (tumor) stage and smoking history being next. Stage I patients (T1N0) have a 90% likelihood of tumor control, whereas stage II patients (T2N0) have greater than 70 to 85% tumor control. Tumor control in stage III patients (T1-2N1, T3N0-1) is site dependent and HPV status dependent and varies from 35 to 85%. Patients with stage IVa and IVb environmentally related disease (T1-3, N2-3, or T4NX) have a 20 to 50% tumor-specific 5-year survival rate compared with 60 to 90% 5-year survival for HPVOC. Bad prognostic signs in advanced-stage (IVb) patients are related to N3 nodal disease and invasion of basic structures (carotid artery encasement, base of the skull, pterygoid muscles). Patients with M1 disease are categorized as stage IVc. Isolated patients with single lung metastases can be cured, whether as a second primary or as an isolated recurrence. Patients with recurrent disease and no curative options have a median survival of 6 to 9 months. Death can occur as a result of compromise of local critical structures, including vessels, breathing, and swallowing.

Distant metastases occur in about 15 to 20% of patients, but this rate is increasing as better local and regional control prolongs survival in patients with locally advanced disease. Oropharyngeal, tonsil, and piriform sinus tumors have the highest risk for distant metastases. In approximately 5% of patients, a synchronous lung tumor or metastasis develops. A single lung metastasis in a patient at initial evaluation or at follow-up can be cured in about 20% of cases.

Salivary gland cancers vary in behavior, depending on their histology. Adenocarcinoma, salivary duct cancer, salivary squamous cell cancer, and high-grade mucoepidermoid cancer not only spread to lymph nodes but also spread rapidly hematogenously. The presence of lymph node metastases

signals a high risk for distant metastases. Adenoid cystic carcinoma infrequently involves lymph nodes but spreads along nerves. Regional recurrences along cranial nerves are frequent and associated with "skip" lesions. Adenoid cystic carcinoma is also associated with the late development of lung metastases, but these patients can have a prolonged lifespan lasting more than 20 years. Low-grade mucoepidermoid cancer and acinic cell carcinoma have little risk of distant spread and are more notable for local recurrence if not completely removed.

LUNG CANCER AND OTHER PULMONARY NEOPLASMS

DAVID S. ETTINGER

BRONCHOGENIC LUNG CANCER

DEFINITION

Lung cancer (e.g., bronchogenic carcinoma) arises from the respiratory epithelium. Lung cancer is divided into two major histologic groups: non–small cell lung cancer (NSCLC) and small cell lung cancer (SCLC). NSCLC accounts for approximately 85% of all lung cancer. Other less common pulmonary neoplasms include adenosquamous carcinoma, carcinoid tumors, bronchial gland tumors, soft tissue tumors (e.g., sarcomas), pulmonary blastomas, and lymphoma.

EPIDEMIOLOGY

Worldwide, lung cancer accounts for approximately 13% of all cancer; more than 1.1 million cases of lung cancer are diagnosed annually, and more than 1 million deaths are caused by the disease. In the United States, 28% of all annual cancer deaths (30% in men, 26% in women) are due to lung cancer; lung cancer is the leading cause of cancer death in both men and women.

The incidence and mortality of lung cancer in American men and women reflect their smoking habits (Chapter 31). Lung cancer deaths started rising in men in the 1950s and in women 10 to 15 years later. Cancer death rates from lung cancer decreased in men by 37% between 1990 and 2005; however, in women, the cancer death rate from lung cancer between 1991 and 2005 increased approximately 8%. Worldwide, increasing lung cancer rates are predicted to continue in less developed countries as a result of increasing endemic use of tobacco.

The U.S. Surveillance, Epidemiology and End Results (SEER) program estimated that 1 in 14 men and women will be at risk for the development of lung cancer during their lifetime. Incidence and mortality rates vary by race/ethnicity (Table 197-1), with African American men having a higher incidence and mortality rate than other racial/ethnic groups. Incidence rates of lung cancer for men and women in the United States from the period 2002 to 2006 are 77.7 and 52.5 per 100,000 people, respectively. The median age at diagnosis in both sexes is 71 years.

Unfortunately, tobacco use in high-school students increased until the mid-1990s, but now it is slowly declining. Despite this decline, 38% of high-school seniors smoke. This smoking at an earlier age may in part explain the occurrence of lung cancer in younger patients.

Risk Factors

Tobacco

It is estimated that cigarette smoking is responsible for approximately 85 to 90% of all cases of lung cancer, including 90% of cases in men and 80% in women. More than 40 carcinogens have been identified in cigarette smoke (Chapter 31). The risk for development of lung cancer correlates with the number of cigarettes smoked per day, lifetime duration of smoking, age at onset of smoking, degree of inhalation, tar and nicotine content of the cigarettes, and use of unfiltered cigarettes. If a lifelong nonsmoker has a relative risk ratio of 1 for the development of lung cancer, cigarette smokers of less than ½ pack/day, ½ to 1 pack/day, 1 to 2 packs/day, and more than 2 packs/day have risk ratios of 15, 17, 42, and 64, respectively. The risk ratio in ex-smokers is dependent on the duration of abstinence of cigarette smoking; to reach a risk ratio of 1.5 to 2.0 requires abstinence of approximately 30 years.

Pipe and cigar smoking are also risk factors for lung cancer, but the risk is thought to be less than that associated with cigarette smoking, possibly because such tobacco products tend to be inhaled less deeply than cigarette smoke. Marijuana and cocaine smoking probably cause an increased risk for lung cancer, but the carcinogenicity of the two drugs is less well studied than that of cigarette smoking.

Environmental Tobacco Smoke

Exposure to environmental tobacco smoke (i.e., passive smoking) by nonsmokers, especially in the workplace, increases the risk for the development of lung cancer. The exposure levels of environmental tobacco smoke depend on the size of the enclosed space and the intensity of smoking.

Other Exposure

The International Agency for Research on Cancer classified the following as group 1 known carcinogens for lung cancer: radon, asbestos, arsenic, beryllium, bis(chloromethyl)ether, cadmium, chromium, nickel, vinyl chloride, and polycyclic aromatic hydrocarbons (PAHs) (Chapters 18 and 93). Group 2A probable carcinogens include acrylonitrile, formaldehyde, and diesel exhaust. Group 2B possible carcinogens include acetaldehyde, silica, and welding fumes. It is estimated that 9% of lung cancers in men and 2% in women are caused by occupational exposure.

Radon, a gaseous decay product of uranium-238 and radium-226, damages lung tissue by emitting alpha particles. Underground mining of uranium

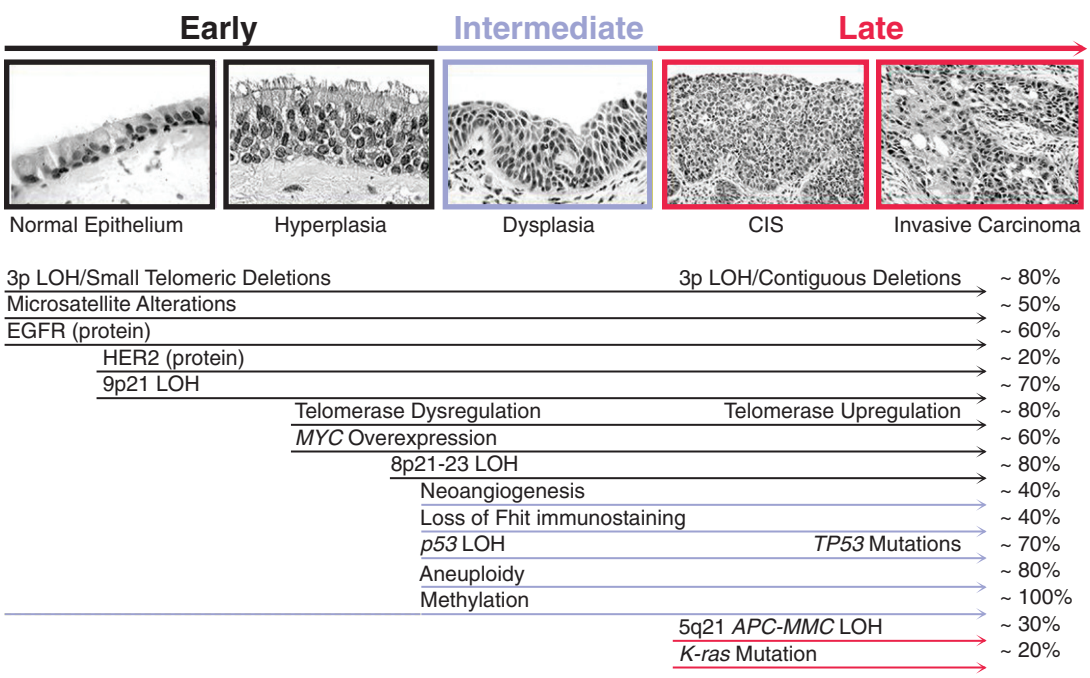

FIGURE 197-1. Sequential changes during the pathogenesis of lung cancer. CIS = carcinoma in situ; LOH = loss of heterozygosity. (From Hirsch FR, Franklin WA, Gazdar AF, et al. Early detection of lung cancer: clinical perspectives of recent advances in biology and radiology. *Clin Cancer Res.* 2001;7:5-22. Updated courtesy of Fred R. Hirsch, MD, PhD, Department of Medical Oncology, University of Colorado Health Sciences Center, and Adi F. Gazdar, MD, Department of Pathology, Southwestern Medical Center.)

exposes miners to radon and its decay products, thus increasing their risk for lung cancer. Radon may appear in homes, especially basements, because it is present in soil rock and ground water and enters the home through defects in pipes or the foundation. The indoor radon level depends on the soil concentration and ventilation rate. Data are conflicting about the risk for lung cancer with exposure to domestic radon, but the consensus is that the risk is increased.

Exposure to asbestos fibers (Chapter 93) occurs in automobile shops, shipyards, mines, and textile and cement plants and in construction and insulation workers. Workers with asbestosis, not just asbestos exposure, have an increased risk for lung cancer. Cigarette smokers with asbestos exposure have a risk of lung cancer that is multiplicative—a 50-fold relative risk compared with unexposed nonsmokers. The latency period for the development of lung cancer in workers exposed to asbestos is 25 to 40 years.

Arsenic, a naturally occurring metal, is a byproduct of copper, lead, zinc, and tin ore smelting. The metal is also present in agricultural pesticides and marine organisms. Exposure to arsenic occurs through air, soil, water, and foods. Cigarette smokers exposed to arsenic are at greater risk for the development of lung cancer than those not exposed to arsenic.

Beryllium, a metal used for alloys, is a pulmonary carcinogen. Exposure occurs in mining and in the manufacture of ceramics and electronic equipment. Bis(chloromethyl)ether is a product of chloromethylation processes used in the manufacture of ion exchange resins, polymers, and plastics. The relative risk for lung cancer in exposed workers is 10, especially for SCLC. Cadmium is a metal used for electroplating metals, batteries, plastics, and pigments. Exposure to cadmium causes an increased risk for lung cancer. Chromium is commonly used for metal alloys, paint pigments, electroplating, cement, rubber, photoengraving, and the composition of floor covering. Exposure to chromium increases the risk for lung cancer two- to three-fold. Nickel is used in electroplating, manufacturing of steel and other alloys, ceramics, storage batteries, electric circuits, and petroleum refining. Nickel exposure increases the risk for lung cancer 1.56-fold. Vinyl chloride is used to make plastics, packaging materials, propellant in cosmetic products, and vinyl floor tiles. Although the risk for development of lung cancer after exposure to vinyl chloride is increased, it is considered small. PAHs are formed from the incomplete combustion of organic material. Exposure to PAHs occurs with cigarette smoke; smelting of nickel-containing ores; aluminum, iron, steel, and coke production; coal tar; and diesel exhaust. PAHs carry a 1.5 to 2.5 relative risk for lung cancer.

Preexisting Lung Disease

Tobacco smoking causes chronic inflammation and destruction of lung tissue, which results in chronic obstructive pulmonary disease (COPD) (Chapter 88). Patients with COPD have an approximately four-fold increased risk for lung cancer. In addition, patients in whom idiopathic pulmonary fibrosis or pulmonary fibrosis from asbestosis or silica develops are at increased risk for the development of lung cancer.

Dietary Factors

Increased consumption of fruits and green and yellow vegetables is associated with a reduced risk for lung cancer, whereas low serum concentrations of antioxidant vitamins such as vitamins A and E are associated with the development of lung cancer. However, β-carotene supplementation increases the incidence of lung cancer.

Increased consumption of dietary fat is also associated with an increased incidence of lung cancer. High blood concentrations of selenium, a mineral involved in the protection of cellular membranes, has been associated with a lower risk for lung cancer.

Gender and Racial Differences

Women who smoke have a 1.2- to 1.7-fold higher risk ratio than men, especially for adenocarcinoma and SCLC. Possible explanations for this difference in lung cancer risk include (1) effects of hormones such as estrogen on the development of lung cancer, (2) gender differences in nicotine metabolism, and (3) gender variations in cytochrome P-450 enzymes involved in the bioactivation of toxic components in cigarette smoke condensate.

The high incidence and mortality of lung cancer in African American males may be due, in part, to (1) increased tobacco use, (2) differences in the metabolism of tobacco smoke, and (3) higher intake of dietary fat.

Human Immunodeficiency Virus Infection

Some studies suggest that the risk for lung cancer is increased in patients infected with human immunodeficiency virus (HIV) (Chapter 398), mostly as a result of cigarette smoking. Most patients are male (10 : 1) and young, in part reflecting the demographics of HIV infection.

Inheritance

First-degree relatives of patients with lung cancer have a two- to six-fold increase in the risk for lung cancer after adjusting for tobacco use. Second-degree relatives of lung cancer patients have a relative risk of 1.28, and third-degree relatives have a relative risk of 1.14. Nonsmokers with a family history of lung cancer have a two- to four-fold increased risk for lung cancer. The familial risk may be due to shared exposure, such as environmental tobacco smoke, or to shared genetic susceptibility to environmental carcinogens.

PATHOBIOLOGY

The development of lung cancer is the result of a multistep process from a premalignant lesion to frank cancer (Fig. 197-1) after a number of years.

Tobacco smoke or other carcinogens promote sequential genetic and epigenetic changes that result in the loss of normal control mechanisms of cellular growth. These changes affect (1) oncogenes, which are homologues of normal cellular genes and, when mutated, result in activation and gain of function; (2) tumor suppressor genes, which are "cancer" genes, in which loss of function by mutation removes inhibitions to control cell growth; and (3) growth factors (Chapter 185).

Oncogenes

The oncogenes that play a role in the pathogenesis of lung cancer include *ras,* the *myc* family, *HER-2/neu* (*ERBB2*), and *Bcl-2*. The *ras* family of oncogenes has three primary members (H-*ras,* K-*ras,* and N-*ras*), one of which, K-*ras,* is activated by point mutations in codon 12 of lung cancer cells. The mutation occurs in 30% of adenocarcinomas of the lung, most often in patients with a history of smoking, but it has not been found in SCLC. Patients who have the K-*ras* mutation have a poorer prognosis, stage for stage.

Amplification and overexpression of the *myc* family oncogenes (a-*myc,* L-*myc,* N-*myc*) are seen in 10 to 40% of SCLC and 10% of NSCLC. The most frequently altered gene, however, is c-*myc,* whose amplification in SCLC tumors that relapse is associated with shorter survival. However, overexpression of the *myc* oncogene is not present in most lung cancers, so its overexpression is probably not a primary event.

The *HER-2/neu* (*ERBB2*) gene, which encodes growth factor receptor or p185 neu (a tyrosine kinase glycoprotein), is activated in NSCLC but not SCLC. Overexpression of *HER-2/neu* in patients with adenocarcinoma of the lung portends a poor survival. *Bcl-2*, an oncogene that encodes a protein that inhibits programmed cell death (apoptosis), is also overexpressed in lung cancer, especially in SCLC.

Tumor Suppressor Genes

Tumor suppressor genes include *p53, Rb,* and *3p* (Chapter 185). The *p53* mutation correlates with cigarette smoking and has been detected in preneoplastic lesions of the lung. Mutations of *p53* are common in both NSCLC (~50%) and SCLC (~80%).

In SCLC, *Rb* is often mutated or deleted, so the Rb protein is not expressed in 90% of SCLC. In NSCLC, Rb is normally expressed, but when Rb is phosphorylated, uncontrolled cell division can occur in NSCLC.

One of the earliest genetic abnormalities in lung cancer occurs with the deletion of genetic material on the short arm of chromosome 3(3p) (p14-p23). The deletion occurs in approximately 50% of NSCLC and 90% of SCLC. The *FHIT* (fragile histidine triad) gene (3p14.2) is abnormal in many lung cancers and may function as a tumor suppressor gene by suppressing tumor growth and causing apoptosis.

Growth Factors

Growth factors secreted by lung cancer cells may reflect adjacent or regional cells (paracrine stimulation) or cause autonomous proliferation of the cells from which they were secreted (autocrine stimulation). Cells that are affected by this autocrine stimulation secrete a biologically active growth factor. Antibodies that bind to this growth factor will inhibit cell growth.

Autocrine (peptide) growth factors that are important in the growth of lung cancer cells, particularly SCLC, include gastrin-releasing peptide (GRP), insulin-like growth factor type I (IGF-I), and hepatocyte growth factor. GRP occurs in approximately 20 to 60% of SCLC and less frequently in NSCLC. Hepatocyte growth factor is expressed mainly in NSCLC.

The oncogene c-*erB-1* encodes the epidermal growth factor receptor (EGFR), a 170-kD tyrosine kinase glycoprotein. Activation of EGFR initiates autophosphorylation of the receptor and eventually leads to cell cycle proliferation. Activating mutations in the *EGFR* gene have been found in 10 to 17% of patients with NSCLC; these patients have had an up to 75% response rate to the tyrosine kinase inhibitors, gefitinib or erlotinib.

Epigenetics

Epigenetics refers to a change in gene expression that is heritable but does not involve a change in DNA sequence. One of these epigenetic modifications involves changes in DNA methylation. These changes, which are very common in lung cancer, can include hypomethylation, dysregulation of DNA methyltransferase I, and hypermethylation. Genes that are methylated in NSCLC include *p16, RAR-β, RASSFIA,* methylguanine-methyltransferase, and death-associated protein kinase (DAP-kinase). This hypermethylation can silence tumor suppressor genes, thereby permitting unregulated cell growth.

CLINICAL MANIFESTATIONS

As many as 15% of patients in whom lung cancer is diagnosed are initially asymptomatic. The diagnosis is usually made incidentally on a chest radiograph obtained for other reasons (e.g., a preoperative study). However, most patients have symptoms and signs that are (1) caused by the pulmonary lesion itself—local tumor growth, invasion, or obstruction; (2) intrathoracic—regional tumor spreading to lymph nodes and adjacent structures; (3) extrathoracic—distant spread of disease; and (4) paraneoplastic syndromes. Nonspecific signs and symptoms of lung cancer include anorexia in about 30% of patients, weight loss, fatigue in third of patients, and anemia and fever in 10 to 20% of patients. More than 80% of patients initially have three or more symptoms or signs as a result of the lung cancer.

Pulmonary Lesion

Symptoms resulting from the primary lung cancer depend on the location and size of the cancer. Such symptoms can be secondary to endobronchial or peripheral growth of the primary tumor. The most common, cough, occurs in approximately 45% of cases, but it is nonspecific and also common in patients who smoke and have COPD. Hemoptysis occurs in more than 30% of patients, but the most common causes of hemoptysis are bronchitis and bronchiectasis. Dyspnea also occurs in 30 to 50% of patients. Wheezing is uncommon as an initial symptom in lung cancer and may signify major airway obstruction, which can cause a postobstructive pneumonia that may not initially be evident on chest radiographs and may be diagnosed only when the pneumonia fails to respond to standard therapy (Chapter 97). Lesions may be cavitary and may be associated with an abscess at the time of diagnosis of the lung cancer.

Peripheral lung tumors may be asymptomatic but are more frequently associated with symptoms of cough and pain from involvement of the pleura or chest wall. Chest pain, which occurs in more than 25% of patients, may be dull in nature, but chest pain that is severe and persists may be due to chest wall involvement.

Intrathoracic Spread

Symptoms associated with intrathoracic spread may be related to direct extension of the tumor or metastasis to regional lymph nodes. Dysphagia may occur secondary to esophageal compression. Although tracheoesophageal or bronchoesophageal fistulas are uncommon, coughing associated with swallowing or the development of aspiration pneumonitis (Chapter 97) should point to this possibility. Hoarseness, which is associated with recurrent laryngeal nerve paralysis, occurs in less than 20% of cases; it is more common with left-sided lung tumors because the nerve on this side has a longer intrathoracic course than the right-sided nerve. Phrenic nerve paralysis with hemidiaphragmatic elevation is associated with dyspnea and hiccups. Apical tumors, such as superior sulcus NSCLC (Pancoast's syndrome), may cause Horner's syndrome (Chapter 427), pain secondary to rib destruction, atrophy of hand muscles, and pain in the distribution of the C8, T1, and T2 nerve roots because of tumor invasion of the brachial plexus.

Blockage of the superior vena cava (SVC) (Chapter 99) as a result of compression or direct invasion by the tumor itself or by enlarged mediastinal lymph nodes may cause dyspnea. Signs of SVC syndrome include facial swelling, plethora, upper extremity swelling, dilated neck veins, and a prominent venous pattern on the anterior surface of the chest. Lung cancer accounts for most cases of SVC syndrome, with most cancer being SCLC and located on the right side.

Other manifestations of intrathoracic spread include pleural effusion (Chapter 99) causing dyspnea; pericardial effusion (Chapter 77) and cardiac extension of the tumor (Chapter 60) causing heart failure, arrhythmia, or tamponade; and lymphangitic spread through the lungs causing dyspnea and hypoxemia.

Extrathoracic Spread

At diagnosis, 30 to 40% of patients with NSCLC and approximately 60% of patients with SCLC have extrathoracic hematogenous spread of their tumor. Bone metastasis occurs in 30 to 40% of patients with lung cancer and commonly involves the vertebrae, ribs, and pelvic bones. Pain is the primary symptom. Liver metastases can produce right upper quadrant abdominal pain as well as nonspecific symptoms of fatigue and weight loss. Adrenal metastases can cause pain but most often cause no symptoms. One gland is usually involved, but bilateral metastases may occur. Brain metastasis, which occurs in 25 to 50% of SCLC and 25% of adenocarcinomas of the lung, may

cause no symptoms but is more commonly associated with nausea, vomiting, headaches, seizures, confusion, personality changes, and focal neurologic signs and symptoms, depending on the site of metastatic disease. Epidural, intramedullary spinal cord metastasis and diffuse leptomeningeal involvement are less common than cerebral and cerebellar metastases.

Paraneoplastic Syndromes

Paraneoplastic syndromes (Chapter 187) occur in approximately 10 to 20% of patients with lung cancer. Endocrine syndromes include hypercalcemia, the syndrome of inappropriate antidiuretic hormone secretion, and ectopic adrenocorticotropic hormone secretion (Chapter 186). Other endocrine paraneoplastic syndromes of lesser clinical significance produce hormones such as the β-subunit of human chorionic gonadotropin, prolactin, gastrin, growth hormone, thyroid-stimulating factor, insulin-like substance, and calcitonin.

Neurologic syndromes are relatively rare, are most commonly associated with SCLC, and may have autoimmune mechanisms. Such syndromes include Eaton-Lambert syndrome, limbic encephalopathy, cerebellar degeneration, subacute sensory neuropathy, autonomic neuropathy, and optic neuritis (Chapter 187). Skeletal manifestations include digital clubbing (see Fig. 450-5 in Chapter 450) and hypertrophic pulmonary osteoarthropathy (Chapter 187).

Hematologic and vascular syndromes include hypercoagulable states, migratory thrombophlebitis (Trousseau's syndrome), and nonbacterial thrombotic endocarditis (Chapters 60 and 179). Cutaneous manifestations include dermatomyositis, acanthosis nigricans, erythema gyratum repens, and hyperkeratosis of the palms and soles of the feet (Chapter 187).

DIAGNOSIS

The diagnosis of lung cancer is made by cytologic examination of tissue biopsy specimens, sputum (Fig. 197-2), bronchial washings and brushings of suspicious lesions (Fig. 197-3), bronchoalveolar lavage fluid, and transbronchial and transthoracic needle aspirates (Fig. 197-4). The greater number of viable tumor cells in biopsy specimens from transthoracic, endobronchial, transbronchial, or open biopsy procedures increases the probability of accurate diagnosis. Sputum cytology may be only 20% sensitive for peripheral lung lesions, but it may be 80% sensitive for central lesions. In general, the sensitivity of a single sputum specimen is approximately 50%, whereas examination of three or more specimens increases the sensitivity to nearly 90%. The sensitivity of a single bronchial washing and brushing for detecting lung cancer is approximately 65%. For bronchoalveolar lavage fluid, the sensitivity is 60 to 65%. The sensitivity of fine-needle aspiration biopsy for detecting lung cancer exceeds 85%.

Solitary Pulmonary Nodule

A solitary pulmonary nodule is an asymptomatic lesion less than 3 cm in diameter surrounded by normal lung parenchyma that is incidentally found on a chest radiograph or computed tomography (CT) scan (Fig. 197-5). A solitary pulmonary nodule is found in up to 0.2% of all chest radiographs, and 10 to 70% are malignant. The chance of any solitary pulmonary nodule being cancerous correlates with the size and growth rate of the nodule, the age of the patient, any history of smoking, and a previous history of a malignancy. It is important to compare previous chest radiographs with the one demonstrating the nodule. A nodule that has not changed in size for at least 2 years is probably benign; a high-resolution CT scan with a resolution of 0.3 mm can best assess its size and growth characteristics. Solitary pulmonary nodules smaller than 4 mm have a 1% risk of malignancy, whereas a nodule larger than 8 mm has a 10 to 20% risk. In the latter situation, serial CT scans are indicated; positron emission tomography (PET) and biopsy should be considered. PET is 96.8% sensitive and 77.8% specific for identifying a malignancy, but because both false-negative and false-positive results can occur, tissue is needed for a definitive diagnosis. Transthoracic fine-needle aspiration biopsy, bronchoscopy, thoracotomy, and video-assisted thoracoscopic surgery (VATS) can establish a diagnosis.

Pathology

The histologic classification of lung cancer includes adenocarcinoma (about 40%), squamous cell (epidermoid) carcinoma (~30%), large cell carcinoma (~15%), and small cell carcinoma (~15%). These four histologic types represent more than 95% of all lung cancer.

Squamous cell carcinoma and adenocarcinoma are further classified by their differentiation: well differentiated, moderately differentiated, and poorly differentiated. The latter types of cells are more aggressive and may have a worse prognosis than well-differentiated tumors. Adenocarcinoma is the most frequent histologic type in women and nonsmokers. Bronchoalveolar carcinoma, a subtype of adenocarcinoma, is well differentiated, grows along intact alveolar septa, and can be localized, multinodular, multifocal, or diffuse.

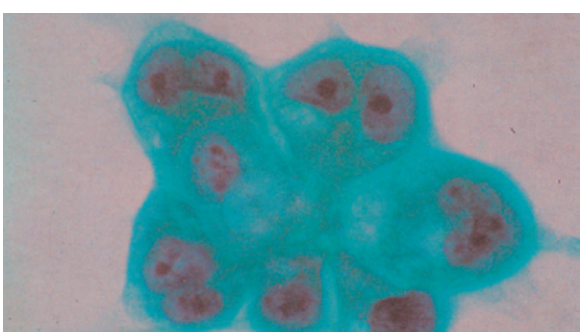

FIGURE 197-2. Adenocarcinoma cells in a sputum smear. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London, Mosby, 2003.)

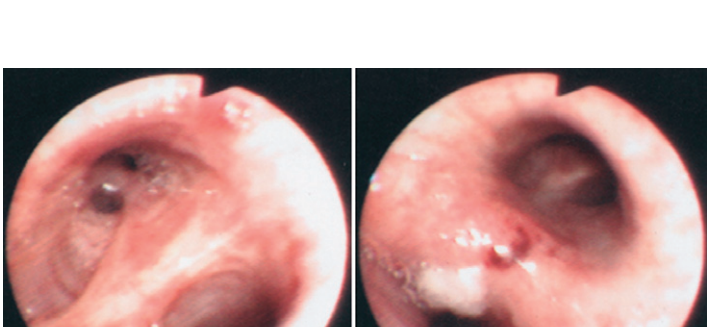

FIGURE 197-3. Squamous cell carcinoma. Left, Carina between the lingular and upper division bronchus of the left upper lobe. Note the well-defined, sharp features of the carina. **Right,** Carina between the left upper and lower lobes in the same patient. Note the swollen, red, infiltrated appearance of the mucosa and the white exophytic lesion. In addition, there is subepithelial hemorrhage. A biopsy specimen demonstrates squamous cell carcinoma. The patient had increased sputum production, positive sputum cytologic findings, and a nonlocalizing chest radiograph and computed tomography scan.

From a practical perspective based on biologic differences, clinical features, growth properties, and treatment, bronchogenic lung cancer is divided into two main categories: NSCLC and SCLC. In general, all NSCLCs are generally treated the same way based on the stage of the disease. SCLC is usually characterized by more aggressive biology, and treatment is dependent on whether the SCLC is limited stage (i.e., locally advanced) or extensive stage (i.e., metastatic disease).

Staging

Staging of NSCLC involves classification according to T (tumor size), N (regional lymph node involvement), and M (presence or absence of distant metastases). In October 2009, the TNM staging for NSCLC changed (Table 197-2). For SCLC, TNM staging is not generally used; rather, SCLC is staged as limited disease, defined as disease that can be encompassed by a single radiation portal, or extensive disease, that extending beyond a single radiation portal (usually metastatic).

Staging Procedures

All patients with lung cancer should be clinically staged using a complete history with a focus on performance status and weight loss; physical examination; pathologic review of all biopsy material; complete blood cell and platelet counts; chemistry profile, including renal and liver function tests, electrolytes, glucose, calcium, and phosphorus; and chest radiograph and chest CT (including the upper part of the abdomen and adrenal glands). Magnetic resonance imaging (MRI) of the brain and radionuclide scan of

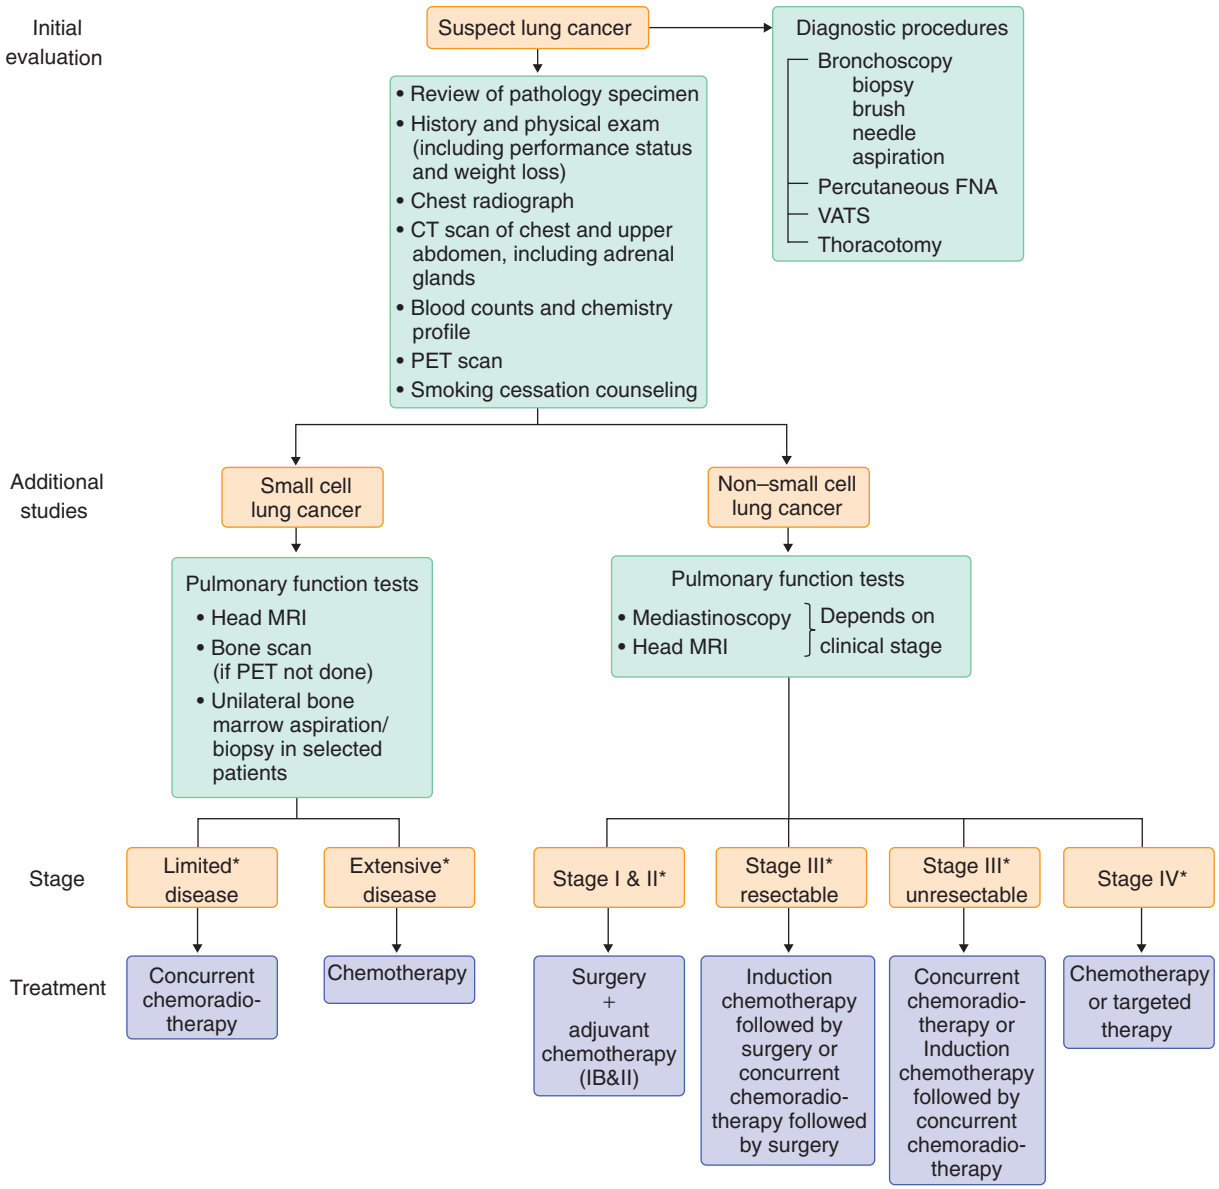

FIGURE 197-4. Schematic overview for diagnosing, staging, and treating non–small cell and small cell lung cancer. See text for details. (Consult practice guidelines in oncology, non–small cell lung cancer, and small cell lung cancer at www.nccn.org as well for specifics.) *See Tables 197-2 and 197-3. CT = computed tomography; FNA = fine-needle aspiration; MRI = magnetic resonance imaging; PET = positron emission tomography; VATS = video-assisted thoracic surgery.

bones should be performed if metastases to these organs are suspected. Radiographs or MRI should be obtained if bone lesions are suggested by radionuclide scanning. PET is used to assess both regional and metastatic spread of tumor. Pulmonary function tests and arterial blood gas determinations should be obtained only if needed for treatment purposes.

For patients with SCLC, the initial pretreatment staging evaluation is similar to that used for NSCLC patients. For patients with peripheral blood count abnormalities, bone marrow aspiration and biopsy are recommended. Twenty to 30% of patients with SCLC will have tumor in bone marrow at the time of diagnosis.

Imaging

Radiography

A standard posteroanterior and lateral chest radiograph, although inexpensive and easy to perform, has limited value in the staging of lung cancer. Although it can detect pulmonary nodules as small as 3 to 4 mm, it is not reliable in detecting hilar or mediastinal lymphadenopathy.

Computed Tomography

A CT scan is commonly used to evaluate whether lung cancer is present in the hilar and mediastinal lymph nodes, liver, and adrenal glands, but its accuracy in identifying mediastinal lymph node involvement is suboptimal (sensitivity of 40 to 65% and specificity of 45 to 90% versus either a PET scan or mediastinoscopy). Most importantly, CT will miss small metastatic foci that do not result in mediastinal lymph node enlargement. Mediastinal lymph nodes that are normal in size (≤1 cm) have an 8 to 15% probability of having metastatic disease, whereas mediastinal lymph nodes that are 1 to 1.5 cm, 1.5 to 2 cm, and greater than 2 cm in size will contain metastases 15 to 30%, approximately 50%, and about 90% of the time, respectively.

Positron Emission Tomography

PET, which uses 2-[^{18}F]fluoro-2-deoxy-D-glucose to identify areas of increased glucose metabolism in lung tumors, is more sensitive than CT in staging lung cancer (see Fig. 197-5); it has a sensitivity of 83%, specificity of 96%, and negative predictive value of 96%. However, increased glucose metabolism also occurs with inflammatory processes. Obtaining both PET and CT scans can enhance accuracy in the staging of lung cancer. PET also enhances detection of bone, liver, and adrenal metastases. However, if treatment decisions are to be based on PET scan results, positive PET scan findings require pathologic or other radiologic confirmation.

Evaluation of Mediastinal Tissue

After initial clinical staging, if a patient with NSCLC has potentially surgically resectable disease, the regional lymph nodes (mediastinum) must be sampled

TABLE 197-2 STAGING OF LUNG CANCER

STAGE	TUMOR	NODE	METASTASIS	GENERAL DESCRIPTION
NON–SMALL CELL LUNG CANCER*				
Local				
IA	T1a,b	N0	M0	T1 tumor: ≤3 cm, surrounded by lung or visceral pleura, not more proximal than the lobar bronchus T1a ≤ 2, T1b > 2 but ≤3 cm
IB	T2a	N0	M0	T2 tumor: >3 cm, but ≤7 cm; or tumor with any of the following: invades visceral pleura; involves main bronchus ≥2 cm distal to the carina; associated with atelectasis/obstructive pneumonia extending to hilum but not involving the entire lung; T2a > 3 but ≤5 cm
IIA	T1a,b T2a T2b	N1 N1 N0	M0	T2b > 5 but ≤ 7 cm N1: involvement of the ipsilateral peribronchial or hilar nodes and intrapulmonary nodes including involvement by direct extension
Locally Advanced				
IIB	T2b T3	N1 N0	M0 M0	T3 tumor: tumor >7 cm or directly invading chest wall, diaphragm, mediastinal pleura, pericardium; or tumor in the main bronchus, <2 cm distal to the carina; or atelectasis or pneumonitis of the entire lung; or separate tumor nodules in the same lobe
IIIA	T1-3 T3 T4	N2 N1 N0,1	M0 M0 M0	N2: involvement of the ipsilateral mediastinal or subcarinal nodes T4 tumor: tumors of any size with invasion of the heart, great vessels, trachea, recurrent laryngeal nerve, esophagus, vertebral body, carina; or separate tumor nodules in a different ipsilateral lobe
Advanced				
IIIB	T4 T1-4	N2 N3	M0 M0	N3: involvement of the contralateral mediastinal or hilar nodes or any supraclavicular nodes
IV	Any T	Any N	M1a,b	M1a: separate tumor nodules in a contralateral lobe; or tumor with pleural nodules or malignant pleural dissemination M1b: distant metastasis
SMALL CELL LUNG CANCER†				
Limited disease				Evidence of tumor confined to the ipsilateral hemithorax; can be encompassed by a single radiation port
Extensive disease				All other diseases, including metastatic disease

The staging classification system was refined by the Union Internationale Contre le Cancer (UICC) and the American Joint Committee on Cancer (AJCC) with help from the International Association for the Study of Lung Cancer (IASLC). T = tumor, N = node, M = metastases. SCLC staging was developed by the Veterans Administration Lung Study Group.

*Detterbeck FC, Boffa DJ and Tanoue LT. The new lung cancer staging system. *Chest.* 2009;136:260-271.

†Stahel RA, Ginsberg R, Havermann K, et al. Staging and prognostic factors in small cell lung cancer: a consensus. *Lung Cancer.* 1989;5:119-126.

for possible metastases. Fiberoptic bronchoscopy to assess the bronchi and transbronchial needle aspirates to evaluate for mediastinal lymphadenopathy are recommended. Transbronchial needle aspirates are positive in 35 to 40% of patients when a CT scan demonstrates hilar or mediastinal lymphadenopathy. The larger the size of the lymph node on CT scan, the greater the chance for the aspirate to be positive.

The gold standard for evaluating the mediastinal lymph nodes for metastatic disease during life is transcervical mediastinoscopy. The subaortic and aortopulmonary window lymph nodes are inaccessible by routine mediastinoscopy, and the subcarinal lymph nodes may be difficult to access. The accuracy of the procedure ranges from 80 to 90%, with a false-negative rate of 10 to 12%. Other procedures used to evaluate the mediastinal lymph nodes include extended cervical mediastinoscopy, anterior mediastinotomy, thoracoscopy, and VATS. Endoscopic ultrasound (EUS) and endobronchial ultrasound (EBUS) biopsies of mediastinal lymph nodes can significantly reduce unnecessary thoracotomies when used in the staging of lung cancer.

TREATMENT

Refer also to Table 197-3 and Figure 197-4.

Non–Small Cell Lung Cancer

Stage I and II Disease

For stage I and II NSCLC, surgery is the initial treatment of choice. Before surgical resection, a comprehensive preoperative medical evaluation is mandatory (Chapter 439). This evaluation must be supplemented by pulmonary function tests (forced expiratory volume at 1 second [FEV_1] and diffusing capacity of the lung for carbon monoxide [DLCO]), as well as blood gas analysis (Chapter 85). FEV_1 and DLCO will determine what surgical procedure can be performed safely—pneumonectomy, lobectomy, wedge resection, or segmentectomy. A preoperative FEV_1 less than 40% of predicted and a DLCO less than 40% of normal are associated with an increase in operative mortality. Threshold levels to define resectability include a preoperative FEV_1 greater than 2.0 L and DLCO greater than 60% for pneumonectomy and a preoperative FEV_1 greater than 1.5 L and DLCO greater than 50% for lobectomy. Other factors for determining resectability include exercise tolerance and comorbid disease. The curability of the patient is dependent on the stage of disease and completeness of the resection and not whether lobectomy or pneumonectomy is performed. By comparison, there is a significant risk of local recurrence in patients undergoing wedge resection or segmentectomy rather than more extensive resection of the tumor. Mortality rates for lobectomy and pneumonectomy are 3% and 9%, respectively. For patients older than 70 years, the mortality rate for pneumonectomy rises to 16 to 25%.

For patients with stage I NSCLC who either refuse surgery or have coexisting illnesses that preclude surgery, the use of stereotactic radiotherapy (SRT) shows high local control rates with minimal toxicity. Randomized trials of SRT and surgery for stage I NSCLC are ongoing.

At surgery, a tumor is considered to be unresectable if metastasis is found in the pleura or contralateral mediastinal lymph nodes or if there is tumor invasion of the mediastinum, heart, great vessels, or other structures. In addition to surgical resection of the tumor, sampling or complete removal of all accessible mediastinal lymph nodes should be performed.

Adjuvant cisplatin-based chemotherapy (e.g., cisplatin, 80 mg/m^2 every 3 weeks for four doses or 100 mg/m^2 every 4 weeks for four doses, plus vinorelbine 30 mg/m^2 weekly or vinblastine 4 mg/m^2 weekly or etoposide 100 mg/m^2 per day for 3 days per cycle) provides a small absolute increase in overall survival at 5 years for stage I, II, and III disease.

Adjuvant radiation therapy for stage I and II disease is not indicated. However, in patients with stage I NSCLC who for medical reasons are not candidates for surgery, radiation therapy can be given with curative intent. Five-year survival rates in patients thus treated range from 10 to 30%.

Stage III—Resectable

For patients with stage III resectable disease (ipsilateral mediastinal spread of disease [N2], tumors [T3] involving the chest wall, diaphragm, or pleura; or superior sulcus tumors [Pancoast's]), surgery alone is suboptimal treatment because of the presence of occult metastatic disease. Neoadjuvant (i.e., induction) chemotherapy given in sequence with or concurrent with radiation therapy before surgery improves survival when compared with surgery alone or surgery plus postoperative radiation therapy. However, concurrent chemoradiation therapy causes significant esophagitis when compared with the use of sequential chemotherapy and radiation therapy.

Stage III—Unresectable

Stage IIIA or IIIB disease may be unresectable. Thoracic radiation therapy (total dose, 60 Gy) relieves symptoms in the chest but has little effect on 5-year survival rates unless combined with induction chemotherapy (e.g., vinblastine plus cisplatin for two cycles), which improves median survival from 9.7 months to 13.8 months and the 5-year survival rate from 7 to 19% when compared with radiation therapy alone.

Concurrent chemotherapy and radiation therapy rather than sequential therapy can improve survival in patients with locally advanced NSCLC but increases side effects, particularly esophagitis, by five-fold. To improve the effectiveness of radiation therapy, different fractionation approaches are under evaluation. Three-dimensional treatment planning permits delivery of higher doses of radiation to the primary tumor and regional lymph nodes without increasing toxicity.

Stage IV—Disseminated Disease

For patients with disseminated NSCLC, treatment generally consists of cisplatin or carboplatin combined with paclitaxel, docetaxel, gemcitabine, vinorelbine, pemetrexed, irinotecan, or topotecan. The response rate to such

TABLE 197-3 GENERAL APPROACH TO THE TREATMENT OF LUNG CANCER ACCORDING TO STAGE*

STAGE	PRIMARY TREATMENT	ADJUVANT THERAPY	OUTCOME
NON–SMALL CELL LUNG CANCER			
I	Surgical resection	Chemotherapy (stage 1B)	5-yr survival rate >60-70%
II	Surgical resection	Chemotherapy	5-yr survival rate >40-50%
IIIA (resectable)	Preoperative chemotherapy followed by surgical resection (preferable) or chemotherapy followed by radiation therapy	Chemotherapy with or without radiation therapy	5-yr survival rate 15-30%
IIIA (unresectable) or IIIB (involvement of the contralateral or supraclavicular lymph nodes)	Chemotherapy plus concurrent radiation therapy (preferable) or chemotherapy followed by radiation therapy	None	5-yr survival rate, 10-20%
IV	Chemotherapy with 2 agents for 4-6 cycles Chemotherapy + bevacizumab (selected patients) EGFR-TKI (erlotinib, gefitinib) in patients with positive *EGFR* gene mutation Surgical resection of solitary brain metastasis and surgical resection of primary (T1) lesion	None	Median survival 8-10 mo 1-yr survival rate 30-35% >70% response rate; PFS-HR 0.48; median survival >20 mo 2-yr survival rate 10-15% 5-yr survival rate 10-15%
SMALL CELL LUNG CANCER			
Limited disease†	Chemotherapy plus concurrent radiation therapy	None	5-yr survival rate 15-25%
Extensive disease†	Chemotherapy	None	5-yr survival rate <5%

*All chemotherapy regimens include either cisplatin or carboplatin. The second drug used as part of the regimen may include etoposide, paclitaxel, docetaxel, vinorelbine, gemcitabine, or irinotecan.
†Prophylactic cranial irradiation is recommended for all patients with a complete response to initial therapy.
EGFR = epidermal growth factor receptor; PFS HR = progression-free survival hazard ratio.
Modified from Spira A, Ettinger DS. Multidisciplinary management of lung cancer. *N Engl J Med.* 2004;350:379-392.

therapy is 20 to 50%, with a median survival of 8 to 10 months, 1-year survival rate of 30 to 35%, and 2-year survival rate of 10 to 15%. Data suggest that two-drug combinations are better than single-agent therapy, but three-drug combinations are not more effective than two-drug combinations. The duration of therapy is four to six cycles, and patients older than 70 years who have good performance status respond to and tolerate chemotherapy as well as younger patients.

Over the past several years, the treatment of patients with disseminated NSCLC has changed. The era of "personalized therapy" has arrived, with treatment decisions being made based on histologic subtypes (nonsquamous vs. squamous cell carcinoma) and EGFR mutation analysis. Pemetrexed in combination with cisplatin has been approved for first-line treatment of patients with metastatic nonsquamous NSCLC.■ The use of bevacizumab (an antiangiogenesis drug) in combination with paclitaxel plus carboplatin demonstrated a significant improvement in overall response rate, progression-free survival, and overall survival compared with chemotherapy alone in patients with non–squamous cell advanced NSCLC.■ EGFR–tyrosine kinase inhibitors such as erlotinib or gefitinib in patients having tumors with activating mutations in the *EGFR* gene have significant clinical efficacy compared with standard chemotherapy when given as first-line treatment in patients with disseminated NSCLC.■ Future therapies for patients with NSCLC will be based on genomic, pharmacogenomic, and proteomic strategies.

Patients with a solitary metastasis may occasionally benefit from resection of the isolated metastatic lesion. For example, resection of a solitary brain metastasis followed by whole brain irradiation can potentially be curative, with 5-year survival rates as high as 20%. Patients with metastatic NSCLC can benefit from palliative radiation therapy to specific lesions that cause bronchial obstruction, SVC syndrome, bone pain, brain masses, and spinal cord compression. Early palliative care promotes quality of life and mood as well as survival in patients with metastatic non–small cell lung cancer.■

Small Cell Lung Cancer

The mainstay of treatment of SCLC is chemotherapy because the disease is characterized by its propensity for a rapid growth rate and spread to distant sites. Unfortunately, management of SCLC has changed little in the past decade.

Limited Stage

Thirty to 40% of SCLC patients have limited-stage disease. Management usually consists of chemotherapy and radiation therapy, and surgery is indicated only in the approximately 5% of patients who have a solitary peripheral pulmonary nodule without evidence of mediastinal lymph node involvement with clinical staging. After surgical removal of the SCLC nodule, patients with negative mediastinal lymph nodes at surgery require only postoperative chemotherapy with etoposide and cisplatin. The 5-year survival rate in patients with no mediastinal lymph node involvement is 30 to 60%. If the nodes contain metastases, chest irradiation is recommended in addition to chemotherapy.

For most patients with limited-stage SCLC, concurrent chemotherapy and radiation therapy appear to be more effective than sequential therapy. In the United States, etoposide and cisplatin plus concurrent radiation therapy (i.e., twice-a-day irradiation—total dose of 45 Gy) is the treatment of choice and produces a 5-year survival rate of 26% compared with 16% when given with the same dose of radiation once a day.

In patients who achieve a complete response to therapy, prophylactic cranial irradiation (24 to 36 Gy) reduces the risk for brain metastases and provides about a 5% survival advantage, but its higher risk of precipitating cognitive abnormalities must be taken into consideration, especially in elderly patients.

Extensive Stage

For extensive-stage SCLC, chemotherapy is the treatment of choice. In the United States, etoposide plus cisplatin or carboplatin is commonly used. Carboplatin causes significantly less nausea, vomiting, and neurotoxicity. The chemotherapy is administered every 3 weeks for four to six cycles. At this time, there is no evidence that maintenance therapy with either chemotherapy or targeted molecular therapy increases survival rates.

SCREENING AND PREVENTION

Screening

Unfortunately, most patients with lung cancer are initially found to have advanced disease that is not curable. Screening chest radiographs have been unsuccessful in improving outcome. Spiral CT scanning is four- to five-fold more sensitive than chest radiography for detecting malignant nodules in high-risk patients, but spiral CT also detects seven to eight benign nodules for every malignant nodule found. A large trial is currently ongoing to determine whether current or former smokers benefit from screening with spiral CT.

Prevention

Primary prevention of lung cancer focuses on ways to prevent individuals from smoking and promotion of smoking cessation (Chapter 31). Trials of supplemental doses of β-carotene and vitamin E, stimulated by epidemiologic evidence of lower serum levels of these antioxidants in patients with lung cancer, have not only been unsuccessful but actually produced a higher risk of lung cancer in smokers who received either of these supplements. High concentrations of selenium in blood are associated with a lower risk of lung cancer, and an ongoing trial is comparing selenium with placebo in patients who have survived resection for stage I lung cancer.

PROGNOSIS

Most patients in whom lung cancer is diagnosed have incurable disease, with an overall 5-year survival rate of approximately 15%. What determines the chance for survival is the stage of disease in NSCLC and whether the disease is extensive or limited in the case of SCLC (Table 197-4).

OTHER PULMONARY NEOPLASMS

Neuroendocrine Lung Tumors

Neuroendocrine lung tumors are classified into four types: carcinoid tumors, atypical carcinoids, SCLC, and large cell neuroendocrine carcinomas. Carcinoid tumors are low-grade neuroendocrine tumors with a 10-year survival rate of greater than 90%. Atypical carcinoid tumors are intermediate-grade tumors, more aggressive than carcinoid, with survival ranging from 10 months to 3 years. Large cell neuroendocrine carcinoma is an aggressive neuroendocrine tumor that does not meet the criteria for either carcinoid, atypical carcinoid, or SCLC.

Bronchial Carcinoid Tumors

Carcinoid tumors (Chapter 240) of the lung account for 1 to 2% of all lung neoplasms. They are neuroendocrine tumors that trace their origin to the Kulchitsky cell present in bronchial epithelium. Typical and atypical carcinoids differ in the number of mitoses (<2 per 10 high-power fields [HPF] vs. 2 to 10 per 10 HPF, respectively), nuclear pleomorphism (absent vs. present), regional lymph node metastases (5 to 15% vs. 20 to 28%), and distant metastases at initial evaluation (rare vs. 20%). Patients with a typical carcinoid tumors rarely die, whereas patients with atypical carcinoid tumors have a 5-year mortality rate of 27 to 47%. Carcinoid tumors are not associated with cigarette smoking, are twice as common in women as in men, usually occur in patients younger than 40 years, and arise in the perihilar area of the lung. Treatment of bronchial carcinoid tumors is based on the stage of the disease. Usually, mediastinal staging is followed by surgical resection. With mediastinal lymph node involvement, radiation therapy is recommended for typical carcinoid tumors if surgery cannot be performed. For atypical carcinoid or metastatic disease, chemotherapy (etoposide plus cisplatin every 3 weeks for four cycles) plus radiation therapy is commonly used, but there is no evidence for the benefit of one therapy over another.

Malignant Mesothelioma

Pleural mesotheliomas (Chapter 99) are related to asbestos exposure (Chapter 93), with a peak risk 30 to 35 years after the initial exposure to asbestos. Approximately 50% of patients in whom a mesothelioma develops give no history of direct asbestos exposure. Other possible risk factors for mesothelioma include radiation and SV40 virus. Mesothelioma is generally diagnosed in the fifth to seventh decade of life (median age, 60 years), with the neoplasm developing in men five times more frequently than in women. Common symptoms include shortness of breath (60%) and chest wall pain or discomfort (60%). Chest radiographs usually reveal the presence of a unilateral pleural effusion. When the tumor progresses, it is generally local; symptomatic distant metastases are a late occurrence, if at all. Cytologic evaluation of pleural fluid to establish the diagnosis is difficult and may be inaccurate. The diagnosis is usually made by a biopsy procedure—under CT guidance or thoracoscopically, including VATS if necessary. Several staging systems have been proposed, but none has achieved complete acceptance. Treatment, which depends on the extent of disease, includes surgery (thoracoscopy with sclerosis, pleurectomy, extrapleural pneumonectomy), radiation therapy, and, often, chemotherapy. These three modalities individually have not significantly improved survival rates, and chemotherapy also has not helped control symptoms. Multimodality and molecularly targeted agents are being evaluated. Mesothelioma remains a fatal disease, with a median survival of 9 to 12 months from the time of diagnosis.

Other Lung Tumors

Carcinomas of the salivary gland type include mucoepidermoid carcinoma and adenoid cystic carcinoma. These tumors are slow-growing neoplasms that arise from the bronchial glands. They represent approximately 0.2% of lung cancers and are usually treated surgically.

Primary sarcomas of the lung are very rare and include malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma, rhabdomyosarcoma, epithelioid hemangioendothelioma, angiosarcoma, and liposarcoma. Surgery is the primary treatment, but radiation therapy or chemotherapy, or both, may be necessary, depending on the size and grade of the tumor and whether the margins are clear (Chapter 209).

Primary lymphomas of the lung account for approximately 0.3% of all primary cancers of the lung. The most common type is a low-grade small lymphocytic lymphoma. Surgery and chemotherapy (Chapter 191) are the usual treatments.

198 NEOPLASMS OF THE ESOPHAGUS AND STOMACH

ANIL K. RUSTGI

NEOPLASMS OF THE ESOPHAGUS

DEFINITION

The esophagus is a hollow tubular organ with primary physiologic functions related to contraction to permit propulsion of solid and liquid food contents into the stomach. Benign disorders of contraction are designated as esophageal motility disorders and discussed in Chapters 138 and 140. The mucosa is a stratified squamous epithelium that covers the submucosa and muscle; the latter is skeletal muscle in the proximal esophagus and smooth muscle in the mid-distal esophagus. Cancers of the esophagus may be classified broadly into epithelial versus nonepithelial. There are benign epithelial tumors referred to as *squamous cell papillomas*. Malignant epithelial tumors are classified into two main subtypes: esophageal squamous cell carcinoma (ESCC) and esophageal adenocarcinoma (EAC) (Table 198-1), which serves as the focus of this chapter's section. Apart from ESCC and EAC, other esophageal epithelially derived tumors include verrucous squamous cell carcinoma, adenosquamous carcinoma, adenoid cystic carcinoma, and mucoepidermoid carcinoma. Benign nonepithelial tumors include leiomyoma, granular cell tumors, fibrovascular polyp, hemangioma, lymphangioma, lipoma, and fibroma. Malignant nonepithelial tumors include leiomyosarcoma and other sarcomas, metastatic carcinoma (originating from breast, lung), and lymphoma.

Esophageal Squamous Cell Carcinoma

EPIDEMIOLOGY

ESCC is the more common type of esophageal cancer worldwide and represents a leading cause of cancer-related mortality in men. ESCC may have rates of up to 100 per 100,000 population in what is often termed the *central Asian belt*, including regions around the Caspian Sea, Iran, India, and China; other areas of high incidence include some Mediterranean countries and South Africa. In the United States, ESCC is more common among African American males than white males, with risks of 15.1 per 100,000 compared with 2.9 per 100,000, respectively. Overall, although the incidence of ESCC

TABLE 198-1 RISK FACTORS FOR ESOPHAGEAL CANCER

Barrett's esophagus

is low in males or females younger than 50 years, it does increase with advancing age.

Risk Factors

Cancers in general are viewed in the context of hereditary or inherited forms versus sporadic or seemingly random diseases that are related to age, environmental exposures, and genetic alterations (see Table 198-1). That being said, the hereditary basis for ESCC is exceedingly rare, consisting of a desquamating condition termed *tylosis palmaris et plantaris*. As implied, the desquamation most dramatically affects the hands and feet, but this extends to the esophagus as well. Another uncommon condition is called *Plummer-Vinson syndrome* or *Paterson-Brown Kelly syndrome*, which entails glossitis, cervical esophageal webs, and iron deficiency anemia. In both conditions, it is likely that chronic inflammation triggers the cascade of events that culminate in ESCC.

The vast preponderance of ESCC cases are attributable to cigarette smoking or alcohol, but especially so in combination because there appear to be synergistic deleterious effects of various chemical carcinogens in both, including *N*-nitroso compounds, polycyclic aromatic hydrocarbons, and aromatic amines. The relative risk for ESCC is 6.2 in those who smoke more than 25 cigarettes on a daily basis. Cessation of cigarette smoking is helpful in attenuating risk after 10 years of abstinence. Cigarette smokers who partake in beer and whiskey have a 10- to 25-fold enhanced risk of developing ESCC. Indeed, it is the type of alcohol and the manner of distillation that are most critical. In endemic areas of the world, deficiencies of vitamins A, B_{12}, C, and E, folic acid, and certain minerals (zinc, selenium, molybdenum) are important risk factors. All these vitamins and minerals exert direct or indirect antioxidant effects, and their deficiencies impair epithelial and tissue homeostasis and regeneration.

Other risk factors for ESCC include achalasia (Chapter 140), a disorder that involves agangliosis of Auerbach's plexus, resulting in dysphagia, chest pain, and weight loss, among other symptoms. The emergence of ESCC may be observed 10 to 20 years after the identification of achalasia in patients. Because head and neck squamous cell carcinoma (HNSCC) (Chapter 196) shares many of the environmental and lifestyle risk factors with ESCC, HNSCC and ESCC may occur synchronously or metachronously. In different parts of the world, ESCC is also associated with chronic esophageal stricture due to lye ingestion, consumption of maté (a hot herb-based beverage), celiac sprue, human papillomavirus infection, and radiation injury.

PATHOBIOLOGY

ESCC involves the transition over time from normal squamous epithelium to squamous dysplasia to cancer. ESCC initiation, progression, and metastasis are associated with a number of genetic alterations. Among the genetic alterations are overexpression of *epidermal growth factor receptor* and *cyclin D1* oncogenes, and inactivation of *TP53*, *p16INK4A*, and *E-cadherin* tumor suppressor genes. The frequency of these changes varies greatly based on the studies, but the oncogenic alterations appear to be generally early onset in dysplasia and early ESCC, whereas the inactivation of the tumor suppressor genes appear to be late events in established primary and metastatic ESCC. From a genomic viewpoint, the SOX-2 transcriptional factor, important in the pluripotent capacity of somatic cells, has been shown to be an important gene involved in ESCC pathogenesis and transformation by virtue of SOX-2 amplification. The ability to model ESCC in vitro and in vivo has witnessed great strides in recent years through the advent and characterization of three-dimensional organotypic culture models, xenograft transplantation mouse models, and genetically engineered mouse models.

CLINICAL MANIFESTATIONS

Symptoms and Signs

Although esophageal squamous dysplasia is typically not associated with symptoms, ESCC, which has a predilection for the proximal to mid esophagus, may be associated with dysphagia, odynophagia, atypical or typical chest pain, gastrointestinal bleeding, nausea, vomiting, weight loss, and malnutrition. ESCC may metastasize to local lymph nodes, lung, liver, and bone. Symptoms attributable to metastatic ESCC may involve bone-related pain, dyspnea, and evidence of jaundice and liver failure, depending on the extent of metastatic disease.

Physical Examination

The patient should be evaluated for changes in hair, skin integrity, and nail beds as a reflection of malnutrition. Weight loss may result in general cachexia and muscle wasting. There may be lymphadenopathy in the anterior cervical and superclavicular regions. Hepatomegaly and complications of liver disease may be present with metastatic disease to the liver.

Laboratory Studies

There may be progressive iron deficiency anemia due to chronic, indolent upper gastrointestinal bleeding. Additional abnormalities may be reflected in metabolic disturbances, such as metabolic alkalosis due to vomiting and hypernatremia due to dehydration. Liver enzyme abnormalities, both hepatocellular and cholestatic, may reflect metastasis to the liver. There are no specific markers for ESCC, but an elevated carcinoembryonic antigen (CEA) level may be used to aid in diagnosis or to monitor disease recurrence after therapy.

DIAGNOSIS

Barium swallow radiography is useful for the diagnosis of ESCC with depiction of a filling defect due to the mucosal lesion or impaired transit of barium due to luminal growth. However, definitive diagnosis involves direct visualization with upper endoscopy; once the mass is visualized, biopsies are necessary for confirmation by histopathology and possibly immunohistochemistry for cytokeratins associated with proliferation and differentiation. ESCC may involve local lymph nodes, which are best detected by endoscopic ultrasound; as needed, samples can be then analyzed for cytopathology by fine-needle aspiration. Evaluation of metastatic disease involves chest and abdominal/computed tomography (CT) scans. Bone scan might be useful in patients who are symptomatic with bone-related pain. Positron emission tomography (PET) has become increasingly used in some settings, although there are no guidelines for its routine use. In totality, these diagnostic modalities also allow for staging of ESCC (Table 198-2), which is important in guiding therapeutic options.

TREATMENT Rx

Surgical Therapy

Surgery is the cornerstone of therapy for curative intent. Technical advances have led to improvements in both operative mortality and postoperative morbidity. The different surgical techniques include transthoracic, transhiatal, and radical en bloc resections. Depending on the location of the ESCC, either total esophagectomy or subtotal esophagectomy is pursued. For the latter, jejunal or colonic interposition can be done.

Minimally invasive surgery may be done for esophagectomy in selected patients.

Medical Therapy

Depending on the stage, there is some variation in whether to proceed with preoperative (neoadjuvant) chemoradiation therapy or postoperative (adjuvant) chemoradiation therapy.

A study in which patients were randomized to receive surgery alone or surgery plus postoperative chemotherapy with 5-fluorouracil and leucovorin and concurrent radiation therapy revealed that the median survival was 36 months for patients in the adjuvant arm compared with 26 months for those in the surgery-only arm. The 3-year overall survival rates were 50% compared with 40%, respectively.

PROGNOSIS

The 5-year survival for treated ESCC is dependent on stage and types of therapies used as indicated previously. For stages T1 and T2 without lymphadenopathy, surgery alone may be curative in more than 60% of cases. For patients with metastatic disease, therapy is palliative involving endoscopically placed expandable prosthetic stents to open the nearly obstructed lumen for passage of food contents, percutaneous endoscopic gastrotomy tubes for delivery of nutrition to the stomach distal to the mass lesion, total parenteral nutrition, pain control, and systemic chemotherapy.

Esophageal Adenocarcinoma

EPIDEMIOLOGY

EAC affects whites more than African Americans and males much more than females (3 : 1 to 5.5 : 1) and increases in incidence after the age of 40 years. The age-adjusted incidence annually is 1.3 per 100,000. We will deal with EAC as a separate entity from gastroesophageal (GE) adenocarcinomas (so-called GE junctional cancer) and gastric cardia adenocarcinomas, although there has been a tendency by some to think of these in aggregate. That being stated, the incidence of EAC is increasing dramatically in developed

*(1) At least maximal dimension of the tumor must be recorded and (2) multiple tumors require the T(m) suffix.
†High-grade dysplasia includes all noninvasive neoplastic epithelia that was formerly called carcinoma in situ.

*Number must be recorded for total number of regional nodes sampled and total number of reported nodes with metastasis.

From *AJCC Cancer Staging Manual*, 7th ed. New York: Springer-Verlag; 2010.

countries, especially in the United States (by 4 to 10% annually) and western and northern Europe.

Etiology

Obesity (central) is an important risk factor for EAC. This may be related to either mechanical factors that foster greater gastroesophageal acid reflux disease (GERD) or the release of proinflammatory cytokines and adipokines that track to the esophagus, or both. The major recognized precursor of EAC is Barrett's esophagus (BE). BE is the replacement of the normal stratified squamous epithelium by an incomplete small intestinal type of epithelium (metaplasia) in the distal esophagus projecting from the GE junction in a distal-proximal gradient. In turn, it has been demonstrated that BE is fostered by GERD but also by an admixture of bile acids in the acid refluxate. Patients with scleroderma (Chapter 275) may be at increased risk for BE. A small subset of BE patients may progress to EAC through intermediate stages of low-grade and high-grade dysplasia. In BE, one case of EAC is estimated to arise in 55 to 441 patient years, which corresponds to an approximately 125-fold increased risk for EAC compared with that in the general population.

PATHOBIOLOGY

BE, or incomplete intestinal metaplasia, involves transdifferentiation from normal esophageal epithelium to an epithelium of the small intestine with columnar enterocytes and secretory goblet cells, but without Paneth cells and enteroendocrine cells—hence the designation of incomplete intestinal metaplasia. By itself, BE metaplasia cannot become EAC. However, if and when BE transitions to low-grade and high-grade dysplasia, there is the aforementioned risk for EAC. BE is associated with abnormal DNA ploidy based on flow cytometry analysis, and certain genetic alterations in epidermal growth factor receptor signaling, *TP53* and *p16INK4A*. Microsatellite instability may be noted as well. Whole genome approaches are revealing gains and losses of chromosomal regions that might lead to identification of known and previously unknown genes critical in the pathogenesis of EAC.

CLINICAL MANIFESTATIONS

Symptoms and Signs

It is estimated that 5 to 15% of GERD patients may develop BE, but such population-based studies are difficult to pursue because vast millions of people are affected with GERD, and most GERD patients do not undergo upper endoscopy. Patients with BE may or may not have symptoms related to GERD. Chronic GERD with BE may be associated with distal esophageal strictures. With EAC, patients may suffer from dysphagia, odynophagia, upper gastrointestinal bleeding, chest pain, nausea, vomiting, early satiety, weight loss, and malnutrition.

Physical Examination

Examination of the patient may reveal signs consistent with malnutrition and weight loss. Lymph adenopathy should be explored. There may be hepatomegaly. Paraneoplastic syndromes are unusual with EAC (as well as with ESCC) in contrast to non–small cell lung cancer (NSCLC) or pancreatic adenocarcinoma. Nevertheless, it is important to ensure that EAC is not mistaken for a benign entity such as a primary esophageal motility disorder.

Laboratory Studies

Patients with EAC may suffer from iron deficiency anemia, metabolic derangements, and abnormal liver enzyme tests due to metastatic disease. CEA may be elevated as a tumor serologic marker.

DIAGNOSIS

Barium swallow radiography may lead one to the suspicion of BE and can diagnose luminal mass lesions consistent with EAC in the distal esophagus. However, the mainstay of diagnosis is upper endoscopy. At that time, one will appreciate a salmon-colored mucosa from the GE junction with frondlike projections in a proximal direction. If the extent of BE is less than or equal to 3 cm, it is termed *short-segment BE;* if it is more than 3 cm, it is referred to as *long-segment BE*. This distinction is important in that the risk for EAC in long-segment BE is greater than in short-segment BE. Noting that the normal esophageal mucosa is more pink-white in hue, one can visually distinguish the two different types of epithelia, with the caveat that the gastric cardia mucosa at the GE junction should not be mistaken for BE. With that in mind, endoscopic mucosal biopsies from the BE region (with control biopsies from the normal esophagus and gastric cardia) are required for diagnosis histopathologically. Features of dysplasia are best appreciated in the absence of reflux-related esophagitis that can lead to nuclear architectural distortion; hence, suppression of acid production with proton pump inhibitor therapy for 6 to 8 weeks is needed, with a view to repeat biopsies.

If the patient has BE metaplasia, upper endoscopy should be repeated every 2 to 3 years. However, low-grade dysplasia requires surveillance endoscopy every 6 to 12 months. High-grade dysplasia, if properly evaluated by the pathologist, may require reconfirmation, but then leads to either medical (radiofrequency ablation, endoscopic mucosal resection) or surgical intervention due to the possibility of missed contiguous EAC. Endoscopic ultrasound may be helpful in discriminating between high-grade dysplasia and EAC.

TREATMENT

Rx

The principles are very similar to those applied to ESCC in terms of surgery. Data support adjuvant chemoradiation therapy for EAC, with median survival of 27 months for surgery alone versus 36 months for surgery plus chemoradiation therapy. Overall prognosis for EAC is not too dissimilar from that noted in ESCC. The treatment options of BE, the main precursor of EAC, have witnessed dramatic growth. Initially, photodynamic therapy was viewed with favor. However, for patients who are not surgical candidates because of comorbid illnesses, endoscopic mucosal resection (EMR) and radio frequency ablation■ are credible options, especially for BE-related high-grade dysplasia or BE associated with intramucosal EAC.

NEOPLASMS OF THE STOMACH

DEFINITION

Gastric neoplasms are predominantly malignant, and nearly 90 to 95% of these tumors are adenocarcinomas. Less frequently observed malignant diseases include lymphomas, especially non-Hodgkin's lymphoma, and sarcomas, such as leiomyosarcoma. Benign gastric neoplasms include leiomyomas, carcinoid tumors, and lipomas.

Adenocarcinoma of the Stomach

EPIDEMIOLOGY

The great geographic variation in the incidence of gastric cancer worldwide strongly indicates that environmental factors influence the pathogenesis of gastric carcinogenesis. Further support for this notion comes from observations that groups emigrating from high-risk to low-risk areas, such as Japanese individuals moving to Hawaii and Brazil, acquire the low risk of the area into which they emigrate, presumably because of adoption of the endogenous lifestyle and exposure to different environmental factors.

Gastric adenocarcinoma was the most frequently observed malignant disease in the world until the mid-1980s, and it remains extremely common among men in certain regions, such as tropical South America, some parts of the Caribbean, and Eastern Europe. Regardless of gender, it remains one of the most common malignancies in Japan and China.

Whereas gastric cancer was the most common cancer in the United States in the 1930s, its annual incidence has steadily decreased. The annual incidence is now fewer than 20,000 new cases per year. However, although the incidence of gastric adenocarcinoma localized to the distal stomach has declined, the incidence of proximal gastric and gastroesophageal adenocarcinomas has been steadily increasing in the United States, a finding that perhaps reflects differences in pathogenic factors. Typically, gastric cancer occurs between the ages of 50 and 70 years and is uncommon before age 30 years. The rates are higher in men than in women by 2 to 1. Five-year survival is less than 20%.

Risk Factors

Risk factors for the development of gastric adenocarcinoma can be divided into environmental and genetic factors as well as precursor conditions (Table 198-3). For example, *Helicobacter pylori* infection is significantly more common in patients with gastric cancer than in matched control groups. Epidemiologic studies of high-risk populations have also suggested that genotoxic agents such as *N*-nitroso compounds may play a role in gastric tumorigenesis. *N*-nitroso compounds can be formed in the human stomach by nitrosation of ingested nitrates, which are common constituents of the diet. High nitrate concentrations in soil and drinking water have been observed in areas with high death rates from gastric cancer. Atrophic gastritis (Chapter 141), with or without intestinal metaplasia, is observed in association with gastric cancer, especially in endemic areas. Pernicious anemia (Chapter 167) is associated with a several-fold increase in gastric cancer. Atrophic gastritis and gastric cancer have certain environmental risk factors in common. It is likely that atrophic gastritis and intestinal metaplasia represent intermediary steps to gastric cancer. The achlorhydria associated with gastritis related to *H. pylori* infection, pernicious anemia, or other causes favors the growth of bacteria capable of converting nitrates to nitrites. The nitrosamine *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine causes a high rate of induction of adenocarcinoma in the glandular stomach of rats. At the same time, most patients with atrophic gastritis do not develop gastric cancer, a finding suggesting that neither atrophic gastritis nor achlorhydria alone is responsible.

Benign gastric ulcers do not appear to predispose patients to gastric cancer. However, patients who have a gastric remnant after subtotal gastrectomy for benign disorders have an increased relative risk for gastric cancer of 1.5 to 3 by 15 to 20 years after surgery.

PATHOBIOLOGY

Gastric adenocarcinomas can be divided into two types based on the Lauren classification: intestinal and diffuse. The intestinal type is typically in the distal stomach with ulcerations, is often preceded by premalignant lesions, and is declining in incidence in the United States. By contrast, the diffuse type involves widespread thickening of the stomach, especially in the cardia, and it often affects younger patients; this form may present as linitis plastica, a nondistensible stomach with the absence of folds and narrowed lumen caused by infiltration of the stomach wall with tumor. Diffuse-type gastric cancers harbor mucin-producing cells. Other conditions may result in linitis plastica, such as lymphoma (Chapter 191), tuberculosis (Chapter 332), syphilis (Chapter 327), and amyloidosis (Chapter 194). The prognosis is generally worse in the diffuse type.

Key histopathologic features of gastric cancer include degree of differentiation, invasion through the gastric wall, lymph node involvement, and the presence or absence of signet ring cells within the tumor itself. Other pathologic manifestations include a polypoid mass, which may be difficult to distinguish from a benign polyp. Early gastric cancer, a condition that is not uncommon in Japan and that has a relatively favorable prognosis, consists of superficial lesions with or without lymph node involvement.

TABLE 198-3 CONDITIONS PREDISPOSING TO OR ASSOCIATED WITH GASTRIC CANCER

ENVIRONMENTAL
Helicobacter pylori infection
Dietary: excess of salt (salted pickled foods), nitrates/nitrites, carbohydrates; deficiency of fresh fruit, vegetables, vitamins A and C, refrigeration
Low socioeconomic status
Cigarette smoking
GENETIC
Familial gastric cancer (rare)
Associated with hereditary nonpolyposis colorectal cancer
Blood group A
PREDISPOSING CONDITIONS
Chronic gastritis, especially atrophic gastritis with or without intestinal metaplasia
Pernicious anemia
Intestinal metaplasia
Gastric adenomatous polyps (>2 cm)
Postgastrectomy stumps
Gastric epithelial dysplasia
Ménétrier's disease (hypertrophic gastropathy)
Chronic peptic ulcer

The leading hypothesis explaining the way in which *H. pylori* predisposes to gastric cancer risk is the induction of an inflammatory response, in which interleukin-1β may be pivotal. Chronic *H. pylori* infection also leads to chronic atrophic gastritis with resulting achlorhydria, which, in turn, favors bacterial growth that can convert nitrates (dietary components) to nitrites. These nitrites, in combination with genetic factors, promote abnormal cellular proliferation, genetic mutations, and eventually cancer. In a mouse model of gastric cancer, *H. pylori* infection may play a role in the recruitment of bone marrow–derived stem cells that facilitate gastric carcinogenesis. Animal models now recapitulate the cardinal features of gastric adenocarcinoma, either through the use of carcinogens or through genetic approaches.

GENETICS

It is clear that genetic factors play a role in gastric cancer. For example, blood group A is associated with a higher incidence rate of gastric cancer, even in nonendemic areas. A three-fold increase in gastric cancer has been reported among first-degree relatives of patients with the disease. Furthermore, albeit rare, germline or inherited mutations in the *E-cadherin* gene have been described in diffuse hereditary gastric cancer, which is seen in young patients. In addition, in hereditary nonpolyposis colorectal cancer type II (Chapter 199), patients have associated extracolonic cancers, including gastric cancer.

It now appears that several genetic mechanisms are important in gastric cancer: oncogene activation, tumor suppressor gene inactivation, and DNA microsatellite instability. For example, loss of heterozygosity of the *APC* (adenomatous polyposis coli) gene has been observed in gastric cancers. The p53 tumor suppressor gene product regulates the cell cycle at the G_1-S phase transition and probably also functions in DNA repair and apoptosis (programmed cell death). The *p53* gene is mutated not only in gastric cancer but also in gastric precancerous lesions, a finding suggesting that mutation of the *p53* gene is an early event in gastric carcinogenesis. Microsatellite DNA alterations or instability in dinucleotide repeats that were originally identified in hereditary nonpolyposis colorectal cancer also occur frequently in sporadic gastric carcinoma. Mutations in genes may accumulate as a result of DNA microsatellite instability.

CLINICAL MANIFESTATIONS

Symptoms and Signs

In its early stages, gastric cancer may often be asymptomatic or may produce only nonspecific symptoms that make early diagnosis difficult. Later symptoms include bloating, dysphagia, epigastric pain, or early satiety. Early satiety or vomiting may suggest partial gastric outlet obstruction, although gastric dysmotility may contribute to the vomiting in patients with nonobstructive cases. Epigastric pain, reminiscent of that associated with peptic ulcer (Chapter 141), occurs in about one fourth of patients, but in most patients with gastric cancer, the pain is not relieved by food or antacids. Pain that radiates to the back may indicate that the tumor has penetrated the pancreas.

When dysphagia is associated with gastric cancer, this symptom suggests a more proximal gastric tumor at the GE junction or in the fundus.

Signs of gastric cancer include bleeding, which can result in anemia that produces the symptoms of weakness, fatigue, and malaise, as well as more serious cardiovascular and cerebral consequences. Perforation related to gastric cancer is unusual. Gastric cancer metastatic to the liver can lead to right upper quadrant pain, jaundice, and fever. Lung metastases can cause cough, hiccups, and hemoptysis. Peritoneal carcinomatosis can lead to malignant ascites unresponsive to diuretics. Gastric cancer can also metastasize to bone.

Physical Examination

In the earliest stages of gastric cancer, the physical examination may be unremarkable. At later stages, patients become cachectic, and an epigastric mass may be palpated. If the tumor has metastasized to the liver, hepatomegaly with jaundice and ascites may be present. Portal or splenic vein invasion can cause splenomegaly. Lymph node involvement in the left supraclavicular area is termed *Virchow's node,* and periumbilical nodal involvement is called *Sister Mary Joseph's node.* The fecal occult blood test may be positive. Metastasis to the ovary is termed *Krukenberg's tumor.*

Paraneoplastic syndromes may precede or occur concurrently with gastric cancer. Examples include the following: Trousseau's syndrome (Chapter 187), which is recurrent migratory superficial thrombophlebitis indicating a possible hypercoagulable state (Chapter 179); acanthosis nigricans (see Fig. 187-1 in Chapter 187), which arises as raised and hyperpigmented skin lesions of flexor areas, neck, axilla, groin, and mucosal membranes; neuromyopathy with involvement of the sensory and motor pathways; and central nervous system syndromes with altered mental status and ataxia (Chapter 187).

Laboratory Studies

Laboratory studies may reveal iron deficiency anemia. Microangiopathic hemolytic anemia has been reported. Abnormalities in liver tests generally indicate metastatic disease. Hypoalbuminemia is a marker of malnutrition. Protein-losing enteropathy is rare but can be seen in Ménétrier's disease, another predisposing condition. Serologic test results, such as those for CEA and CA 72.4, may be abnormal. Although these tests are not recommended for initial diagnosis, they may be useful for monitoring disease after surgical resection.

DIAGNOSIS

The diagnostic accuracy of upper endoscopy with biopsy and cytologic examination approaches 95 to 99% for both types of gastric cancer. Cancer may arise as a small mucosal ulceration, a polyp, or a mass (Fig. 198-1). In some patients, gastric ulceration may first be noted in an upper gastrointestinal barium contrast study. A benign gastric ulcer is suggested by a smooth, regular base, whereas a malignant ulcer is manifested by a surrounding mass, irregular folds, and an irregular base. Although these and other radiographic characteristics historically helped to predict benign versus malignant disease, upper gastrointestinal endoscopy with biopsy and cytologic examination is mandatory whenever a gastric ulcer is found in the radiologic study, even if the ulcer has benign characteristics.

Staging of gastric cancer and, at times, diagnosis have been greatly enhanced by the advent of endoscopic ultrasonography (EUS) (Table 198-4). The extent of tumor, including gastric wall invasion and local lymph node involvement, can be assessed by EUS (Fig. 198-2), which provides information complementary to that obtained from CT scans. EUS can help guide aspiration biopsies of lymph nodes to determine their malignant features, if any.

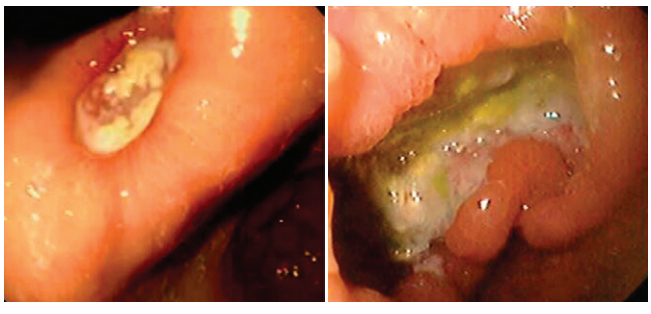

FIGURE 198-1 Benign *(left)* and malignant *(right)* gastric ulcer. Note the shaggy, thickened, and overhanging edges of the cancer. (Courtesy of Pankaj Jay Pasricha, MD.)

CT of the chest, abdomen, and pelvis should be performed to document lymphadenopathy and extragastric organ (especially lung and liver) involvement. In some centers, staging of gastric cancer entails bone scans because of the proclivity of gastric cancer to metastasize to bone.

TREATMENT Rx

Surgical Therapy

The only chance for cure of gastric cancer remains surgical resection, which is possible in only 25 to 30% of cases. If the tumor is confined to the distal stomach, subtotal gastrectomy is performed with resection of lymph nodes in the porta hepatis and in the pancreatic head. By contrast, tumors of the proximal stomach merit total gastrectomy to obtain an adequate margin and to remove lymph nodes; distal pancreatectomy and splenectomy are usually also performed as part of this procedure, which carries with it higher mortality and morbidity rates. The addition of para-aorta nodal dissection does not improve survival. Even if a curative procedure is not possible because of metastasis, limited gastric resection may be necessary for patients with excessive bleeding or obstruction. If cancer recurs in the gastric remnant, limited resection may again be necessary for palliation. Most recurrences in both types of gastric cancer are in the local or regional area of the original tumor.

Medical Therapy

Gastric cancer is one of the few gastrointestinal cancers that is somewhat responsive to chemotherapy.■ In patients with gastric cancer who undergo gastrectomy and extended lymph node dissection with curative intent, S-1 (an oral fluoropyrimidine, 80 mg daily for 4 weeks followed by 2 weeks off, repeated in 6-week cycles for 1 year starting within 6 weeks after surgery) significantly improves 3-year survival from 70% to 80%.■ Chemotherapy with the combination of epirubicin, cisplatin, and fluorouracil, given both

TABLE 198-4 TNM STAGING OF STOMACH CANCER

PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor

T1	Tumor invades lamina propria, muscularis mucosa, or submucosa
T1a	Tumor invades lamina propria or muscularis mucosa
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria*
T3	Tumor penetrates subserosal connective tissue without invasion of visceral peritoneum or adjacent structures†,‡
T4	Tumor invades serosa (visceral peritoneum) or adjacent structures†,‡
T4a	Tumor invades serosa (visceral peritoneum)
T4b	Tumor invades adjacent structures
REGIONAL LYMPH NODES (N)	
NX	Regional lymph nodes(s) cannot be assessed
N0	No regional lymph nodes metastasis§
N1	Metastasis in 1 to 2 regional lymph nodes
N2	Metastasis in 3 to 6 regional lymph nodes
N3	Metastasis in 7 or more regional lymph nodes
N3a	Metastasis in 7 to 15 regional lymph nodes
N3b	Metastasis in 16 or more regional lymph nodes
DISTANT METASTASIS (M)	
M0	No distant metastasis
M1	Distant metastasis

**Note:* A tumor may penetrate the muscularis propria with extension into the gastrocolic or gastrohepatic ligaments, or into the greater or lesser omentum, without perforation of the visceral peritoneum covering these structures. In this case, the tumor is classified T3. If there is perforation of the visceral peritoneum covering the gastric ligaments or the omentum, the tumor should be classified T4.

†The adjacent structures of the stomach include the spleen, transverse colon, liver, diaphragm, pancreas, abdominal wall, adrenal gland, kidney, small intestine, and retroperitoneum.

‡Intramural extension to the duodenum or esophagus is classified by the depth of the greatest invasion in any of these sites, including the stomach.

§*Note:* A designation of pN0 should be used if all examined lymph nodes are negative, regardless of the total number removed and examined.

From *AJCC Cancer Staging Manual,* 7th ed. New York: Springer-Verlag, 2010.

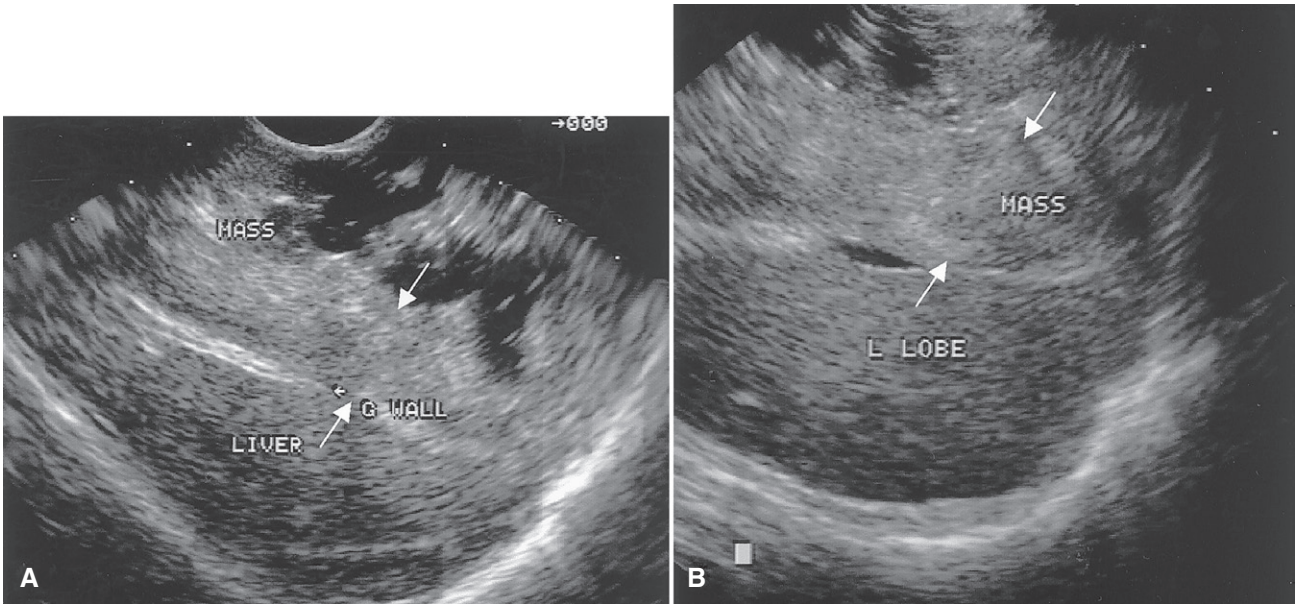

FIGURE 198-2. Gastric mass. Endoscopic ultrasonography depicting a large gastric mass that is compressing the liver and gallbladder wall (**A**) and, on a different view, the left lobe of the liver (**B**).

preoperatively and postoperatively, significantly improves 5-year survival from 23% to 36% in patients with resectable gastroesophageal cancer. Similarly, the combination of chemotherapy (fluorouracil and leucovorin) with radiation therapy has been shown to improve median survival from 27 months to 36 months compared with surgery alone in patients with adenocarcinoma of the stomach or gastroesophageal junction.

Single-agent chemotherapy treatment, which provides partial response rates of 20 to 30%, is reserved for patients with a poor performance status. Combination regimens that can yield partial response rates of 35 to 50% include the following: ECF, which is most popular in Europe (epirubicin, 50 mg/m^2 on day 1; cisplatin, 60 mg/m^2 on day 1; 5-fluorouracil, 200 mg/m^2/day as a continuous infusion through a central venous access device [CVAD] given throughout treatment, repeated every 21 days for a maximum of eight cycles); CF (5-fluorouracil infusion, 1000 mg/m^2/day for 4 days; cisplatin, 75 to 100 mg/m^2 on day 1, every 4 weeks); or TCF (docetaxel [Taxotere], 75 mg/m^2 on day 1; cisplatin, 75 mg/m^2 on day 1; and 5-fluorouracil, 750 mg/m^2/day for 5 days, every 3 weeks), or capecitabine plus cisplatin. A randomized trial of triple chemotherapy for advanced esophagogastric cancer showed that oral capecitabine is at least as effective as infused fluorouracil and that oxaliplatin (which does not require hydration) is at least as effective as cisplatin (which does require hydration) with respect to overall survival. Trastuzumab (8 mg/kg intravenously once, then 6 mg/kg every 3 weeks) can increase survival of HER2-positive advanced gastric or gastro-esophageal junction cancer from 11.1 months to 13.8 months. Radiation therapy alone is ineffective and is generally employed only for palliative purposes in the setting of bleeding, obstruction, or pain. Gene therapy and immune-based therapy are currently only investigational in animal models.

General Methods

Implicit in the management of the patient with gastric cancer is meticulous attention to nutrition (jejunal enteral feedings or total parenteral nutrition), correction of metabolic abnormalities that arise from vomiting or diarrhea, and treatment of infection from aspiration or spontaneous bacterial peritonitis. *H. pylori* eradication treatment reduces the risk for metachronous gastric carcinoma by about two thirds. To maintain lumen patency, endoscopic laser treatment or prosthesis placement can be used in a palliative fashion.

PROGNOSIS

Approximately one third of patients who undergo a curative resection are alive after 5 years. In aggregate, the overall 5-year survival rate in patients with gastric cancer is less than 10%. Prognostic factors include anatomic location and nodal status. Distal gastric cancers without lymph node involvement have a better prognosis than proximal gastric cancers with or without lymph node involvement. Other prognostic factors include depth of penetration and tumor cell DNA aneuploidy. Linitis plastica and infiltrating lesions have a much worse prognosis than polypoid disease or exophytic masses. In the subset of mostly Japanese patients with early gastric cancer that is confined to the mucosa and submucosa, surgical resection may be curative and definitely improves the 5-year survival rate to more than 50%. In fact, when early gastric cancer is confined to the mucosa, endoscopic mucosal resection may be an alternative.

Lymphoma of the Stomach

EPIDEMIOLOGY

Gastric lymphoma represents about 5% of all malignant gastric tumors and is increasing in incidence. Most gastric lymphomas are non-Hodgkin's lymphomas (Chapter 191), and the stomach is the most common extranodal site for non-Hodgkin's lymphomas. Patients with gastric lymphoma are generally younger than those with gastric adenocarcinoma, but the male predominance remains.

CLINICAL MANIFESTATIONS

Patients commonly present with symptoms and signs similar to those of gastric adenocarcinoma. Lymphoma in the stomach can be a primary tumor, or it can be secondary to disseminated lymphoma.

B-cell lymphomas (Chapter 191) of the stomach are most commonly large cell with a high-grade type. Low-grade variants are noted in the setting of chronic gastritis and are termed *mucosa-associated lymphoid tissue* (MALT) lymphomas. MALT lesions are strongly associated with *H. pylori* infection.

DIAGNOSIS

Radiographically, gastric lymphomas usually arise as ulcers or exophytic masses; diffusely infiltrating lymphoma is more suggestive of secondary lymphoma. Thus, upper gastrointestinal barium studies usually show multiple nodules and ulcers for a primary gastric lymphoma and typically have the appearance of linitis plastica with secondary lymphoma. As with gastric adenocarcinoma, however, upper endoscopy with biopsy and cytologic examination are required for diagnosis and have an accuracy of nearly 90%. Apart from conventional histopathologic analysis, immunoperoxidase staining for lymphocyte markers is helpful in diagnosis. As with gastric adenocarcinoma, proper staging of gastric lymphoma involves EUS, chest and abdominal/pelvic CT scans, and bone marrow biopsy as needed.

TREATMENT

Rx

Treatment of gastric diffuse large B-cell lymphoma is best pursued with combination chemotherapy with or without radiation therapy (Chapter 191). For MALT lesions, eradication of *H. pylori* infection with antibiotics should be attempted (Chapter 141), but patients with refractory lesions that are confined to the stomach can sometimes be cured with radiotherapy (Chapter 191).

Other Malignant Tumors of the Stomach

Leiomyosarcoma, which constitutes approximately 1% of all gastric cancers, usually occurs as an intramural mass with central ulceration. Symptoms may include bleeding accompanied by a palpable mass. Leiomyosarcomas are often relatively indolent; surgical resection yields a 5-year survival rate of about 50%. Metastasis can occur to lymph nodes and the liver. Other gastric sarcomas include liposarcomas, fibrosarcomas, myosarcomas, and neurogenic sarcomas.

Most gastrointestinal stromal tumors (GISTs) have been associated with activating mutations in the C-*kit* gene; a subset of such tumors are associated with mutations in the platelet-derived growth factor receptor *(PDGFR)* gene. C-*kit* mutations are also found in chronic and acute myelogenous leukemia (Chapters 189 and 190), and approximately 50% of GISTs respond to imatinib mesylate, which is also used in chronic myelogenous leukemia. If imatinib is not successful, sunitinib increases survival.■ Carcinoid tumors (Chapter 240) may begin in the stomach and are curable by removal if they have not yet spread to the liver.

Primary tumors can also spread to the stomach. In addition to lymphomas, other tumors found in the stomach include primary lung (Chapter 197) and breast (Chapter 204) cancers as well as malignant melanoma (Chapter 210).

LEIOMYOMAS AND BENIGN TUMORS

Leiomyomas, which are smooth muscle tumors of benign origin, occur with equal frequency in men and women and are typically located in the middle and distal stomach. Leiomyomas can grow into the lumen, with secondary ulceration and consequent bleeding. Alternatively, they can expand to the serosa with extrinsic compression. Endoscopy may reveal a mass that has overlying mucosa or mucosa replaced by ulceration. On upper gastrointestinal series, leiomyomas are usually smooth with an intramural filling defect, with or without central ulceration. However, benign leiomyomas can be difficult to distinguish from their malignant counterparts radiographically or endoscopically; tissue diagnosis is imperative. Symptomatic leiomyomas should be removed, but those without associated symptoms do not require therapy.

Other benign gastric tumors include lipoma, neurofibroma, lymphangioma, ganglioneuroma, and hamartoma, the last associated with Peutz-Jeghers syndrome (Chapter 199) or juvenile polyposis (restricted to the stomach).

ADENOMAS

Gastric adenomas and hyperplastic polyps are unusual but may be found in middle-aged and elderly patients. Polyps may be sessile or pedunculated and are also found in nearly 50% of patients with familial adenomatosis polyposis (Chapter 199). Gastric adenocarcinoma arising in the antrum has been described in such patients. Although isolated gastric adenomatous polyps are generally asymptomatic, some patients may have dyspepsia, nausea, or bleeding. Gastric adenomas and hyperplastic polyps are smooth and regular on upper gastrointestinal series, but the diagnosis must be confirmed by upper endoscopy with biopsy. Pedunculated polyps that are larger than 2 cm or that have associated symptoms should be removed by endoscopic snare cautery polypectomy, whereas large sessile gastric adenomatous polyps may merit segmental surgical resection. If polyps progress to an intermediary stage of severe dysplasia or culminate in cancer, treatment is the same as for gastric adenocarcinoma.

199 NEOPLASMS OF THE SMALL AND LARGE INTESTINE

CHARLES D. BLANKE AND DOUGLAS O. FAIGEL

NEOPLASMS OF THE SMALL INTESTINE

EPIDEMIOLOGY

The small intestine accounts for the majority of the length (≈75%) and surface (≈90%) of the gastrointestinal (GI) tract. Nonetheless, it is a rare site for the development of neoplastic disease, as only 1 to 2% of primary GI tumors originate in the duodenum, jejunum, or ileum. In fact, half of all small bowel neoplasms represent metastatic disease from other sites, particularly elsewhere in the GI tract. Small bowel malignancies constitute less than 0.5% of all cancers, although the incidence of small bowel tumors (especially carcinoids) seems to be increasing. Overall, the mean age at diagnosis of a small bowel tumor is about 67 years; neoplasms are more common in males, and they occur more commonly in African Americans than in whites.

PATHOBIOLOGY

Adenocarcinomas, arising from mucosal glands, were formerly the most frequent primary small bowel tumor. They now constitute 25% of small bowel neoplasms, including benign growths, and 40% of all malignant tumors. Adenocarcinomas most commonly arise in the duodenum (65% of all small intestinal adenocarcinomas), even though the duodenum represents only a tiny fraction of the length of the small bowel. They occur less commonly in the jejunum and least commonly in the ileum. The majority are well or moderately differentiated.

Small bowel carcinoids, which derive from enterochromaffin cells in the crypts of Lieberkühn, are now the most common small bowel tumors, accounting for approximately 30 to 40% of malignancies. They tend to be quite well differentiated. In contrast to glandular tumors, small intestinal carcinoids tend to arise in the distal ileum, and up to 30% are multifocal. Other small bowel neuroendocrine tumors are occasionally seen, including biochemically active neoplasms such as gastrinomas and somatostatinomas. Very rarely, high-grade true small cell carcinomas occur.

Malignant connective tissue tumors account for 10% of small bowel neoplasms. Gastrointestinal stromal tumors (GISTs), which derive from the interstitial cells of Cajal or a common precursor, account for approximately 85% of these neoplasms (Fig. 199-1). GISTs, like adenocarcinomas, disproportionately arise in the duodenum, and the small bowel itself is the second most common primary site for these mesenchymal neoplasms (33% derive from small bowel). Morphologically, GISTs often resemble leiomyosarcomas

FIGURE 199-1. Small bowel gastrointestinal stromal tumor with ulceration.

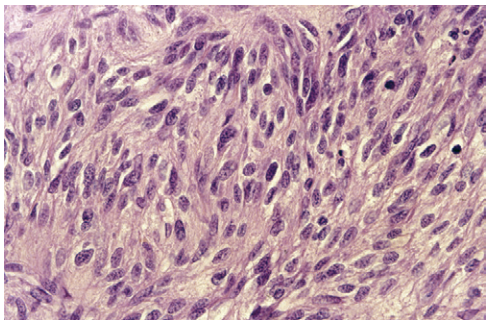

FIGURE 199-2. Histopathology of gastrointestinal stromal tumor.

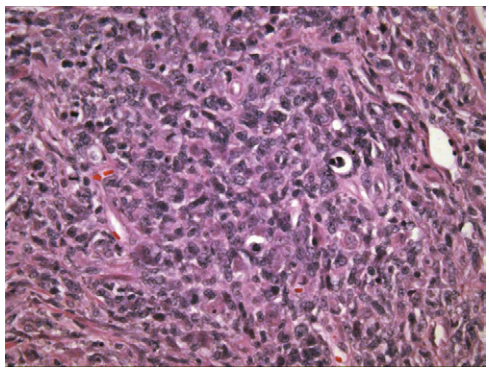

FIGURE 199-3. Histopathology of small bowel non-Hodgkin's lymphoma. (Courtesy Dr. M. K. Washington.)

(Fig. 199-2), but they can be differentiated by the expression of the Kit protein (CD117). Other small bowel sarcomas such as true leiomyosarcomas are seen more rarely (Chapter 209).

Primary GI lymphomas are the most common extranodal lymphomatous variation, and the small intestine is the second most common GI site for such tumors (Chapter 191). The ileum, rich in submucosal lymphoid follicles, is the most common small bowel site. Tumors may be low or higher grade and can arise from precursor B or T lymphocytes. The overwhelming majority are non-Hodgkin's tumors (Fig. 199-3). Lymphomas involving the small bowel may also be a manifestation of true systemic disease.

Malignant melanoma (Chapter 210) can develop as a primary mucosal small bowel tumor, probably arising from schwannian neuroblasts associated with GI innervation. In addition, the small bowel is the most common GI site for melanoma metastases.

Finally, a variety of common benign tumors may originate in the small bowel, including adenomas, leiomyomas, and lipomas. Desmoids, most often seen in patients with familial adenomatous polyposis (FAP); hamartomas; and hemangiomas are relatively rare. Benign growths are more common in the distal small intestine.

The small intestine can be involved by advanced cancers from other sites through direct invasion, extension of peritoneal metastases, or hematogenous spread. As noted, the small bowel is the most common GI site for melanoma metastases; in addition, involvement is fairly common with ovarian, breast, lung, and other GI neoplasms.

Predisposing Conditions

Inflammatory bowel disease (Chapter 143) predisposes to adenocarcinoma. Additionally, many of the polyposis syndromes are associated with small bowel neoplasms. Most notably, FAP (see later) is associated with adenomas and carcinomas of the duodenum and jejunum, but especially in the ampullary and periampullary region. At least 90% of FAP patients develop duodenal adenomas, and up to 10% develop cancer. The risk of cancer is related to the number of polyps, their size and histologic type, and the presence of high-grade dysplasia. Patients with FAP should undergo regular screening for duodenal neoplasia with both forward- and side-viewing endoscopes beginning around the time of colectomy and repeated at 1- to 5-year intervals, depending on the presence and degree of duodenal polyposis. Patients with MUTYH polyposis likewise develop duodenal neoplasia and should undergo screening. Patients with hereditary nonpolyposis colon cancer (HNPCC) are also at increased risk for small intestine adenocarcinoma, which may be the first manifestation of their disease. HNPCC-associated small bowel cancer may present at a young age (median, 39 years) and occurs with decreasing frequency from the duodenum to the ileum, with about 50% of occurrences in the duodenum. Screening may be considered beginning at age 30. Patients with sprue are at an increased risk for small bowel lymphomas.

CLINICAL MANIFESTATIONS

The most common presenting symptom of small bowel tumors is abdominal pain, especially for those that are true cancers. Less common are symptoms such as weight loss, nausea, GI bleeding, and symptoms related to perforation. Approximately 25% of patients have GI obstruction, and duodenal periampullary tumors can lead to obstructive jaundice. Only a minority of malignancies are asymptomatic, whereas benign tumors may cause no symptoms in up to half of patients. Carcinoid tumors in the small bowel are often asymptomatic, although in the setting of advanced disease they may secrete bioactive amines, leading to flushing, diarrhea, wheezing, and eventually symptoms of right heart failure (related to valvular fibrosis) (Chapter 240). This is more common with tumors originating in the jejunum and ileum. Benign tumors tend to be found incidentally, although intraluminal growth may eventually cause symptoms of obstruction, and some may grow large enough to ulcerate and bleed.

DIAGNOSIS

The physical examination in patients with small bowel tumors is often unremarkable, although there is occasionally a palpable mass and, in more advanced cases, ascites. As discussed earlier, patients with periampullary neoplasms may be jaundiced and/or icteric. Obstructive signs such as hyperperistalsis may be present, and those with lymphoma may also have splenomegaly or other signs of systemic involvement, such as lymphadenopathy. Laboratory findings may include iron deficiency anemia or increased hepatic enzymes (the latter is especially common in those with liver metastases or biliary obstruction). Serum levels of the carcinoembryonic antigen (CEA) tumor marker may be elevated in small bowel adenocarcinoma, especially in advanced cases, but it is neither sensitive nor specific enough for routine diagnostic use. Patients with neuroendocrine tumors may demonstrate elevated levels of serotonin, chromogranin A, tumor-specific bioactive amines (e.g., gastrin), or urinary 5-hydroxyindoleacetic acid. Variants of intestinal lymphomas may show heavy chain immunoglobulin A fragments in serum and urine.

Proper imaging is crucial for both diagnosis and staging of small bowel neoplasms, but no one method is clearly the best. Standard radiographic techniques of value include upper GI with small bowel follow-through (helpful in demonstrating both masses and potential mucosal defects), angiography (which may show a site of bleeding or tumor blush with specific neoplasms), and computed tomography (CT) or magnetic resonance imaging (MRI) enteroclysis (double-contrast studies are both sensitive and specific for small bowel masses). Transabdominal ultrasound and standard CT may indicate a primary mass as well as metastases; MRI appears to be superior to CT in detecting and characterizing liver metastases.

Primary neuroendocrine tumors and their metastases are often apparent on indium-111 octreotide scanning. A wide variety of histologies may have uptake on positron emission tomography (PET) scanning. However, PET does not yet have a well-defined role in the diagnosis of most small bowel

malignancies, although PET scans are useful in those with GISTs to monitor response to systemic therapy (see later). Plain films rarely help make the diagnosis, but they may demonstrate intestinal obstruction.

Capsule endoscopy uses a wireless endoscopic device that allows minimally invasive imaging of the small intestine. The system consists of the capsule camera—a swallowable, self-contained battery-operated device that transmits two images per second—a receiver worn on the patient's belt, and a computerized work station for downloading and viewing the images. The primary indications for capsule endoscopy are the evaluation of obscure GI bleeding and Crohn's disease. Tumors are found in about 2 to 3% of patients undergoing capsule endoscopy for obscure GI bleeding, and they may be more common in younger patients. Tumors detected include lymphoma, adenocarcinoma, metastatic disease, carcinoid tumor, and GIST. Capsule endoscopy has also been used to assess the small intestines of patients with FAP and Peutz-Jeghers syndrome (PJS), although its clinical utility for the routine screening of these patients has not been established.

Surveillance

Patients with FAP, MUTYH polyposis, PJS, and probably HNPCC require regular surveillance of the small intestine, with specific recommendations as noted earlier. Patients with sporadic small intestine adenomas and possibly carcinoid tumors should undergo colonoscopy, because they are at increased risk for colonic neoplasia. No specific guidelines exist for following patients with resected small bowel adenocarcinomas.

Staging

The staging systems for small bowel tumors vary by histology. Adenocarcinomas and, more recently, neuroendocrine cancers and GISTs are staged using the American Joint Committee on Cancer's TNM classification of malignant tumors system. Intestinal non-Hodgkin's lymphomas, whether primary or part of a systemic process, are staged in accordance with a modified Ann Arbor system originally used in Hodgkin's disease (Chapter 191).

TREATMENT

Rx

In general, surgical excision is the treatment of choice for most localized small bowel tumors. The extent of excision necessary depends on the tumor's location and histology. Adenocarcinomas involving the first and second portions of the duodenum require pancreaticoduodenectomy, whereas those in the more distal small intestine may be treated with segmental or wide local resection, including regional lymph nodes. Low-grade neuroendocrine tumors should be managed with en bloc resection, again including regional nodes. GISTs, which very rarely spread to regional nodes, may be treated with excision without lymphadenectomy (except in cases with gross involvement of nodes). Primary surgery for lymphomas may be offered for low-stage malignancies and may also be required for complications of disease (e.g., intussusception). Local management of benign small bowel tumors varies from observation (incidentally discovered lipomas) to endoscopic polypectomy (small adenomas) to pancreaticoduodenectomy (periampullary villous adenomas).

The need for and types of adjuvant therapy vary as well. Fully resected benign tumors require no additional therapy. Adenocarcinomas are often treated according to the principles developed for colorectal cancer, with some experts advocating fluoropyrimidine-based systemic chemotherapy, at least for patients with nodal involvement. Chemoradiotherapy has also been recommended for those with more locally advanced duodenal adenocarcinomas. So far, no randomized trials have proved either strategy to be superior to surgery alone. Fully excised well- to moderately differentiated neuroendocrine cancers do not require adjuvant therapy. Postoperative imatinib mesylate treatment (see later) clearly postpones the recurrence of intermediate- and high-risk GISTs, but it is not yet known whether the cure rate is improved, and questions remain with regard to dose and duration of therapy. There is no defined role for the postoperative treatment of other mesenchymal tumors. Lymphomas treated with excision alone have high rates of recurrence, and systemic chemotherapy is advocated for high-grade variants; some experts also recommend chemotherapy for low-grade subtypes.

Patients with advanced small bowel adenocarcinomas are often treated with systemic chemotherapy regimens known to be effective against cancers of similar histology originating in the colon. However, the data supporting any specific regimen are scant and are not derived from randomized trials. Approximately 90% of patients with incurable GISTs have durable disease control when treated with the tyrosine kinase inhibitor imatinib mesylate, and the median survival for patients with metastatic disease has recently improved from approximately 18 months to 5 years.

Patients with small bowel lymphomas may be treated with chemotherapy that is effective in tumors of nodal origin.

PROGNOSIS

Patients with small bowel adenocarcinomas generally do worse than those with similarly staged colonic glandular tumors. Also, patients with duodenal primaries may have poorer outcomes than those with more distal small bowel cancers. In general, 5-year survival rates range from 4% for those with metastases to 80% for those with very early disease confined to the small bowel wall. Five-year survival in patients with small bowel carcinoids exceeds 50%. In the pre-imatinib era, patients with surgically resected small bowel GISTs had recurrence rates from 0 to 90% or higher, depending on the tumor's size, precise location, and mitotic rates, and those with more distal tumors had a worse prognosis than those with duodenal primaries. Patients with recurrences almost invariably died within 2 years because salvage surgery and systemic chemotherapy were ineffective. True life expectancy in this era of postoperative imatinib use is unknown, but the median survival of patients with advanced GISTs likely exceeds 5 years. Small intestinal lymphomas have 5-year survival rates surpassing 60%, although this is highly variable and depends on the histologic subtype.

NEOPLASMS OF THE LARGE INTESTINE

Colorectal cancer is the third most common cancer in the United States. Disease that has spread beyond regional lymph nodes is, for the most part, incurable, and colorectal cancer in general remains the second leading cause of neoplastic death. The lifetime risk of developing colorectal cancer for the average patient is about 1 in 18 to 20.

EPIDEMIOLOGY

Almost three quarters of large bowel cancers arise proximally (i.e., are of colonic origin). Although colorectal cancer is primarily a disease of the elderly (median age, ≈73 years), about 10% of cases occur in those 50 years of age or younger. Colorectal cancer incidence and mortality have decreased overall recently, although the incidence has been increasing in the young. Incidence rates for right-sided cancers have also been decreasing, possibly but not solely owing to effective distal large bowel screening with flexible sigmoidoscopy. Colorectal cancer is slightly more common in men than in women and in African Americans than in whites. Men develop colorectal cancer an average of 5 to 10 years earlier than women; similarly, large bowel cancers seem to arise an average of 5 to 10 years earlier in African Americans than in whites. There is much geographic variation in incidence that is probably based more on environmental factors than on genetic ones, as suggested by migration studies.

PATHOBIOLOGY

Between 96 and 98% of colorectal cancers are adenocarcinomas. Rarely seen histologies include neuroendocrine cancers, epidermoid carcinomas, lymphomas, and sarcomas (including GISTs). Additionally, composites, such as adenocarcinomas with neuroendocrine differentiation, are increasingly being described.

Adenocarcinomas derive from colonic columnar glandular epithelium in the colorectal mucosal lining. They are equally common in males and females and are most frequently reported in the sigmoid colon. Adenocarcinomas most commonly present at a localized or regional (nodal) stage. About two thirds are of moderate grade. The majority are nonmucinous, although the mucinous phenotype constitutes up to one fifth of all colorectal cancers. Another variant is the true signet ring carcinoma, identified by large quantities of single tumor cells with nuclear displacement by intracytoplasmic mucin. Mucinous tumors likely have a worse prognosis (data are controversial to date), whereas a signet ring histology almost always indicates a poorly differentiated or undifferentiated tumor and is clearly associated with a worse outcome.

Neuroendocrine cancers can have a variety of histologies, ranging from bland, well-differentiated carcinoids to high-grade small cell carcinomas. True carcinoids are the second most common histologic colorectal subtype. They are more common in nonwhites and make up the vast majority of non-adenocarcinoma epithelial cancers.

Distal bowel carcinoids are hormonally inactive. Noncarcinoid neuroendocrine cancers tend to be high grade and commonly present with hepatic and other distant metastases.

Epidermoid carcinomas are rare overall but still account for up to one fourth of colorectal cancers. Most are squamous cell subtypes. They are more common in women and Hispanics. Epidermoid carcinomas are located in the rectum more than 90% of the time, and they are usually moderately or poorly

TABLE 199-1 GENERAL FEATURES OF THE INHERITED COLORECTAL CANCER SYNDROMES

SYNDROME	POLYP HISTOLOGY	POLYP DISTRIBUTION	AGE OF ONSET	RISK OF COLON CANCER	GENETIC LESION	CLINICAL MANIFESTATIONS	ASSOCIATED LESIONS
Familial adenomatous polyposis	Adenoma	Large intestine, duodenum	16 yr (range, 8-34 yr)	100%	5q (*APC* gene)	Rectal bleeding, abdominal pain, bowel obstruction	Desmoids, CHRPE
Peutz-Jeghers syndrome	Hamartoma	Large and small intestine	First decade	Slightly above average	19p (*STK11*)	Possible rectal bleeding, abdominal pain, intussusception	Orocutaneous melanin pigment spots, other tumors
MUTYH-associated polyposis	Adenoma	Large intestine, duodenum	45-50 yr (range, 13-60 yr)	75% (range, 50-100%)	1p (*MYH* gene)	Rectal bleeding, abdominal pain, bowel obstruction	CHRPE, osteomas
Juvenile polyposis	Hamartoma (rarely adenoma)	Large and small intestine	First decade	≈9%	*PTEN, SMAD4, BMPR1*	Possible rectal bleeding, abdominal pain, intussusception	Pulmonary AVMs
Hereditary nonpolyposis colon cancer	Adenoma	Large intestine	40 yr (range, 18-65 yr)	30%	Mismatch repair genes*	Rectal bleeding, abdominal pain, bowel obstruction	Other tumors (e.g., ovary, uterus, pancreas, stomach)

*Including *hMSH2, hMSH3, hMSH6, hMLH1, hPMS1,* and *hPMS2.*
AVM = arteriovenous malformation; CHRPE = congenital hypertrophy of the retinal pigment epithelium.

differentiated. Interestingly, they commonly present as localized cancers, regardless of their degree of differentiation.

Primary colorectal lymphomas are fairly rare, constituting 10 to 20% of all GI lymphomas but less than 1% of colorectal cancers. They are much more common in males and in the elderly. The cecum is the most common site of origin. Tumors are usually of B-cell origin.

Sarcomas of the large bowel have no gender or racial predilections. More than 50% have been classified as leiomyosarcomas, most commonly found in the rectum. They are usually diagnosed at a localized stage, regardless of grade, although about 40% are actually poorly differentiated. Kaposi's sarcomas and GISTs are other sarcoma histologies found in the large bowel; many of the distal tumors called *leiomyosarcomas* in older registries were likely true GISTs.

Predisposing Conditions

Predisposing conditions for colonic neoplasia include age (discussed previously), gender, race, inflammatory bowel disease, family history, and defined inherited syndromes. Defined genetic cancer syndromes, however, account for only a small percentage of colorectal cancers (see later). Patients with first-degree relatives who also have colon neoplasia (adenomas or carcinomas) are commonly seen. Individuals with a first-degree relative with colorectal cancer face a two- to three-fold increased risk for malignancy, and this risk rises to five- or six-fold if two first-degree relatives are affected. Patients whose relatives have adenomas face a 1.8-fold increased risk for colorectal cancer, and this rises to 2.6 if the relative is younger than 60 years.

Patients with ulcerative colitis and Crohn's disease (Chapter 143) are at increased risk for colorectal cancer in proportion to the amount of bowel involved and the duration of illness. For example, adenocarcinoma of the colon is 10 to 20 times more common in persons with ulcerative colitis than in the general population. Between 2 and 4% of all patients with long-term ulcerative colitis develop this malignancy, and the cumulative incidence over a 25-year period is approximately 12%. Patients with both ulcerative colitis and primary sclerosing cholangitis seem to be at even greater risk. For those with Crohn's colitis, patients with extensive disease involving more than one third of the colon are at increased risk (six- to eight-fold), similar to those with ulcerative colitis. Isolated proctitis is not a risk factor. Patients with ulcerative colitis or extensive Crohn's disease should undergo screening colonoscopy every 1 to 2 years beginning 8 to 10 years after disease onset. At colonoscopy, multiple biopsies (at least 32 for pan-colitis) are obtained, and any suspicious lesions are sampled. The purpose of this is to identify the presence of dysplasia. The presence of high-grade dysplasia, any dysplasia in a mass or lesion that cannot be excised endoscopically, or multifocal low-grade dysplasia should prompt colectomy.

Patients who have had ureterocolostomy and those with acromegaly are also at increased risk. Case-control studies suggest that obesity, low physical activity, smoking, excessive alcohol, high-fat diet, and lack of dietary fiber increase the colorectal cancer risk. Patients with *Streptococcus bovis* bacteremia or endocarditis have increased rates of colorectal cancer and should undergo colonoscopy.

FIGURE 199-4. Resected colon lined with hundreds of adenomatous polyps in a patient with familial adenomatous polyposis.

Polyposis Syndromes

Several defined dominant and recessive genetic conditions have been identified that convey an increased risk of colorectal cancer (Table 199-1). These include FAP, HNPCC, MUTYH-associated polyposis, PJS, juvenile polyposis, PTEN hamartoma syndrome, and Cronkhite-Canada syndrome.

FAMILIAL ADENOMATOUS POLYPOSIS

FAP is an autosomal dominant condition characterized by the development of hundreds to thousands of adenomatous polyps and colorectal cancer by age 40 (Fig. 199-4). Estimates of disease prevalence are 1 in 8000 to 15,000 births.

PATHOBIOLOGY

FAP is inherited as an autosomal dominant disease with incomplete penetrance. It has been mapped to the adenomatous polyposis coli *(APC)* gene located on the long arm of chromosome 5 (5q21). *APC* is a tumor suppressor gene that is a critical regulator of intestinal epithelial cell growth. Inherited mutations generally result in a truncated gene product. Patients with the familial syndrome inherit one mutant copy of *APC;* when a loss-of-function mutation develops in the other *APC* allele, mucosal epithelial cell growth is no longer controlled normally, and polyps develop. Variable phenotypes can be partly attributed to differences in the location of the *APC* mutation, with attenuated FAP being seen in mutations at the 5′ and 3′ ends of the gene.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Adenomas begin to appear early in the second decade of life, and GI symptoms begin to appear in the third or fourth decade. Polyps are distributed relatively evenly throughout the colon, although a slight predominance has been noted in the distal colon. Almost all patients with FAP develop frank colorectal carcinoma by age 40 years if the condition is left untreated. Gastric polyps (mostly nonadenomatous) occur in 30 to 100% of patients, and duodenal adenomas are found in 45 to 90%. Periampullary duodenal cancer develops in approximately 10% of cases. Small bowel lesions that are distal to the duodenum rarely progress to malignancy. In attenuated FAP, fewer than 100 colonic adenomas develop, there is a right colon predominance, and cancer develops approximately 10 years later. Genetic testing may identify the mutation in up to 85% of affected individuals and is useful for family screening.

TREATMENT Rx

The primary treatment option in FAP patients is total proctocolectomy with conventional ileostomy or ileoanal (pouch) anastomosis. Individuals with *APC* mutations and those with no identified mutation but clinical FAP in their families should be screened with annual sigmoidoscopy beginning at age 10 to 12 years. In families with known *APC* mutations, individuals who test negative do not require heightened surveillance but should undergo routine risk screening. FAP patients should be screened for duodenal polyposis with upper endoscopy beginning at age 20 years, with subsequent surveillance depending on polyp burden and histology.

GARDNER'S SYNDROME

Gardner's syndrome is a phenotypic subtype of FAP that is also caused by mutations in the *APC* gene. It is distinguished by the presence of extraintestinal manifestations, including osteomas (particularly mandibular), soft tissue tumors (including lipomas, sebaceous cysts, and fibrosarcomas), supernumerary teeth, desmoid tumors, mesenteric fibromatosis, and congenital hypertrophy of the retinal pigment epithelium. The phenotypic differences between Gardner's syndrome and FAP appear to result from variations in the location of the *APC* mutation, the presence of modifying genes, and environmental factors. Adenomatous polyps in Gardner's syndrome have the same malignant potential as those found in FAP, and colorectal cancer screening and treatment recommendations are the same.

TURCOT'S SYNDROME

A hallmark of Turcot's syndrome is the combination of colorectal polyposis and malignant diseases of the central nervous system. Mutations in the *APC* gene account for two thirds of cases, and the remaining one third result from mutations in the DNA mismatch repair genes that are also mutated in HNPCC. Central nervous system manifestations include medulloblastomas, glioblastomas, and ependymomas.

HEREDITARY NONPOLYPOSIS COLON CANCER

HNPCC, also known as *Lynch syndrome*, is the most common hereditary colorectal cancer syndrome and accounts for approximately 2% of all cases of colorectal cancer (Chapter 184). It is an autosomal dominant trait and is highly penetrant. Clinically, HNPCC has been defined by the presence of all three of the following: (1) three or more relatives with histologically verified HNPCC-associated cancer (colorectal cancer or cancer of the endometrium, small bowel, ureter, or renal pelvis), one of whom is a first-degree relative of the other two, in the absence of FAP; (2) colorectal cancer involving at least two generations; and (3) one or more family members with cancer diagnosed before age 50 years.

PATHOBIOLOGY

HNPCC is caused by loss-of-function germline mutations in a set of genes involved in the repair of DNA base pair mismatches that occur during DNA replication (also known as the *mutation mismatch repair system*). The genetic basis of HNPCC (Lynch syndrome) is described in greater detail in Chapter 184.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The median age for diagnosis of HNPCC is the mid-40s. Although several adenomas may be present, the diffuse polyposis characteristic of FAP is not found. Colonic neoplasia has a right-sided predominance (proximal to the splenic flexure). Although the cancers tend to be poorly differentiated, they generally have a better prognosis than similar sporadic colorectal cancers. Synchronous and metachronous colorectal cancer is common. Patients with HNPCC are also at high risk for other malignant diseases, especially endometrial carcinoma, as well as cancers of the ovary, stomach, small bowel, hepatobiliary tract, ureter, and pancreas. The Muir-Torre syndrome variant is associated with cutaneous lesions and visceral malignancies. Screening for HNPCC may begin with testing of the tumor for microsatellite instability, performing immunohistochemical staining for products of mismatch repair genes (including *hMSH2, hMSH3, hMSH6, hMLH1, hPMS1,* and *hPMS2*), and/or *BRAF* gene mutation testing. A positive screen does not definitely indicate HNPCC because up to 15% of sporadic tumors may have these features; this should be followed with germline testing.

TREATMENT Rx

Persons potentially affected with HNPCC should undergo a colonoscopy every 2 years beginning at age 21 years and annually beginning at age 40. Patients with colorectal cancer or large adenomas should undergo subtotal colectomy. Women in HNPCC-affected families should have pelvic examinations every 1 to 3 years beginning at age 18 years; annual pelvic examinations, transvaginal ultrasonography, and endometrial biopsy have been recommended beginning at age 25 years. Prophylactic total abdominal hysterectomy with bilateral salpingo-oophorectomy may also be considered at the time of colectomy.

MUTYH-ASSOCIATED POLYPOSIS

MUTYH-associated polyposis is a recently described autosomal recessive syndrome caused by mutations in the *MYH* gene. It is characterized by colonic polyposis and a high rate of colorectal cancer. In a Finnish colon cancer registry, 0.4% of patients were homozygous for *MYH* mutations.

PATHOBIOLOGY

MUTYH-associated polyposis is caused by a biallelic inherited defect in the *MYH* gene located on chromosome 1p. Inherited as an autosomal recessive trait, this leads to defects in base excision repair and acquired mutations of the *APC* gene and other genes, such as *KRAS*. This results in adenoma formation and the subsequent development of adenocarcinoma.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Phenotypically, affected patients are similar to those with attenuated FAP. Patients have five to hundreds of adenomas. The onset is later than in classic FAP, with cancers more likely to be right sided and to occur at age 45 to 50 years. Associated extracolonic features include gastroduodenal polyps, duodenal carcinoma, breast and ovarian cancer in female carriers, bladder cancer, skin cancer, congenital hypertrophy of the retinal pigment epithelium, and osteoma. Monoallelic carriers do not appear to have an increased cancer risk.

The diagnosis is suggested by the presence of colonic polyposis in the absence of FAP, or when there appears to be recessive inheritance. In these cases, genetic testing for *MYH* gene mutations should be considered. Whether heterozygote carriers are at increased risk has not been established, but screening similar to that for individuals with first-degree relatives with colorectal cancer may be advisable (i.e., colonoscopy at age 40 and then every 5 years).

TREATMENT Rx

Patients with numerous polyps should undergo colectomy. Patients with mild disease and a relatively small number of polyps may be considered for colonoscopy with polypectomy and regular surveillance. Colonoscopy should be performed beginning at age 18 to 20 and repeated every 1 to 2 years. Regular endoscopic surveillance for duodenal polyps should also be performed beginning at age 25 to 30.

PEUTZ-JEGHERS SYNDROME

PJS is an intestinal hamartomatous polyposis of the upper and lower GI tract that is associated with characteristic mucocutaneous pigmentation. The

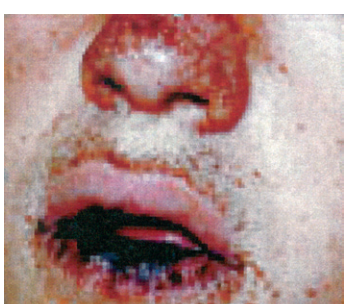

FIGURE 199-5. Mucosal pigmentation in a patient with Peutz-Jeghers syndrome.

average age at diagnosis is in the mid-20s. PHS predisposes to both intestinal and extraintestinal malignancies.

PATHOBIOLOGY

PJS is a rare autosomal dominant syndrome with high penetrance. The prevalence is between 1 in 8300 and 1 in 29,000. The gene responsible for the syndrome is the serine-threonine kinase *(STK11)* gene located on chromosome 19p; a mutation in *STK11* is found in approximately 60% of patients with this syndrome. The hamartomatous polyps in PJS are located predominantly in the small intestine (64 to 96%), stomach (24 to 49%), and colon (60%). Histologically, these polyps are benign; they are unique, in that a layer of muscle that extends into the submucosa or muscularis propria may surround the glandular tissue. Adenomatous and hyperplastic polyps may also be found.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

The most common symptoms are small bowel intussusception, obstruction, and GI bleeding that may require surgery and may be recurrent. PJS is associated with an increased risk of cancer, with an estimated 47% of patients developing a malignancy by age 65. The most common cancers are those of the small intestine, stomach, colon, pancreas, testes, breast, ovary, cervix, and uterus. More than 95% of patients have a characteristic pattern of melanin spots on the lips, buccal mucosa, and skin (Fig. 199-5). Because genetic testing is not widely available, first-degree relatives should be screened beginning at birth with an annual history, physical examination, and evaluation for melanotic spots, precocious puberty, and testicular tumors.

TREATMENT

Rx

Standard medical care for patients with PJS involves an annual physical examination that includes evaluation of the breasts, abdomen, pelvis, and testes, as well as a complete blood count. Surveillance for cancer includes small bowel radiography every 2 years, esophagogastroduodenoscopy and colonoscopy every 2 years, and endoscopic ultrasound of the pancreas every 1 to 2 years. For women, annual Pap smear, transvaginal ultrasound, CA125, and mammography are recommended. Polyps larger than 1 cm should be removed endoscopically. Laparotomy and resection are recommended for recurrent or persistent small intestinal intussusception, obstruction, or intestinal bleeding.

JUVENILE POLYPOSIS

Familial juvenile (non-neoplastic, hamartomatous) polyposis is a rare (<1 in 100,000 births) syndrome characterized by 10 or more non-neoplastic, hamartomatous polyps throughout the GI tract or any number of polyps in a patient with a family history of juvenile polyposis. The syndrome is inherited in an autosomal dominant manner with high penetrance and is caused by mutations in the *SMAD4, PTEN,* or *BMPR1A* gene. The hamartomas are histologically distinct from the polyps seen in PJS. Patients generally present with rectal bleeding, anemia, abdominal pain, or intestinal obstruction in childhood or early adolescence. Extraintestinal symptoms include pulmonary arteriovenous malformations in some probands. The risk of malignancy in juvenile polyposis is reportedly as high as 20% and occurs in adulthood (median age, 37 years). Affected individuals should undergo regular colonoscopic surveillance. Patients with numerous, large, or high-grade dysplastic polyps may be considered for subtotal colectomy. Family members should be screened with colonoscopy every 3 to 5 years beginning at age 12 until age 40.

PTEN HAMARTOMA SYNDROME

PTEN hamartoma syndrome is a rare, autosomal dominant syndrome consisting of multiple hamartomatous polyps of the skin and mucous membranes, including GI polyps, facial tricholemmomas, oral papillomas, and keratoses of the hands and feet. It was previously referred to as Cowden's syndrome and Bannayan-Riley-Ruvalcaba syndrome. The causative genetic lesion has been mapped to the *PTEN* tumor suppressor gene. The rate of associated malignancy is high, particularly in the thyroid, breast, and reproductive organs. The polyps in PTEN hamartoma syndrome are benign.

CRONKHITE-CANADA SYNDROME

Cronkhite-Canada syndrome is a rare, sporadic, acquired condition characterized by multiple hamartomatous polyps throughout the GI tract, along with alopecia, dermal pigmentation, and atrophy of the nail beds. Symptoms include diarrhea, protein-losing enteropathy, GI bleeding, intussusception, and rectal prolapse. It carries a poor prognosis, with 5-year mortality rates as high as 55%. Patients are at risk for gastric and colorectal cancer, and endoscopic surveillance has been recommended.

Polyps of the Colon

A *polyp* is defined as a grossly visible mass of epithelial cells that protrudes from the mucosal surface into the lumen of the intestine. A polyp may be sessile, flat, or pedunculated when it is attached by a stalk. Polyps are classified as either non-neoplastic or neoplastic (adenomatous). Polyps may rarely cause symptoms such as bleeding, prolapse, or obstruction. Neoplastic polyps have the potential to become malignant.

NONADENOMATOUS POLYPS

Nonadenomatous polyps, which account for approximately 90% of all mucosal polyps detected in the large bowel, can be found in more than 50% of people older than 60 years. These polyps, which are also termed *non-neoplastic polyps,* can be subcategorized into hyperplastic, inflammatory, lymphoid, and juvenile polyps. Most non-neoplastic polyps are hyperplastic polyps that arise as a result of abnormal maturation of the mucosal epithelial cells; these polyps are usually small in diameter and are found predominantly in the distal sigmoid colon and rectum. Hyperplastic polyps are not malignant and are not thought to be associated with any measurable increase in malignant potential. However, those with multiple, large right-sided hyperplastic polyps may be at increased risk. Patients with inflammatory bowel disease may develop inflammatory pseudopolyps, which may require biopsy or removal to distinguish them from neoplastic polyps. Lymphoid polyps are regions of the mucosa that contain exaggerated intramucosal lymphoid tissue. Juvenile polyps usually develop in the rectum of children younger than 5 years and are termed *hamartomatous* because they are focal malformations that resemble tumors but are caused by abnormal development of the lamina propria; these polyps require no therapy unless they cause symptoms, such as obstruction or severe bleeding, or are part of a genetic syndrome.

ADENOMATOUS POLYPS

DEFINITION

Adenomatous polyps (or adenomas) are neoplastic polyps with malignant potential. They are benign glandular tumors that exhibit either low- or high-grade dysplasia under microscopy. Their anatomic distribution parallels that of colorectal adenocarcinoma. Adenomatous polyps manifest in a range of sizes and may be sessile, flat, or pedunculated in morphology. They are believed to be the precursor lesion to colorectal adenocarcinoma, a process that occurs according to the adenoma-carcinoma sequence. Evidence supporting the adenoma-carcinoma sequence comes from several sources. Patients with genetic conditions that predispose to adenoma formation (e.g., FAP) develop cancer at high rates. Animal studies in which adenomas are induced by either carcinogens or genetic manipulation show carcinoma formation. Correlative evidence includes the observations that the epidemiology is similar for adenomas and carcinomas, that both lesions are more common in the same anatomic locations, and that adenomatous tissue can often be found in small adenocarcinomas. Intervention studies have shown that the removal of adenomatous polyps leads to a significant decrease in the risk for colorectal cancer.

EPIDEMIOLOGY

Adenomatous polyps are relatively common, particularly in elderly populations. Among healthy screening populations older than 50 years, adenomas are found in more than 15% of women and 25% of men. The prevalence of adenomas tends to be high in regions of the world where colorectal cancer is common. The importance of genetic risk factors is clear in the hereditary polyposis syndromes, and sporadic adenomas have a familial component; for example, individuals with a positive first-degree family history have a fourfold greater risk of developing adenomatous polyps. Blacks in the United States have an increased risk for developing adenomas and carcinomas relative to whites; the risk in Asians and Hispanics is similar to that in whites.

PATHOBIOLOGY

The layer of epithelial cells lining the surface of the normal large bowel undergoes continuous self-renewal, with a turnover period of 3 to 8 days. Undifferentiated stem cells located at the base of invaginated crypts give rise to cells that migrate toward the lumen as they differentiate further into specialized enterocytes; these cells are subsequently removed by apoptosis, by extrusion, or by phagocytes underlying the epithelial layer. The development of adenomatous polyps is associated with a sequence-specific accumulation of genetic lesions that cause an imbalance between epithelial cell proliferation and cell death. As a result, cells accumulate at the luminal surface, where they remain undifferentiated and continue to undergo cell division, eventually leading to the abnormal development of a mass of adenomatous tissue.

Adenomas are classified into three main histologic subtypes: tubular adenomas, villous adenomas (Fig. 199-6), and tubulovillous adenomas. Tubular adenomas, which are the most common type, account for 70 to 85% of all adenomas removed at colonoscopy. They are often small and pedunculated, and they consist of dysplastic tubular glands that divide and branch out from the mucosal surface; they rarely contain concomitant high-grade dysplasia or carcinoma. In contrast, villous adenomas are rarer (<5% of all adenomas), are generally large and sessile, and are composed of strands of dysplastic epithelium that project, finger-like, into the lumen of the gut; they have a much higher prevalence of high-grade dysplasia or carcinoma. Tubulovillous adenomas (10 to 25% of all adenomas) have a mixture of tubular and villous architecture. Advanced adenomas are defined as those that measure 1 cm or greater or have any villous histology or high-grade dysplasia. Patients with advanced adenomas or multiple adenomas (three or more) are at much greater risk for synchronous (developing simultaneously) or metachronous (developing after a time interval) colorectal cancer.

CLINICAL MANIFESTATIONS

Patients with adenomatous polyps generally remain asymptomatic, but they may present with an asymptomatic positive stool occult blood test or with evident hematochezia. The lifetime incidence of additional adenomas in a patient with one known adenoma is 30 to 50%. Less than 5% of all adenomas eventually develop into carcinomas. Two critical factors that determine the likelihood of an adenoma developing into an invasive lesion are the size of the polyp and the grade of dysplasia. For polyps less than 1 cm, the risk for carcinoma is 1 to 3%; polyps between 1 and 2 cm have a 10% risk of becoming cancerous; and more than 40% of polyps greater than 2 cm progress to an invasive lesion. All adenomatous polyps contain some degree of dysplasia, but they can be further categorized as low or high grade to indicate the degree of dysplasia and the corresponding risk for invasive carcinoma. High-grade dysplasia is associated with a 27% rate of eventual transformation into carcinoma.

DIAGNOSIS

Adenomatous polyps in the colon and rectum can be diagnosed by endoscopy, barium radiography, or CT scanning (CT colography or virtual colonoscopy). Colonoscopy is the preferred method for diagnosing adenomas because of its high accuracy and the ability to immediately biopsy and resection most polyps. Barium enema, as assessed in the National Polyp Study, missed 52% of polyps measuring 1 cm or more. CT colography has good sensitivity for detecting large (>1 cm) polyps (>85%) and for detecting cancers (96%), but it is less sensitive and specific for smaller polyps. CT colography requires bowel preparation, exposes the patient to ionizing radiation, and cannot remove polyps. Colonoscopy may miss 6 to 12% of large (≥1 cm) polyps and 5% of cancers. Of note is that nonpolypoid (flat and depressed) colorectal neoplasms are found in about 9% of asymptomatic and symptomatic adults on colonoscopy and are more likely to contain a carcinoma than are polypoid lesions; these lesions may not be visible on barium radiography or CT.

Flexible sigmoidoscopy, which is often used to screen asymptomatic persons at average risk for colorectal adenocarcinoma, detects 50 to 60% of all polyps and cancers. Generally, patients who have polyps detected by barium radiography, CT colography, or flexible sigmoidoscopy should undergo colonoscopy to remove the lesion and search for additional polyps. In one study in which patients with polyps discovered by flexible sigmoidoscopy underwent subsequent colonoscopy, there was an 80% reduction in the incidence of colorectal cancer.

TREATMENT Rx

The goal of treatment for adenomatous polyps is to remove or destroy the lesion during endoscopy. This recommendation is based on overwhelming evidence that endoscopic polypectomy reduces the subsequent incidence and mortality of colorectal cancer. Pedunculated adenomas are generally removed by snare polypectomy, with subsequent submission of the tissue for pathologic analysis. Piecemeal snare resection may be required to remove sessile polyps. Surgical resection of a polyp is indicated when endoscopic resection of an advanced adenoma is not possible. The biopsied polyp must be evaluated histologically to determine the presence or absence of carcinoma; if a malignant lesion is found, its histologic grade, vascular and lymphatic involvement, and proximity to the margin of resection should be determined. Unfavorable histopathologic factors that should prompt surgical resection include poorly differentiated histology, vascular invasion, lymphatic invasion, and incomplete endoscopic resection. Pedunculated polyps with cancer confined to the submucosa, with no evidence of unfavorable histologic features, can be definitively treated with endoscopic resection, without the need for surgical resection. Whether similar malignant sessile polyps can be managed nonoperatively is controversial. In these cases, the risk of surgery versus the risk of recurrence or lymphatic metastases needs to be balanced.

PROGNOSIS

Patients who have undergone resection of an adenomatous polyp are at increased risk for the subsequent development of adenoma and colorectal adenocarcinoma. This risk is influenced by the size, histology, and number of adenomas, and the surveillance intervals differ (Table 199-2). Low-risk patients—those with only one or two small tubular adenomas—should

TABLE 199-2 POST–ADENOMA RESECTION SURVEILLANCE INTERVALS

FINDINGS	INTERVAL
1-2 adenomas, <1 cm	5 yr
3-10 adenomas, adenoma with villous features, ≥1 cm, or with high-grade dysplasia	3 yr
>10 adenomas	<3 yr
Sessile adenoma ≥2 cm, piecemeal excision	2-6 mo

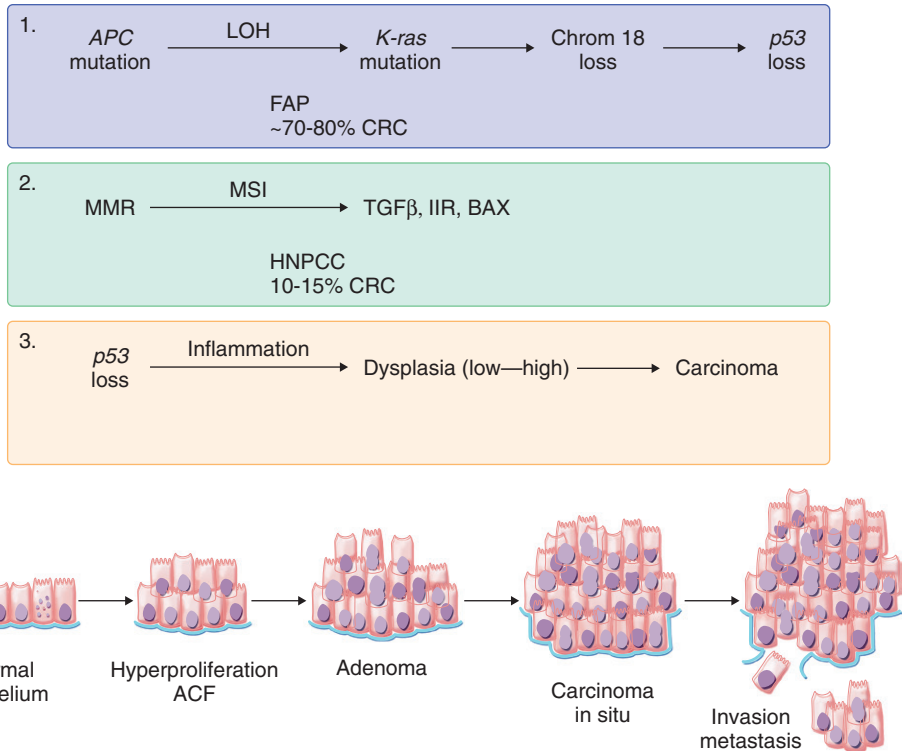

FIGURE 199-7. The molecular basis of colorectal cancer. Sequence-specific genetic lesions result in the transition from normal large bowel mucosa to invasive carcinoma. ACF = aberrant crypt foci; BAX = apoptosis-related protein; CRC = colorectal cancer; HNPCC = hereditary nonpolyposis colorectal cancer; IIR = type II receptor; LOH = loss of heterozygosity; MMR = mutation mismatch repair; MSI = microsatellite instability; TGFβ = transforming growth factor-β.

undergo colonoscopy in 5 years. Patients with multiple (more than two) adenomas, large (≥1 cm) adenomas, or adenomas with villous or high-grade histology should undergo colonoscopy in 3 years. Patients with numerous (>10) adenomas should undergo colonoscopy within 3 years. Patients who have had polypectomy of a large (≥2 cm) adenoma or an adenoma that had to be removed in pieces (piecemeal resection) should undergo colonoscopy within 6 months to evaluate the completeness of the resection.

Adenocarcinoma of the Colon and Rectum

PATHOBIOLOGY

Colorectal cancer is caused by the accumulation of multiple genetic lesions in sequence over time. Both the tissue architecture and the cellular genotype change as the disease progresses (Fig. 199-7). Early in the pathogenesis, mutations occur in either the *APC* gene (approximately 80% of sporadic colon cancers) or one of the mismatch repair genes (15% of sporadic colon cancers). The *APC* gene regulates cell growth and apoptosis, and mutations result in aberrant crypt foci, crypt dysplasia, and adenoma formation; 50% of sporadic adenomas have *APC* mutations. Mismatch repair gene mutations result in the failure to repair DNA transcription errors and the accumulation of additional mutations. Germline mutations in *APC* are the cause of FAP, and germline mutations of mismatch repair genes cause HNPCC (Lynch syndrome). Colorectal cancer pathogenesis requires additional mutations, including *DCC* ("deleted in colon cancer"), a tumor suppressor gene; *p53*, a regulator of the cell cycle; and *KRAS*, involved in the transduction of mitogenic signals across cell membranes. The accumulation of mutations leads to genetic instability and loss of heterozygosity where cells have only one allele of a gene owing to the loss of individual chromosomes during mitosis. DNA methylation can result in inactivation of tumor suppressor genes such as *p14* and *p16*. Other genetic and epigenetic alterations, including the expression of genes capable of cleaving extracellular matrix and a protein tyrosine phosphatase, lead to metastasis.

CLINICAL MANIFESTATIONS

The majority of patients with colorectal cancer present with symptoms that may be emergent. Common symptoms related to primary disease include rectal bleeding with or without manifestations of anemia, abdominal pain, and change in bowel function. Patients with systemic disease may exhibit anorexia, weight loss, and symptoms related to hepatic dysfunction, such as jaundice, icterus, and ascites (the last may also be seen with peritoneal metastases). Symptoms vary, depending on the primary site (Fig. 199-8):

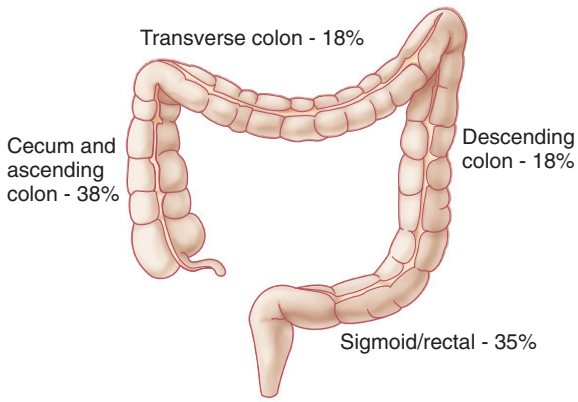

FIGURE 199-8. Sites of development of large bowel adenocarcinoma.

proximal lesions are more likely to present with bleeding and associated symptoms; more distal disease has a higher risk of obstruction and perforation. Rectal cancers can also manifest with tenesmus and changes in stool caliber. They involve sacral nerve plexi, causing significant neuropathic pain. Patients with PJS or Gardner's syndrome may exhibit extraintestinal manifestations.

DIAGNOSIS

The history, physical examination, and judicious use of both laboratory and radiologic tests are important in diagnosing colorectal cancer. The history should include prior colorectal cancer or adenomatous polyps, inflammatory bowel disease, and family history of colonic neoplasia. On physical examination, extraintestinal lesions characteristic of PJS or Gardner's syndrome may be noticed. Metastatic disease is suggested by enlargement, characteristically of the supraclavicular lymph nodes (Virchow's nodes) or the liver, or by the presence of an umbilical mass (Sister Mary Joseph's node) or ascites. The digital rectal examination may reveal a distal rectal cancer or spread of the tumor to the rectal shelf or pelvis (Blumer's shelf). The stool shows evidence of frank or occult blood in 40 to 80% of advanced cases. Iron deficiency anemia or an elevation in liver enzymes may aid in the diagnosis. The CEA level may be elevated, but it cannot be relied on for diagnosis owing to inadequate sensitivity.

TABLE 199-3 OPTIONS FOR COLORECTAL NEOPLASIA SCREENING*

TEST	INTERVAL
TESTS THAT DETECT ADENOMATOUS POLYPS OR CANCER	
Colonoscopy	Every 10 yr
Flexible sigmoidoscopy†	Every 5 yr
CT colography†	Every 5 yr
Double-contrast barium enema†	Every 5 yr
TESTS THAT DETECT PRIMARILY CANCER†	
Fecal occult blood tests	
High-sensitivity guaiac-based fecal occult blood test	Annually
Fecal immunochemical test	Annually
Stool DNA	Interval uncertain

*Beginning at age 50 for average-risk individuals.
†A positive test should prompt full colonoscopy.
CT = computed tomography.

Methods for diagnosing colorectal cancer are similar to those used to detect adenomatous polyps. Colonoscopy is the procedure of choice for all patients who have occult blood in their stools, unexplained iron deficiency anemia, or signs and symptoms suggestive of colorectal cancer (Fig. 199-9). Colonoscopy is more accurate than barium radiographic studies for the detection of colorectal neoplasms of all sizes and has the advantage of enabling the clinician to detect synchronous cancers and to obtain tissue for histologic analysis.

Additionally, accurate *local* staging of rectal cancers is paramount. Endoscopic ultrasound combines high-frequency ultrasonography with videoendoscopy. It is superior to CT and allows an accurate determination of the degree of invasion and detection and sampling of enlarged lymph nodes. Endoscopic ultrasound is also highly sensitive for the detection of rectal cancer recurrence after local resection or low anterior resection. MRI using either endorectal or phased array coils can also provide accurate local staging of rectal cancer. Local staging of nonrectal large bowel cancer is generally not performed preoperatively because this information is not used to guide therapy.

Many expert consensus guidelines now recommend CT scans of the abdomen and pelvis for colorectal cancer patients because liver metastases would preclude resection of an asymptomatic primary. Chest imaging with plain films or CT is recommended as well. PET scans have specific uses in defined cases of colorectal cancer, such as precluding additional systemic disease before resection of a solitary metastatic site. They may also be used to further describe abnormalities seen on CT. However, there is no role for PET in the routine work-up. Plain abdominal films are useful only in diagnosing obstruction.

Screening

The purpose of screening is to reduce colorectal cancer–related mortality by removing the precursor adenomas and detecting prevalent cancers at earlier, more curable stages. The long latency between adenoma development and subsequent cancer, on the order of 10 to 20 years, makes colorectal cancer a preventable disease through colonoscopy with polypectomy. It is an age-associated disease, and most patients should begin screening at age 50. There is a range of options for average-risk individuals (Table 199-3). These can be divided into two categories: stool tests, which include tests for occult blood and abnormal DNA, and structural tests, which include colonoscopy, flexible sigmoidoscopy, CT colography, and double-contrast barium enema. Stool tests are best suited for detecting prevalent cancers (and some advanced adenomas), whereas structural tests detect both cancers and adenomas. These tests may be used alone or in combination. Current multisociety guidelines recognize the multiple screening options but encourage the use of structural tests that have the ability to both detect and prevent colorectal cancer.

Tests for fecal occult blood detect hemoglobin in the stool from bleeding tumors. These tests are either guaiac based or immunochemical based. The guaiac tests detect blood in stool through the pseudoperoxidase activity of heme or hemoglobin. The immunochemical tests react with human globin and are therefore more specific. Guaiac testing consists of collecting two samples from three consecutive stools. To improve test accuracy, individuals undergoing guaiac testing are instructed to avoid aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), vitamin C, red meat, poultry, fish, and some vegetables. Three large, prospective randomized trials demonstrated that guaiac-based testing decreased colorectal cancer mortality by 15 to 33%, with one large U.S. study also showing a 20% decrease in colorectal cancer incidence, attributed to the relatively higher rates of colonoscopy in the study group. Guaiac-based tests have sensitivities for cancer from 35 to 80%. Immunochemical-based tests do not rely on a peroxidase reaction and therefore may have fewer false-positives and false-negatives. They do not require the dietary restrictions of guaiac-based tests. Despite these advantages, studies have not demonstrated a clear-cut benefit of immunochemical tests over highly sensitive guaiac-based tests. Fecal occult blood tests are repeated annually, and any positive test should prompt colonoscopy.

Stool DNA tests rely on the observation that both adenomas and carcinomas contain altered DNA, and this DNA is shed in the stool. Tests contain a multiple marker panel designed to detect mutations in *KRAS*, *APC*, and *p53*; a probe for BAT-26 (a marker of microsatellite instability); and a marker of DNA integrity analysis. Collection kits are designed to facilitate stool collection (at least 30 g) and mailing. In a screening population, stool DNA had better sensitivity for colorectal cancer (52%) than a relatively insensitive guaiac-based test (unrehydrated Hemoccult II; 13% sensitivity). Stool DNA did not have good sensitivity for advanced adenomas (defined as >1 cm, villous, or with high-grade dysplasia), detecting only 15%. Stool DNA testing is more expensive than fecal occult blood testing, and the optimal screening interval has not been defined.

Flexible sigmoidoscopy is capable of examining the distal 60 cm of the colon, or roughly the splenic flexure to the rectum. It can be done with minimal bowel preparation, does not require sedation, and can be performed by primary care providers, nurses, or physician's assistants. Flexible sigmoidoscopy can detect either left-sided cancers or polyps. The detection of an adenoma should prompt referral for full colonoscopy, owing to the high prevalence of synchronous neoplasia in the unexamined proximal colon. In case-control studies, flexible sigmoidoscopy is associated with 60 to 80% reduction in colorectal cancer mortality in the area of the examined colon—an effect that persists for up to 10 years. In one randomized trial, a single flexible sigmoidoscopy performed once between ages 55 to 64 years reduced colorectal cancer incidence by 23% and mortality by 31%. Sigmoidoscopy should be repeated every 5 years and may be combined with yearly fecal occult blood testing.

Colonoscopy allows complete examination of the colon, as well as adenoma removal and thus cancer prevention. In the United States it is generally done under sedation, after an oral bowel preparation, and by physicians with specific training in colonoscopy and polypectomy. There are no direct randomized studies assessing the efficacy of colonoscopy for screening, although there is a large amount of indirect evidence. Colonoscopy is generally used as the "gold standard" in assessing other screening methods. In a large, randomized Minnesota study of fecal occult blood testing, a decrease in cancer incidence was observed that could be explained only by the use of colonoscopy and polypectomy at a higher rate in the screened population. Case-control studies of sigmoidoscopy demonstrate a colorectal cancer mortality benefit that should also apply to colonoscopy. The National Polyp Study, which followed patients after polypectomy, found that the incidence of colorectal cancer was reduced 76 to 90% compared to three reference populations. However, recent dietary and chemotherapeutic intervention

trials found less of an effect, so the magnitude of the benefit is currently uncertain. If the initial screening colonoscopy is normal, further screening can be deferred for 10 years.

Double-contrast barium enema evaluates the entire colon by coating the mucosal surface with high-density barium and insufflating with air via a rectal tube. Multiple radiographs are obtained while varying the patient's position under fluoroscopy. It requires a colon preparation and exposes the patient to a small amount of ionizing radiation. There are no studies of double-contrast barium enema as a screening test. It is 85 to 97% sensitive for colon cancer, but its sensitivity for detecting large adenomas is only 48 to 73%. It should be repeated every 5 years. The finding of a polyp larger than 5 mm should prompt colonoscopy.

CT colography (also known as *virtual colonoscopy*) uses multidetector CT technology to obtain two- and three-dimensional images of the entire colon. It requires an adequate colon preparation and gaseous distention of the bowel using a rectal tube. Tagging of residual stool with barium or iodinated contrast material is frequently used. CT scanning is performed with the patient in the supine and prone positions. No studies have been done to evaluate the efficacy of CT colography in decreasing colorectal cancer incidence or mortality. CT colography has been compared with standard colonoscopy for the detection of neoplasia in screening populations.[7] The sensitivity of CT colography for large (≥10 mm) polyps is 85 to 93%, with a specificity of 97%. For polyps 6 to 9 mm, CT colography is 70 to 86% sensitive and 86 to 93% specific. Sensitivity for colorectal cancer (96%) is similar to that of colonoscopy. Although the optimal interval for testing has not been established, it is recommended that CT colography screening begin at age 50; if negative, it should be repeated at 5-year intervals. If a polyp greater than 5 mm is found, colonoscopy should be performed.

Staging

Accurate staging of colorectal cancer is of the utmost importance in determining both prognosis and the most relevant and effective therapy. The versions of the TNM classification system for large bowel cancers used by the American Joint Committee on Cancer and the International Union Against Cancer are identical (Table 199-4). Differing from many solid tumors (although not those of other GI origin, except for anal cancer), colorectal cancers are not staged according to size. Stage I cancers penetrate into but not through the bowel wall (T1–2N0M0), while stage II cancers penetrate through the wall without spreading to regional lymph nodes. About 40% of patients present with stage I or II disease in the United States. Stage III cancers involve regional lymph nodes and constitute about 40% of presenting cases. Stage IV colorectal tumors commonly spread to liver, lung, distant nodes, and peritoneum, with about 20% of patients presenting with distant disease. Rectal primaries, because of early access to the systemic circulation, may involve the lungs without liver metastases; this pattern of spread is distinctly unusual in proximal large bowel cancers.

Surveillance

Surveillance should be undertaken in patients fit enough to undergo metastasectomy or systemic therapy for recurrent colorectal cancer. The American Society of Clinical Oncology recommends annual CT of the chest and abdomen for 3 years following resection of high-risk primary tumors, with pelvic CT added in cases of rectal origin. Colonoscopy should also be done at 3 years and then every 5 years, with flexible proctosigmoidoscopy offered to rectal cancer patients who have not received irradiation. Physical examinations should be performed every 3 to 6 months for 3 years, then biannually for at least 2 more years. CEA levels should be checked every 3 months for at least 3 years.

PROGNOSIS

The prognosis for patients with colorectal cancer depends primarily on stage. Five-year survival for patients with proximal (colonic) adenocarcinomas ranges from a low of 6 to 8% for those with metastatic disease to approximately 95% for those with stage I resected tumors. Corresponding rates for rectal cancers are similar to slightly inferior overall, ranging from 4 to 72%. Besides TNM stage, additional factors that are prognostic for poorer outcomes in patients undergoing potentially curative resection include signet ring histologic subtype (see the preceding discussion under Pathobiology), lymphovascular and perineural invasion, absence of host lymphoid response, presence of clinical obstruction preoperatively, high preoperative serum levels of the CEA tumor marker, positive margins, high tumor grade, and microsatellite-stable disease. Differing from many solid tumors originating outside the GI tract, colorectal cancers do not have different prognoses based on size.

Genetic factors are important as well, even in the metastatic setting. Patients with tumors harboring *BRAF* mutations appear to have a worse outcome. *KRAS* mutations were formerly thought to be prognostic but now appear to be only predictive for lack of benefit from certain types of systemic therapy.

TABLE 199-4 STAGING FOR COLORECTAL ADENOCARCINOMAS

STAGE	TUMOR	NODE	METASTASIS
0	Tis	N0	M0
I	T1, T2	N0	M0
IIA	T3	N0	M0

Tis = in situ; T1 = submucosa; T2 = muscularis propria; T3 = subserosa, pericolorectal tissues; T4a = visceral peritoneum; T4b = other structures.
N1a = 1 regional node; N1b = 2-3 regional nodes; N1c = satellite(s) without regional nodes; N2a = 4-6 regional nodes; N2b = ≥7 regional nodes.
M1a = 1 organ; M1b = >1 organ, peritoneum.

TREATMENT Rx

Chemoprevention

NSAIDs, including aspirin, are believed to reduce adenoma formation and inhibit colon cancer development by inhibiting cyclooxygenase and subsequent prostaglandin generation (Chapter 36). Prostaglandins (e.g., E_2) promote cell proliferation and tumor growth. The NSAID sulindac causes regression of existing adenomas and inhibits the formation of new adenomas in patients with FAP. Epidemiologic studies have shown decreased colorectal cancer rates in regular users of NSAIDs. Randomized trials of aspirin have shown 20 to 40% reductions in adenoma recurrence and a 70% reduction in the incidence of colorectal cancer when at least 75 mg of aspirin daily is continual for 5 or more years.[8] The selective cyclooxygenase 2 inhibitor celecoxib has shown similar decreases in adenoma recurrence, but its use is limited by concerns about cardiovascular risk. Calcium supplementation (1200 mg/day) was shown to decrease the rate of metachronous adenomas by 20%. However, the large Women's Health Trial, with 36,000 participants, found that calcium (1000 mg) plus vitamin D (400 IU) had no effect in reducing colorectal cancer incidence.[9] Currently, the routine use of aspirin and calcium for prevention is not recommended, but it may be considered on an individual basis.

Dietary Prevention

Epidemiologic studies have reported correlations between colorectal cancer and obesity, smoking, inactivity, excessive alcohol use, and diets high in fat and low in fruits, vegetables, and fiber. These observations suggest that lifestyle modifications may decrease colorectal cancer risk. Unfortunately, three randomized intervention trials of modest dietary changes (10% less fat, 25 to 75% more fiber, 50% more fruits and vegetables) found no significant reductions in adenomas or colorectal cancer over 3 to 8 years of follow-up.

Surgery

Resection is the primary treatment modality for patients with regionally confined colorectal cancer. Highly selected patients with metastatic disease may also undergo surgery with curative intent. The goal of curative surgery for colonic adenocarcinoma is margin-negative elimination of the tumor, plus en bloc removal of the primary feeding arterial vessel and corresponding lymphatics for that segment of bowel. A minimum of 12 lymph nodes should be

retrieved for microscopic examination to assure staging accuracy. Synchronous colon cancers may be removed individually or with subtotal colectomy, and tumors adherent to adjacent structures should be resected en bloc. Prophylactic oophorectomy is no longer recommended, but women with one ovary grossly involved with cancer should undergo bilateral oophorectomy because of the relatively high risk of involvement of the other side. Laparoscopic resection is currently thought to be as effective as open resection and requires a modestly shorter recovery time.[5]

In general, surgical considerations for rectal primaries are similar. Total mesorectal excision (en bloc removal of the lymphovascular and fatty envelope surrounding the rectum) is recommended for distal cancers, whereas tumor-specific mesorectal excision (en bloc removal of the mesorectum 5 cm distal to the tumor) should suffice for upper rectal tumors. Local transanal excision is acceptable for selected low rectal cancers thought to have minimal risk of nodal involvement. Selection criteria include the following: T1 disease, size less than 3 cm, low grade (well differentiated), location within 8 cm of the anal verge, no lymphovascular invasion, and less than one-third circumferential.

Until fairly recently, patients presenting with synchronous colorectal cancer primaries and unresectable metastases underwent resection of the primary tumor, regardless of whether they were symptomatic. This practice pattern could obviously delay systemic treatment in patients who are markedly more likely to die from their metastases before suffering significant complications from the intact large bowel tumor. Recent data suggest that stage IV patients with an asymptomatic primary tumor can safely begin systemic therapy without undergoing surgery, with only a small chance of developing serious complications requiring urgent operative interaction. Patients with rectal primaries may be at slightly higher risk for developing complications than those with tumors originating in the proximal large bowel.

Obstructing tumors that can be fully removed should be resected, with bowel anastomosis usually being acceptable in this setting. Proximal diversion alone, especially in the setting of very locally advanced unresectable cancer, may be necessary; if the primary tumor responds to the point where it can later be removed, resection followed by ostomy closure is reasonable. Endoscopic stenting may be useful to relieve acute obstruction. Perforated bowel is usually resected, with the choice of anastomosis, with or without diversion, depending on a number of factors, including degree of fecal contamination and general health of the patient.

Radiation Therapy

Radiation therapy may be used as curative or palliative treatment of large bowel cancers. In general, it plays a markedly larger role in treating rectal than colonic primaries. Single-institution trials have shown that irradiation improves local control following resection of high-risk proximal large bowel (colonic) cancers, but these findings were not confirmed in a randomized intergroup trial that closed early owing to slow accrual. Current recommendations for adjuvant radiation to the tumor bed following colon cancer resection include positive margins and localized perforation. Some authorities also advocate its use in colon cancers at particularly high risk of local recurrence (T4, T3N1–2 tumors in the ascending or descending colon), but that recommendation is not universally accepted. Irradiation may still play a role in treating colon cancer metastases to bone, brain, liver, and lung, as well as in cases of bleeding, obstruction, and locally advanced unresectable disease.

A major use for radiation in the definitive treatment of large bowel adenocarcinoma involves perioperative therapy for resectable rectal cancer. It is also commonly employed with chemotherapy for locally advanced invasive tumors, which occasionally become resectable after therapy. As with colon primaries, irradiation may be used to palliate bleeding, obstruction, or selected metastases from rectal cancers.

Systemic and Combination Therapies

The backbone of colorectal cancer treatment in both the adjuvant and metastatic settings is a fluorinated pyrimidine. The most commonly used drug is 5-fluorouracil (5-FU), although oral prodrugs are increasingly been utilized. 5FU targets the enzyme thymidylate synthase, inhibiting DNA synthesis and/or repair. It also may be incorporated into RNA, interfering with further processing. Although not particularly effective as a single agent (see later), 5-FU's efficacy can be enhanced by changing its means of administration (prolonging infusion) and by administering it with a variety of biochemical modulators, most commonly leucovorin. Other agents commonly used in treating colorectal cancer include irinotecan, a topoisomerase I inhibitor, and oxaliplatin, a later-generation platin that forms bulky DNA adducts that inhibit replication.

Patients with resected stage I colon cancers have a high cure rate, and this cannot easily be improved on with systemic therapy. Stage II patients have a higher chance of relapse (event-free survival ≈76% at 3 years), and systemic therapy with 5-FU and leucovorin improved that figure by about 3% for an unselected group of node-negative patients. Patients harboring highly microsatellite-unstable tumors have a better prognosis in general but may actually have worse outcomes with 5-FU treatment, although that is controversial. Treatment of stage II patients remains controversial in general: some experts suggest that the proportional benefit of systemic therapy is as great as it is in stage III disease, while others point out the low absolute magnitude of benefit and do not advocate its use. Some categories of stage II disease are believed to be at particularly high risk for recurrence (e.g., clinical obstruction). These patients usually receive postoperative chemotherapy, often with regimens commonly prescribed for patients with stage III cancer. Radiation has been tested in patients thought to be at higher than average risk of local relapse (T4 tumors), but its use is not standard. Finally, it is likely that gene studies will eventually be used to identify patients at higher risk of relapse or who have a greater chance of benefiting from systemic therapy, and treatment of carefully selected patients with stage II disease may become standard.

Five-year disease-free survival for patients with stage III colon cancer is only in the 40 to 45% range. Barring significant comorbidities or other confounding factors, all patients with node-positive disease receive adjuvant systemic therapy. Combinations of 5-FU and oxaliplatin (usually FOLFOX [fluorouracil, leucovorin, oxaliplatin]) clearly improve long-term survival rates and represent standard care.[6] Regimens containing irinotecan and biologics (bevacizumab, cetuximab) are highly effective in the treatment of advanced disease (see later), but oddly, they do not clearly benefit patients when they are given in the postoperative setting. Patients who are not candidates for combination chemotherapy are sometimes offered capecitabine, an oral prodrug activated to 5-FU in sequential enzymatic steps. Capecitabine has also been combined effectively and relatively safely with oxaliplatin for adjuvant use. Important outstanding questions regarding adjuvant chemotherapy is whether a shorter duration (3 months vs. the standard 6) might be equally effective, and whether elderly patients obtain greater benefit from newer combination regimens versus simple fluoropyrimidine use.

Rectal Adenocarcinoma

Radiation considerations are slightly different for patients with primary rectal adenocarcinomas, owing to the difficulty of achieving negative circumferential (radial) margins. Specifically, the risk of local recurrence is much more significant. In general, rectal cancer patients undergoing standard resection for stage I tumors do not receive additional treatment. However, higher-risk patients (T2 disease, T1 with poorly differentiated histology, perineural or lymphovascular invasion, or close margins) treated with local excision should receive postoperative pelvic irradiation with or without 5-FU chemotherapy, or they should return to the operating room for total mesorectal excision. Irradiation is standard for those with stage II and III rectal adenocarcinomas to decrease local relapse rates, increase the chance of sphincter preservation (when used in selected preoperative settings for low-lying cancers), and possibly improve survival. The major considerations are timing (pre- or postoperative use), course (short or long), and whether to combine it with fluoropyrimidine-based chemotherapy. Short-course (5-day) preoperative irradiation without chemotherapy may be considered and used if tumor downsizing is not necessary. When short-course radiation is used, patients still require postoperative systemic therapy, with either a fluoropyrimidine alone (stage II) or a fluoropyrimidine-oxaliplatin combination regimen (node-positive disease), to minimize the risk of distant metastases. Long-course irradiation (approximately 5.5 weeks) is particularly important when tumor response is necessary to make surgery easier or more feasible. It is usually combined with continuous-infusion 5-FU or capecitabine, and it can be given preoperatively or postoperatively (if the patient did not receive preoperative short-course radiation). Including oxaliplatin preoperatively does not improve results and is not recommended independent of a clinical trial, owing to its higher toxicity profile. Oxaliplatin may be used postoperatively if the pathology specimen demonstrates nodal involvement. With long-course irradiation, preoperative (compared with postoperative) treatment is less toxic and may offer improved local control.[7] However, it requires accurate preoperative staging (to avoid treating patients who might have stage I disease). Highly selected rectal cancer patients thought to be at low risk of local recurrence (T3N0 or T1–2N1) may receive total mesorectal excision plus best systemic therapy without irradiation, usually postoperatively.

Metastatic Colorectal Cancer

Metastatic disease is treated identically, regardless of the site of origin (colon vs. rectum). Patients with incurable metastatic colorectal cancer have a median survival of approximately 6 months with best supportive care alone; however, incremental gains made through the adoption of new systemic therapies have extended that time to almost 2 years. For example, treatment with single-agent fluoropyrimidines leads to median survival in the 10- to 13-month range; adding one more effective chemotherapy drug (either irinotecan or oxaliplatin) affords survival of about 15 to 20 months, and adding both drugs to 5-FU has been reported to extend life to 23 months. Interestingly, long-term results seem to be similar regardless of which drug (oxaliplatin or irinotecan) is added to 5-FU first (although the toxicity pattern varies, depending on which drug is given), or even regardless of whether 5-FU is used first and combination chemotherapy is used subsequently, as long as patients are eventually exposed to all active agents.

Additional improvements have arisen through the development of drugs that are more convenient and/or less toxic than standard agents, although they may not be more effective. Capecitabine, an oral prodrug activated to 5-FU in three sequential enzymatic steps, can be substituted for that agent

alone and in combination with oxaliplatin (although patients still need intravenous access for the latter drug).

Recent breakthroughs have all been related to use of biological agents (Chapter 35). Successful drugs to date have all been monoclonal antibodies, whereas small molecule tyrosine kinase inhibitors generally appear to be ineffective. Bevacizumab is a humanized monoclonal antibody directed against vascular endothelial growth factor, an important mediator of angiogenesis. Bevacizumab has little single-agent activity against colorectal cancer, but it improves the interval without progression when added to irinotecan- or oxaliplatin-containing chemotherapy.[8,9] Bevacizumab with FOLFOX or FOLFIRI (fluorouracil, leucovorin, irinotecan) now represents first-line treatment for patients with advanced large bowel cancer in the United States.

The epidermal growth factor receptor (EGFR) is another important target in advanced colorectal cancer. Cetuximab and panitumumab are monoclonal antibodies (chimeric and human, respectively) directed against the EGFR. They have single-agent activity against colorectal cancers,[10,11] and both may be combined with chemotherapy to improve at least progression-free survival.[9,11] Although both agents appear effective in front-line or later use, efficacy is restricted to patients whose tumors harbor no mutations in *KRAS*.

Locally Directed Treatment of Metastatic Disease

Complete resection of hepatic or pulmonary metastases may result in long-term survival and is the standard of care for selected patients with colorectal cancer. The majority of data exist for hepatic metastasectomy. Actuarial 5-year survival rates from single-institution series have been in the 25 to 40% range. However, relapse after 5 years still occurs, suggesting that this percentage does not reflect the number actually *cured* with surgery. That figure, calculated from 10-year survival rates, is probably between 17 and 25%, which still compares quite favorably with the survival rate for patients with colorectal cancer metastatic to the liver who do not undergo surgery. The actual role of perioperative systemic therapy in those undergoing metastasectomy is not well defined, but most experts advocate 6 months of fluoropyrimidine-based chemotherapy, with or without oxaliplatin. Importantly, bevacizumab can affect wound healing and should not be used in the immediate perioperative period.

Small liver metastases that are not resectable because of anatomic location or in a frail patient unable to undergo hepatic resection may be treated with radio frequency ablation, which uses alternating electrical current to generate heat, destroying malignant cells through protein coagulation. Although it has never been directly compared with resection in a randomized trial, radio frequency ablation appears to offer inferior local control of disease. Some advocate the placement of a hepatic artery pump to infuse fluoropyrimidine-based chemotherapy to treat unresectable liver-predominant metastases. Other techniques useful in noncolorectal liver-based tumors (e.g., hepatocellular carcinoma), such as chemoembolization, have no proven role for large bowel liver metastases.

CONCLUSION

Colorectal cancer remains a significant problem, despite the fact that most cases can be prevented. Large gains have been made in terms of overall survival, but the vast majority of patients with advanced disease still succumb to their malignancy. Although minimal tailoring can be offered to patients (e.g., selecting a chemotherapeutic agent based on toxicity or not using an anti-EGFR antibody in those with *KRAS*-mutated tumors), the dream of truly individualized therapy remains elusive.

PANCREATIC CANCER

MARGARET TEMPERO AND RANDALL BRAND

DEFINITION

The term *pancreatic cancer* usually refers to ductal adenocarcinomas because more than 90% of pancreatic neoplasms are of ductal epithelial origin. Other pancreatic tumors include endocrine tumors (Chapter 201), carcinoid tumors (Chapter 240), lymphomas, cystic neoplasms, and the rare squamous cell carcinomas, giant cell carcinomas, carcinosarcomas, malignant fibrous histiocytomas, solid pseudopapillary neoplasms, sarcomas, and pancreaticoblastomas.

EPIDEMIOLOGY

Pancreatic cancer is the fourth most common cause of cancer death in the United States despite its low incidence: about 42,500 pancreatic neoplasms are diagnosed and 35,200 will die annually from cancer-related causes. Worldwide, pancreatic cancer accounts for 2% of all malignant diseases. Its incidence is higher in developed than in developing countries, but there is less than a two-fold variation in incidence worldwide. The 5-year survival rate for adenocarcinoma of the pancreas is less than 5%, and most patients die within the first 2 years. The risk for developing a pancreatic carcinoma increases with age, with a mean age of onset in the seventh and eighth decades of life. There is almost an equivalent risk in men and women.

Pancreatic cancer is more common in African Americans, Maori New Zealanders, and Polynesians. Cigarette smoking is the most reproducible environmental risk factor, causing a 1.5- to 5.5-fold increased rate of pancreatic cancer. Other risk factors include increased body mass index, chronic pancreatitis (Chapter 146), high intake of animal fat, and prolonged contact with petroleum products and wood pulp. A modest, less than two-fold increased risk for pancreatic cancer is associated with blood groups A, AB, and B relative to blood group O, and with selected polymorphisms that map to three loci on chromosomes *13q22.1*, *1q32.1*, and *5p15.33*.

The association between pancreatic cancer and diabetes is complex. Diabetes or impaired glucose tolerance is observed in up to 80% of patients at the time of diagnosis of their pancreatic cancer, and diabetes is often described as a risk factor. However, the diabetes is usually of recent onset and may improve or resolve after resection of the tumor. A population-based study suggests that about 1% of patients who develop diabetes after age 50 years will have a diagnosis of pancreatic cancer within 3 years before or after the onset of diabetes, and most of these individuals will be diagnosed with diabetes within 6 months of detection of the pancreatic cancer. Thus, diabetes may be a sign of underlying pancreatic cancer.

The greatest risk factor for developing pancreatic cancer is genetic predisposition. It is estimated that up to 10% of patients with pancreatic cancer have one or more first- or second-degree relatives with the disease. Recognized inherited syndromes include hereditary pancreatitis (Chapter 146), mutation of the *BRCA2* gene (Chapter 204), familial atypical multiple mole–melanoma syndrome and a *p16* germline mutation, hereditary nonpolyposis colorectal cancer (Chapter 199), Peutz-Jeghers polyposis (Chapter 199), and ataxia-telangiectasia (Chapter 258). In most families, the genetic factors responsible for the predisposition are unknown.

Pancreatic cysts are increasingly recognized with the widespread use of abdominal imaging and can be categorized as neoplastic or non-neoplastic. Neoplastic cystic lesions consist of those with malignant potential such as intraductal papillary mucinous neoplasms (IPMNs), mucinous cystic neoplasms, and the rare solid pseudopapillary tumors. Those without malignant potential include serous cystadenomas and lymphoepithelial cysts. IPMNs equally affect women and men and are usually located in the head of the pancreas. Other cystic neoplasms most commonly occur in young to middle-aged women and are located in the body or tail of the pancreas.

PATHOBIOLOGY

Three major precursors to invasive pancreatic adenocarcinoma have been identified: pancreatic intraepithelial neoplasia (PanIN), IPMN, and mucinous cystic neoplasm (MCN). The PanIN is the most prevalent type of precursor lesion, arising from the ductal epithelial cells. It is presumed that these lesions follow a pathway of progression from no dysplasia to moderate dysplasia (borderline) to high-grade dysplasia (carcinoma in situ) to invasive carcinoma. As the extent of ductal atypia rises, there is an increasing frequency of associated genetic alterations (Fig. 200-1). Unlike PanIN lesions, the IPMNs and MCNs are detectable by computed tomography (CT) or endoscopic ultrasound (EUS). Although only responsible for a minority of pancreatic cancers (less than 15%), IPMNs and MCNs do offer the opportunity to identify a premalignant lesion in the pancreas, especially with the increasing use of high-resolution noninvasive abdominal imaging procedures.

Ductal adenocarcinoma and its variants are characterized by a dense, desmoplastic reaction surrounding a compact mass of hard pancreatic tissue that can invade surrounding mesenteric vessels and can involve perineuronal tissue and lymphatic channels or nodes. Because approximately 75% of pancreatic carcinomas are located in the head of the pancreas, the usual clinical presentations are related to invasion or compression of the bile or pancreatic ducts. The duodenum, stomach, and colon may be invaded or compressed. Pancreatic cancers other than ductal adenocarcinoma, such as islet cell tumors or lymphomas, tend to be softer and less fibrotic and thus tend to cause distortion rather than encasement or compression of adjacent structures.

Tumor suppressor genes that are most frequently mutated in pancreatic adenocarcinoma are *p16* (95%), *p53* (50 to 75%), and *DPC4* (55%). *K-ras*, which is the most commonly activated oncogene, occurs in about 95% of advanced pancreatic cancers. An extensive genetic analysis of 24 pancreatic cancers, performed using state-of-the-art DNA sequencing of 20,735 genes, as well as both gene expression and gene copy number analysis, revealed on average a total of 63 altered genes per tumor. Although there was marked variability from tumor to tumor in the specific genes that were mutated, 12 cellular signaling pathways and processes that had at least one gene genetically altered in at least 70% of the tumors were identified. The six specific pathways that had alterations of at least one of the genes in all of the 24 pancreatic cancers were *K-ras* signaling, apoptosis, Wnt/Notch signaling, transforming growth factor-β (TGF-β) signaling, hedgehog signaling, and regulation of G_1 to S phase transition.

CLINICAL MANIFESTATIONS

Early symptoms include nonspecific abdominal discomfort, nausea, vomiting, sleeping difficulties, anorexia, and generalized malaise. Despite the historic perception that a mass in the head of the pancreas manifests initially with painless jaundice, the more common presenting symptoms are epigastric pain, obstructive jaundice, and weight loss. Although these symptoms prompt evaluation of the pancreas and biliary tree, they occur late in the disease and are usually associated with advanced tumor at the time of diagnosis. The finding of a palpably distended, nontender gallbladder as a result of obstruction of the distal common bile duct by pancreatic cancer has been called *Courvoisier's sign*. Patients may manifest superficial or deep vein thrombosis (Trousseau's syndrome; Chapter 187).

The most common laboratory abnormalities include anemia and elevation of serum levels of alkaline phosphatase, bilirubin, and aminotransferases. Approximately 80% of patients have jaundice related to biliary obstruction. Diabetes or hyperglycemia is seen in up to 80% of patients, and pancreatic cancer should be considered in the differential diagnosis of the cause of new-onset diabetes in patients who older than 50 years and who do not have a family history of diabetes.

Tumors of other histologic types arising in the pancreas may also cause nonspecific symptoms. Patients with functioning islet cell tumors can present with symptoms related to the overproduction of peptides manufactured in the islets (Chapter 201). Cystic neoplasms generally remain asymptomatic until they become quite large, at which point patients can present with a palpable mass, abdominal pain, nausea, emesis, and weight loss. Obstruction of the common bile duct is less common than with ductal adenocarcinoma. Intraductal papillary mucinous tumors may cause symptoms of acute pancreatitis or pancreatic insufficiency owing to obstruction of the pancreatic duct.

DIAGNOSIS

Differential Diagnosis

The differential diagnosis of pancreatic ductal cancer includes conditions that can manifest as a solid mass in the pancreas or especially acute or, more commonly, chronic pancreatitis (Chapter 146). Ampullary carcinomas and distal cholangiocarcinomas also manifest with biliary obstruction and jaundice (Chapters 158 and 202). It may be difficult to differentiate cystic pancreatic neoplasms from non-neoplastic pancreatic pseudocysts based on noninvasive imaging studies; a cystic neoplasm should always be considered in patients who present with isolated cystic lesions and have no prior history of acute or chronic pancreatitis.

Imaging

For all patients with suspected pancreatic tumors, the preferred imaging study is a multidetector CT scan using dynamic contrast with thin cuts

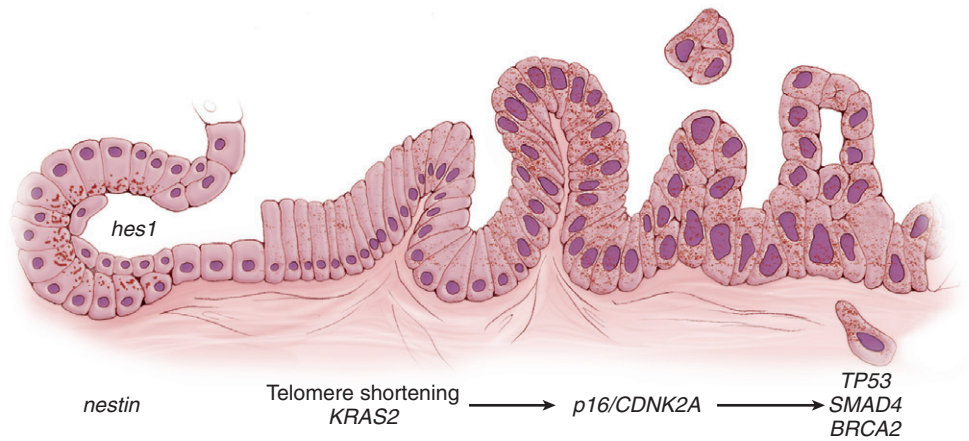

FIGURE 200-1. Molecular progression model of pancreatic cancer (PanINs). Molecular abnormalities in PanINs can usually be stratified into "early" changes (e.g., expression of *MUC5* and prostate stem antigen, or loss of *p16*), "intermediate" changes (e.g., expression of cyclin D1), and "late" changes (e.g., expression of *p53*, proliferation antigens, *MUC1*, mesothelin, and 14-3-3s, or loss of *SMAD4/DPC4*). (Adapted from Maitra A, Adsay NV, Argani P, et al. Multicomponent analysis of the pancreatic adenocarcinoma progression model using a pancreatic intraepithelial neoplasia tissue microarray. *Mod Pathol*. 2003;16:902-912).

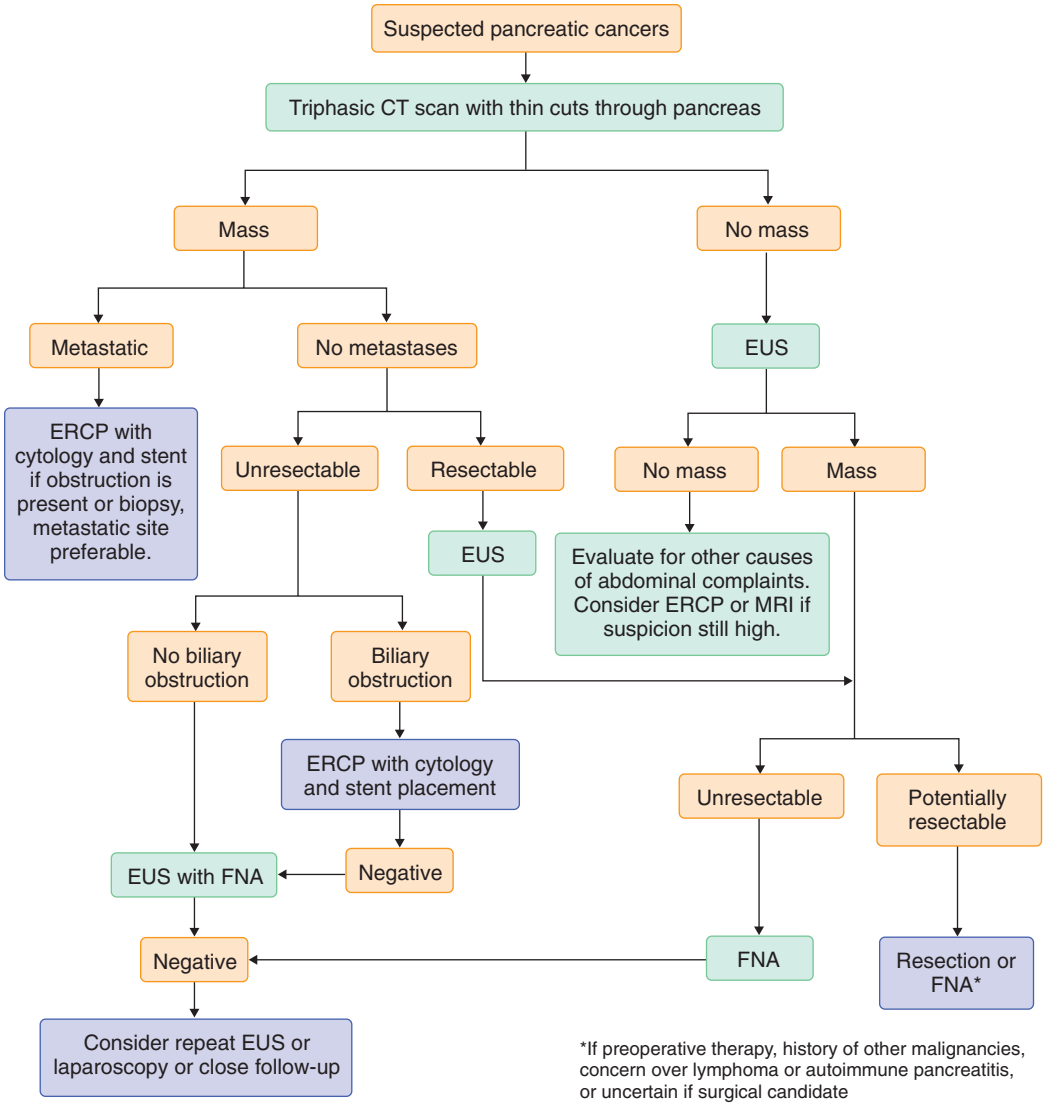

FIGURE 200-2. Diagnostic algorithm for pancreatic cancer. Intraoperative fine-needle aspiration (FNA) is used if the tumor is found to be inoperable during surgery. CT = computed tomography; ERCP = endoscopic retrograde cholangiopancreatography; EUS = endoscopic ultrasonography; MRI = magnetic resonance imaging.

through the pancreas (Fig. 200-2). The CT scan provides important information about vascular involvement and metastases, and it is approximately 90% accurate in assessing resectability. EUS may be useful in patients with equivocal findings on the CT scan. When a preoperative biopsy is needed, it is preferable to obtain a fine-needle aspiration under endoscopic guidance to minimize the chance of tumor seeding, but patients with potentially resectable disease can proceed directly to surgery. False-negative biopsy findings can result from the desmoplastic reaction characteristic of pancreatic ductal adenocarcinoma. Laparoscopy can identify patients who may have occult metastases in the peritoneum or the surface of the liver. Patients whose CT scans indicate an unresectable tumor based on local extension or the presence of metastases should have a definitive diagnosis established by a fine-needle aspiration biopsy of the primary or metastatic site.

Biomarkers

The clinical role for tumor markers is limited. CA-19-9, a sialylated Lewis[a] antigen associated with circulating mucins, is the most widely used marker for pancreatic disease. At the most commonly used cutoff level of 37 U/mL, its sensitivity ranges from 81 to 85%, and its specificity ranges from 81 to 90%; CA-19-9 levels higher than 1000 U/mL are associated with unresectable disease. Although this test is not a substitute for a histologic diagnosis, it is useful for monitoring the response to treatment.

The aforementioned radiographic studies also apply to other pancreatic tumors. EUS with fine-needle aspiration can be useful in the evaluation of cystic lesions, and it often provides additional detail not seen by CT and permits sampling of the cystic fluid for tumor marker levels, amylase content, viscosity, and cytologic examination. Carcinoembryonic antigen (CEA) levels of 192 mg/mL are approximately 80% accurate for identifying mucinous as compared with nonmucinous cystic lesions. For obvious reasons, it is important to clarify whether the lesion is a simple cyst, which would suggest a pseudocyst, or a cystic neoplasm.

TREATMENT AND PROGNOSIS

Rx

In the absence of metastatic disease, surgical resection is the initial treatment of choice for all patients with pancreatic adenocarcinomas. The procedure should be performed in centers that have a high volume of pancreatectomies because surgical outcomes are improved with more volume and experience. Routine preoperative biliary drainage in patients with obstructive jaundice caused by pancreatic head tumor increases the rate of complications of surgery for the cancer.[1] For periampullary adenocarcinoma, pancreaticoduodenectomy is the standard of care, and distal gastrectomy and extended lymphadenectomy do not improve outcome.[2] Tumors are considered resectable if a clear fat plane is present around the celiac and superior mesenteric arteries and if the mesenteric and portal veins are patent. After successful resection, adjuvant therapy with intravenous 5-fluorouracil (425 mg/m^2) and folinic acid (20 mg/m^2) daily for 5 days and then monthly for 6 months or gemcitabine (1000 mg/m^2 over 30 minutes) weekly for 3 weeks out of 4 for 6 months improves survival compared with observation alone,[3,4] but the addition of gemcitabine to fluorouracil plus folinic acid does not provide incremental benefit.[5] Radiation therapy may not confer any added value beyond chemotherapy alone. In general, successful resection followed by adjuvant therapy results in a 5-year survival rate of approximately 20%.

Borderline resectable tumors include those with venous involvement of the superior mesenteric vein (SMV)–portal vein demonstrating tumor abutment with or without impingement and narrowing of the lumen, encasement of the SMV–portal vein but without encasement of the nearby arteries,

short-segment venous occlusion secondary to either tumor thrombus, or encasement but with suitable vessel proximal and distal to the area of vessel involvement allowing for safe resection and reconstruction, gastroduodenal artery encasement up to the hepatic artery with either short-segment encasement or direct abutment of the hepatic artery without extension to the celiac axis, and tumor abutment of the superior mesenteric artery (SMA) not to exceed more than 180 degrees of the circumference of the vessel wall. Because there is a higher risk for positive margins with these tumors, some advocate preoperative chemotherapy and radiation, although this is controversial.

Surgery can also have an important palliative role. Patients who undergo surgical exploration but who are found not to have a resectable tumor may benefit from a biliary or gastric bypass procedure, depending on the clinical setting. However, there is now substantial experience in the placement of both biliary and luminal (duodenal) stents, so the more invasive operative procedure can be avoided in most instances. In addition, intraoperative, EUS-guided, or percutaneous chemical splanchnicectomy can provide protracted pain control.

Patients with locally unresectable disease are usually managed with a combination of chemotherapy and radiation therapy, followed by additional chemotherapy. The most commonly used drug is 5-fluorouracil, given by low-dose continuous infusion, combined with radiation therapy, but gemcitabine is also being studied. The median survival time for these patients is 10 to 12 months.

For patients with metastatic disease, single-agent gemcitabine (1000 mg/m^2 intravenously, weekly times 7 for 8 weeks and then weekly times 3 every 4 weeks) remains the standard of care and improves survival. A small improvement in survival has been observed with the addition of erlotinib (orally, 100 mg/day).■

For all patients with locally advanced and metastatic disease, optimal management of pain and of local complications is critical. Biliary obstruction can be managed surgically or with placement of a plastic or expandable metal stent. Narcotic analgesics (Chapter 29) and palliative care (Chapter 3) are cornerstones of therapy.

Most patients with a cystic neoplasm should be considered for surgical resection. The long-term survival rate following resection of malignant pancreatic cystic neoplasms exceeds 70%, and adjuvant therapy is currently not recommended.

FUTURE DIRECTIONS

Future research in pancreatic adenocarcinoma will focus on identifying individuals at high risk, developing strategies for early detection, and optimizing treatment. Drugs that interact with tyrosine kinase receptors, downstream signaling events, or tumor-supporting pathways in the microenvironment are under active investigation.

PANCREATIC ENDOCRINE TUMORS

ROBERT T. JENSEN

DEFINITION

Pancreatic endocrine tumors (PETs) are also called islet cell tumors; however, because the cell of origin of most is unknown, the general term PET is preferred. This term is also a misnomer because PETs can also occur outside the pancreas. Ten PETs are well established (Table 201-1). Other additional functional PET syndromes have been rarely reported: PETs secreting renin, PETs secreting erythropoietin, PETs secreting luteinizing hormone that causes virilization, and PETs secreting insulin-like growth factor II causing hypoglycemia. In addition, PETs synthesizing neurotensin, calcitonin, and ghrelin are reported, but no distinct syndrome has been described.

PETs frequently are classified as functional or nonfunctional (see Table 201-1) depending on whether a clinical syndrome resulting from the autonomously released hormone is present. Nonfunctional PETs frequently release hormones and peptides (pancreatic polypeptide, neurotensin, α- and β-subunits of human chorionic gonadotropin, neuron-specific enolase, chromogranin A and breakdown products) that cause no distinct clinical syndromes.

EPIDEMIOLOGY

PETs are uncommon, having a prevalence of less than ten cases per 1 million population. Insulinomas, gastrinomas, and nonfunctional PETs are the most common, with an incidence of one to three new cases per 1 million population.

PATHOBIOLOGY

All PETs share certain features. PETs are classified as APUDomas (amine precursor uptake and decarboxylation), which share cytochemical features with carcinoid tumors, melanomas, and other endocrine tumors (pheochromocytomas, medullary thyroid cancer). Except for insulinomas, these tumors are frequently malignant. All PETs appear similar histologically, with few mitotic figures. Ultrastructurally, they have dense granules containing peptides, amines, and products of neuroendocrine differentiation (neuron-specific enolase, chromogranins, synaptophysin). The presence of chromogranin immunoreactivity in the tumor is now widely used to identify these tumors as endocrine tumors.

Molecular studies show that PETs have a different pathogenesis than common gastrointestinal adenocarcinomas because they infrequently demonstrate alterations in common tumor suppressor genes (e.g., retinoblastoma gene, *p53*) or common oncogenes (*ras*, *c-Jun*, *c-Fos*). Alterations in $p16^{INK4a}$, the *MEN1* gene, and the expression of growth factors, as well as chromosomal losses (1q, 3p, 3q, 6p, X) and gains (17p, 17q, 20q), have been associated with a worse prognosis in numerous studies. A number of other factors have prognostic significance, the most important of which is the presence of liver metastases. Recently, a World Health Organization TNM grading and classification system has been proposed for PETs based on tumor size, presence of metastases, invasiveness, and proliferative indices and has been recently shown to have prognostic value in a number of studies.

Four autosomal dominant–inherited disorders are associated with an increased occurrence of PETs: multiple endocrine neoplasia type 1 (MEN 1; 80 to 100% develop PETs), von Hippel-Lindau disease (VHL; 10 to 17% have PETs), von Recklinghausen's disease (neurofibromatosis 1([NF-1]; 12% develop duodenal somatostatinomas), and tuberous sclerosis (<1% develop PETs).

FUNCTIONAL PANCREATIC ENDOCRINE TUMOR SYNDROMES

Zollinger-Ellison Syndrome (Gastrinomas)

DEFINITION AND EPIDEMIOLOGY

Zollinger-Ellison syndrome (ZES) is a clinical syndrome caused by a gastrin-releasing endocrine tumor usually located in the pancreas or duodenum and characterized by clinical symptoms and signs resulting from gastric acid

TABLE 201-1 PANCREATIC ENDOCRINE TUMORS

NAME OF TUMOR	NAME OF SYNDROME	MAIN SIGNS OR SYMPTOMS	LOCATION	MALIGNANCY (%)	HORMONE CAUSING SYNDROME
I. FUNCTIONAL PET					
Gastrinoma	Zollinger-Ellison syndrome	Abdominal pain, diarrhea, esophageal symptoms	Pancreas—30% Duodenum—60% Other—10%	60-90	Gastrin
Insulinoma	Insulinoma	Hypoglycemic symptoms	Pancreas—100%	5-15	Insulin
Glucagonoma	Glucagonoma	Dermatitis, diabetes/glucose intolerance, weight loss	Pancreas—100%	60	Glucagon
VIPoma	Verner-Morrison, pancreatic cholera, WDHA	Severe watery diarrhea, hypokalemia	Pancreas—90% Other—10% (neural, adrenal, periganglionic tissue)	80	Vasoactive intestinal peptide (VIP)
Somatostatinoma	Somatostatinoma	Diabetes mellitus, cholelithiasis, diarrhea	Pancreas—56% Duodenum/jejunum—44%	60	Somatostatin
GRFoma	GRFoma	Acromegaly	Pancreas—30% Lung—54% Jejunum—7% Other—13% (adrenal, foregut, retroperitoneum)	30	Growth hormone–releasing factor (GRF)
ACTHoma	ACTHoma	Cushing's syndrome	Pancreas—4-16% of all ectopic Cushing's cases	>95	Adrenocorticotropic hormone (ACTH)
PET causing carcinoid syndrome	PET causing carcinoid syndrome	Diarrhea, flushing	Pancreas—<1% of all carcinoids	60-90	Serotonin, tachykinins
PET causing hypercalcemia	PET causing hypercalcemia	Signs/symptoms of hypercalcemia	Pancreas (rare cause of hypercalcemia)	>85	PTHrP, other unknown
II. NONFUNCTIONAL PET					
Nonfunctioning PPoma	Nonfunctional PPoma	Weight loss, abdominal mass, hepatomegaly	Pancreas—100%	60-90	None: pancreatic polypeptide chromogranin released but no known symptoms due to hypersecretion

PET = pancreatic endocrine tumor; PP = pancreatic polypeptide; PTHrP = parathormone-related peptide; WDHA = watery diarrhea, hypokalemia, and achlorhydria.

hypersecretion (peptic ulcer disease, diarrhea, esophageal reflux disease). ZES occurs most frequently between the ages of 35 and 65 years and is slightly more common in men (60%).

PATHOBIOLOGY

In recent surgical series, gastrinomas occur two to five times more frequently in the duodenum than in the pancreas. Duodenal gastrinomas are generally small (<1cm), whereas pancreatic gastrinomas are generally larger. Occasionally ZES results from a gastrinoma in the splenic hilum, mesentery, stomach, or only in a lymph node or in the ovary. Extrapancreatic gastrinomas producing ZES have been reported in the heart and as a result of small cell lung cancer. As with other PETs, malignancy can be reliably determined only by demonstrating the presence of metastatic disease, and no light microscopic or ultrastructural finding can clearly establish malignant behavior.

Gastrin stimulates parietal cells to secrete acid and also has a growth effect on cells of the gastric mucosa. Chronic hypergastrinemia thus leads to increased gastric mucosal thickness, prominent gastric folds, and increased numbers of parietal cells and gastric enterochromaffin-like cells. Patients with gastrinomas have increased basal and maximal acid outputs. *Helicobacter pylori* appears not to be important in the pathogenesis of the ulcer disease in ZES, in contrast to that of routine peptic ulcers (Chapter 141). Diarrhea is common because the large-volume gastric acid output leads to structural damage to the small intestine (inflammation, blunted villi, edema), interference with fat transport, inactivation of pancreatic lipase, and precipitation of bile acids. These same mechanisms, if prolonged, can lead to steatorrhea. If acid hypersecretion is controlled, the diarrhea will stop.

CLINICAL MANIFESTATIONS

Abdominal pain resulting from a peptic ulcer is the most common symptom (>80%). Most ulcers occur in the duodenum (>85%), but they occasionally occur in the postbulbar area, jejunum, or stomach, or in multiple locations. Initially, the pain is usually similar to that of patients with typical peptic ulcers (Chapter 141). With time, the symptoms become persistent and, in general, respond poorly to treatments aimed at eliminating *H. pylori* and to conventional doses of histamine-2 receptor antagonists, as well as to the now rarely used surgical treatments for ulcer disease. By comparison, conventional doses of proton pump inhibitors (PPIs) (e.g., omeprazole, lansoprazole, pantoprazole, esomeprazole, rabeprazole) can mask the symptoms of most patients with ZES and can also cause hypergastrinemia as seen in ZES. The widespread use of PPIs has delayed the diagnosis of ZES.

Heartburn is also common (20%). Diarrhea (60 to 70%) occurs frequently and may be the first symptom (10 to 20%). Twenty to 25% of ZES patients have MEN 1 (Chapter 239). These patients have hyperplasia or tumors of multiple endocrine glands (parathyroid hyperplasia [>90%], pituitary tumors [60%], and PETs [80 to 100%]). In MEN 1, ZES is the most common functional PET syndrome (54%), although patients typically first develop renal stones related to hypercalcemia from hyperparathyroidism or have elevated prolactin levels resulting from pituitary tumors and only later develop ZES. However, studies show that 20 to 40% of patients with MEN and ZES initially present with ZES symptoms.

In ZES patients, almost all the symptoms result from the effects of gastric acid hypersecretion, but late in the disease, patients can have tumor-related symptoms. Approximately one third of patients have metastatic liver disease at presentation, but less than 20% of other patients develop metastatic disease to the liver during a 10-year follow-up period.

Up to 5% of patients with ZES develop Cushing's syndrome (Chapter 234) as a result of adrenocorticotropic hormone (ACTH) secretion by the gastrinoma. These patients usually have a metastatic gastrinoma in the liver, ZES without MEN 1, and a poor prognosis.

DIAGNOSIS

ZES should be suspected in any patient whose peptic ulcer disease is accompanied by diarrhea, is recurrent, does not heal with treatment, is not associated with *H. pylori* infection, is associated with a complication (bleeding,

obstruction, esophageal stricture), is multiple or occurs in unusual locations, or is associated with a pancreatic tumor. ZES should also be suspected in patients with chronic secretory diarrhea (Chapter 142), peptic ulcer disease associated with large gastric folds, a family or personal history of renal stones or endocrinopathies, or the laboratory finding of hypercalcemia, hypergastrinemia, or gastric acid hypersecretion.

When suspected, the initial test is a fasting serum gastrin level, which is elevated in 99 to 100% of ZES patients. However, other causes of hypergastrinemia include renal failure, *H. pylori* infections, and a physiologic response to achlorhydria or hypochlorhydria because of pernicious anemia, atrophic gastritis, or the use of PPIs. If the serum gastrin level is elevated, the fasting gastric pH should be determined. If the serum gastrin is more than 1000 pg/mL (normal, <100) and the pH is less than 2.0, the patient almost certainly has ZES; approximately 40% of patients have this combination. If the gastrin is increased more than ten-fold and the pH is less than 2.0, basal acid output and a secretin test should be performed. Basal acid output is increased in patients with ZES, and more than 95% have a value greater than 15 mEq/hour if no previous gastric acid–reducing surgery has been performed. Because of their long duration of action, PPIs must be stopped for at least 1 week, if possible, to ensure that the cause of the hypergastrinemia is not the drug itself.

Differential Diagnosis

A secretin test can exclude *H. pylori* infection, retained gastric-antrum syndrome, antral G-cell hyperfunction or hyperplasia, chronic renal failure, and gastric outlet obstruction that may mimic ZES. Physiologically normal individuals show a less than 120 pg/mL increase in the gastrin level after intravenous secretin, whereas 94% of ZES patients with a fasting gastrin level that is elevated less than ten-fold above normal have a positive test. No false-positive results are reported, except in patients with achlorhydria. In all patients with ZES, evaluation must exclude MEN 1 syndrome by searching for other endocrinopathies and assessing family history.

Imaging and Endoscopy

All patients should have imaging studies to localize the tumor. Somatostatin receptor scintigraphy using single photon emission computed tomography after injection of indium-111–[diethylenetriamine pentaacetic acid-D-phenylalanine-1] octreotide is the localization method of choice; it identifies 60% of primary gastrinomas and more than 90% of patients with metastatic liver disease with a sensitivity equal to all conventional imaging studies (magnetic resonance imaging [MRI], computed tomography [CT], ultrasound, angiography) combined. For pancreatic gastrinomas, endoscopic ultrasound is particularly sensitive. Small duodenal gastrinomas (<1 cm) are frequently not detected by an imaging modality but can be found at surgery if routine duodenotomy is performed. Recent studies show that two new imaging techniques may be useful for small gastrinomas and other PETs: the use of hybrid scanning with CT or MRI and somatostatin receptor scintigraphy (SRS) and the use of positron emission tomographic scanning, especially with gallium-68-labeled somatostatin analogues.

TREATMENT

Medical Therapy

Patients need medical therapy directed at controlling the gastric acid hypersecretion and, if possible, surgical therapy to remove the gastrinoma. PPIs are now the drugs of choice. Because of their long duration of action, acid hypersecretion can be controlled in all patients with once- or twice-daily doses. The recommended starting dose for omeprazole is 60 mg once a day. In 30% of patients, higher doses are needed, particularly in patients with MEN 1, previous gastric surgery, or a history of severe esophageal reflux. Patients must be treated indefinitely unless surgically cured. Long-term therapy is safe, and patients have been treated for up to 20 years with omeprazole without loss of efficacy, although reduced vitamin B_{12} levels may occur and require vitamin B_{12} supplementation (Chapter 167). Histamine-2 receptor antagonists are also effective, but frequent (every 4 to 6 hours) high doses are needed. Total gastrectomy, the historical treatment, is now performed only for patients who cannot or will not take oral antisecretory medications. Selective vagotomy reduces acid secretion, but many patients continue to require a low dose of drug. Parathyroidectomy should be performed in MEN 1 patients with hyperparathyroidism and ZES because it reduces acid secretion and increases the sensitivity to antisecretory drugs.

Surgical Therapy

Surgical exploration for cure is recommended in all patients without liver metastases, MEN 1, or complicating medical conditions that limit life expectancy. Tumors are found by experienced endocrine surgeons in 95% of patients at surgery. Surgical resection decreases the metastatic rate, increases survival, and results in a 5-year cure rate of 30%. Patients with metastatic gastrinoma in the liver have a poor prognosis, with a 5-year survival rate of 30%.

Metastatic Disease

If the metastatic disease is slowly increasing in size or is symptomatic, treatment with octreotide (100 to 450 µg two to three times daily) alone or in combination with interferon-α (1 to 5 million U 3 to 7 days/week) is effective in inhibiting further tumor growth in 50 to 60% of patients. If this treatment fails or if the tumor is rapidly growing, chemotherapeutic agents (streptozotocin, 5-fluorouracil, doxorubicin) are recommended. For patients with extensive metastatic disease, somatostatin receptor–directed radiation therapy using analogues labeled with yttrium-90, lutetium-177, or indium-111 is increasingly used. Newer treatments targeting PETs using radiolabeled somatostatin analogues or targeting PET growth factors or their receptors, intracellular signaling cascades (mTor), and a DTIC-related compound, temozolomide, show some promise in a small number of gastrinomas and other PET patients. Liver transplantation is occasionally performed in the rare patient with metastases limited to the liver.

PROGNOSIS

Approximately 25% of gastrinomas show aggressive growth. The most important prognostic predictor is the development of liver metastases. The presence of a large primary tumor, a pancreatic tumor, bone metastases, development of ectopic Cushing's syndrome, or a high fasting gastrin level is associated with aggressive growth.

Glucagonomas

DEFINITION

Glucagonomas are endocrine tumors of the pancreas that ectopically secrete glucagons, causing a specific syndrome (see Table 201-1).

PATHOBIOLOGY

Glucagon hypersecretion explains the glucose intolerance. The exact origin of the rash is unclear; some studies report that prolonged glucagon infusions can cause the characteristic skin lesions. A role for possible zinc deficiency has been proposed because of the similarity of the rash to that seen with zinc deficiency (acrodermatitis enteropathica) and because the rash improves in some patients who are given zinc. The hypoaminoacidemia is thought to be secondary to the effect of glucagon on amino acid metabolism by altering gluconeogenesis. The wasting and weight loss are intrinsic parts of the glucagonoma syndrome, and recent studies suggest that a novel anorectic substance distinct from glucagon is responsible.

CLINICAL MANIFESTATIONS

The cardinal clinical features are a distinct dermatitis (necrolytic migratory erythema, seen in 70 to 90%), diabetes mellitus and glucose intolerance (40 to 90%), weight loss (70 to 96%), anemia (30 to 85%), hypoaminoacidemia (80 to 90%) with deficiencies of essential fatty acids, thromboembolism (10 to 25%), diarrhea (15 to 30%), and psychiatric disturbances (0 to 20%). The characteristic skin rash is usually found at intertriginous and periorificial sites, especially in the groin and buttocks (Fig. 201-1). It is initially erythematous, becomes raised, and develops central bullae whose tops detach, with the eroded areas becoming crusty. Healing occurs with hyperpigmentation.

DIAGNOSIS

The diagnosis is established by demonstrating elevated plasma glucagon levels. Normal levels are 150 to 200 pg/mL; in patients with glucagonomas, levels usually (>90%) are higher than 1000 pg/mL. However, in some recent studies, up to 40% of patients had plasma glucagon values of 500 to 1000 pg/mL. Increased plasma glucagon levels also occur in renal insufficiency, acute pancreatitis, hypercorticism, hepatic diseases, celiac disease, severe stress and prolonged fasting, in patients treated with danazol, and in familial hyperglucagonemia. In these conditions, the level is usually less than 500 pg/mL except in patients with hepatic diseases or in those with familial hyperglucagonemia.

FIGURE 201-1. A patient with a glucagonoma with the characteristic rash (necrolytic migratory erythema). The rash is usually at intertriginous areas or periorificial sites and shows various stages of erythema, blistering, and crusting. (From Forbes CD, Jackson WF. *Color Atlas and Text of Clinical Medicine*, 3rd ed. London: Mosby; 2003.)

Glucagonomas are generally large when discovered (mean, 5 to 10 cm), and they most frequently occur in the pancreatic tail (>50%). Liver metastases are commonly present at the time of diagnosis (45 to 80%).

TREATMENT

Rx

Subcutaneous administration of the synthetic long-acting somatostatin analogue, octreotide (100 to 400 micrograms two to three times daily), controls the rash in 80% of patients and improves weight loss, diarrhea, and hypoaminoacidemia, but it usually does not improve the diabetes mellitus. Increasingly, long-acting depot formulations of octreotide (octreotide-LAR) or lanreotide autogel are being given by monthly injection. Zinc supplementation and infusions of amino acids or fatty acids, or both, can diminish the severity of the rash. After tumor localization, surgical resection is preferred; even debulking of metastatic tumor may be of benefit. For advanced disease, chemotherapy (with dacarbazine or streptozotocin and doxorubicin), hepatic embolization, or chemoembolization may control symptoms in refractory cases.

PROGNOSIS

The prognosis is now largely determined by the growth of the tumor per se because the symptoms of glucagon excess can be largely controlled by somatostatin analogues. This is particularly true with glucagonomas because in many series more than 50 to 80% are metastatic at presentation, and patients usually present late with large primary tumors. The mean 5-year survival rate is 50%; however, extended survivals (>15 years) are reported in some patients with treatment with somatostatin analogues and other tumor-directed therapies.

VIPomas

DEFINITION

The VIPoma syndrome, also called the Verner-Morrison syndrome, pancreatic cholera, and the WDHA syndrome (for watery diarrhea, hypokalemia, and achlorhydria), results from an endocrine tumor, usually in the pancreas that ectopically secretes vasoactive intestinal polypeptide (VIP).

EPIDEMIOLOGY AND PATHOBIOLOGY

VIPomas in adults are found in the pancreas in 80 to 90% of cases; rare cases result from intestinal carcinoids, ganglioneuromas, ganglioneuroblastomas, and pheochromocytomas. In children younger than 10 years and rarely in adults (<5%), the VIPoma syndrome is caused by ganglioneuromas or ganglioneuroblastomas at extrapancreatic sites. VIPomas are usually large and solitary; 50 to 75% of these tumors occur in the pancreatic tail, and 40 to 70% have metastasized at diagnosis. VIPomas frequently secrete both VIP and peptide histidine methionine, but VIP is responsible for the symptoms. VIP is a potent stimulant of secretion in the small and large intestine, which causes the cardinal clinical features of the VIPoma syndrome. VIP also causes relaxation of gastrointestinal smooth muscle, and this may contribute to the dilated loops of bowel that are common in this syndrome as well as a dilated, atonic gallbladder that is sometimes seen. Hypochlorhydria is thought to result from the inhibitory effect of VIP on acid secretion, the flushing is related to the vasodilatory effects of VIP, and the hyperglycemia is caused by the glycogenolytic effect of VIP. The mechanism of the hypercalcemia remains unclear.

CLINICAL MANIFESTATIONS

The cardinal clinical feature is severe, large-volume, watery diarrhea (>1 L/day) (100%), which is secretory and occurs during fasting. Hypokalemia (67 to 100%) and dehydration (83%) commonly occur because of the volume of the diarrhea. Achlorhydria is occasionally noted, but hypochlorhydria is usually found (34 to 72% of cases). Flushing occurs in 20% of patients, hyperglycemia in 25 to 50%, and hypercalcemia in 41 to 50%. Steatorrhea is uncommon (16%) despite the volume of diarrhea.

DIAGNOSIS

The diarrhea of VIPomas characteristically persists during fasting and is large in volume (>3 L/day in 70 to 80%); the diagnosis is excluded when fasting stool volume is less than 700 mL/day. To differentiate VIPomas from other causes of large-volume, fasting diarrhea, fasting plasma VIP levels should be determined. The normal value in most laboratories is less than 190 pg/mL, and elevated levels are present in 90 to 100% of patients in various series. The differential diagnosis of large-volume, fasting diarrhea (>700 mL/day) includes ZES, diffuse islet cell hyperplasia, surreptitious use of laxatives, the pseudopancreatic cholera syndrome, and, rarely, human immunodeficiency virus (HIV) infection (Chapter 397). Serum gastrin levels identify patients with ZES, and plasma VIP levels are normal in most patients who abuse laxatives, in 82% of patients with pancreatic islet cell hyperplasias, and in patients with HIV-induced secretory diarrhea.

TREATMENT

Rx

The symptoms caused by the VIP are controlled initially in more than 85% of patients by daily doses of octreotide (50 to 400 µg once to three times daily) or by monthly injections of the depot form, octreotide-LAR or lanreotide autogel, but increased doses may be needed over time. Before the availability of octreotide, small numbers of patients were reported to respond to a variety of agents, including high-dose prednisone (60 to 100 mg/day; 40 to 50%), clonidine, lithium carbonate, indomethacin, loperamide, metoclopramide, and phenothiazines. After tumor localization studies, surgical resection should be attempted if it is possible to remove all visible tumor; however, more than 50% of patients have generalized liver metastases at diagnosis, so complete resection may not be possible. For patients with advanced cases and refractory symptoms, chemotherapy with streptozotocin and doxorubicin, hepatic chemoembolization, and hepatic embolization have been beneficial.

PROGNOSIS

The prognosis is now largely determined by the growth of the tumor per se because the symptoms of VIP excess can be largely controlled by somatostatin analogues. This is particularly true in patients with VIPomas because they frequently (>50%) present with advanced metastatic disease. The mean 5-year survival is 50 to 70%.

Somatostatinomas

DEFINITION AND PATHOBIOLOGY

Somatostatinomas are endocrine tumors that occur in the pancreas or upper small intestine and ectopically secrete somatostatin. In the gastrointestinal tract, somatostatin inhibits basal and stimulated acid secretion, pancreatic secretion, intestinal absorption of amino acids, gallbladder contractility, and release of numerous hormones, including cholecystokinin and gastrin.

CLINICAL MANIFESTATIONS

Most reported somatostatinomas are diagnosed histologically as an endocrine tumor containing somatostatin-like immunoreactivity and are not associated with a distinct clinical syndrome (the somatostatinoma syndrome). The somatostatinoma syndrome includes diabetes mellitus, gallbladder disease, diarrhea, steatorrhea, and weight loss. Sixty percent of somatostatinomas occur in the pancreas, and 40% are found in the duodenum or jejunum. Pancreatic somatostatinomas occur in the pancreatic head in 60 to 80% of cases; 70 to 92% have metastasized at diagnosis, and they are usually large (mean, 5 cm) and solitary. In contrast, duodenal somatostatinomas are smaller (mean, 2.4 cm), frequently associated with psammoma bodies on histologic examination (11%), and less frequently have metastases at diagnosis (30 to 40%).

The somatostatinoma syndrome occurs much more commonly (80 to 95% of all cases) in patients with pancreatic than duodenal or intestinal somatostatinomas. Duodenal somatostatinomas occur in up to 10% of patients with von Recklinghausen's disease and are usually asymptomatic.

DIAGNOSIS

Somatostatinomas are usually found by accident, particularly during exploratory laparotomy for cholecystectomy, during endoscopy, or on imaging studies. The presence of psammoma bodies on histologic examination of a duodenal endocrine tumor or any duodenal lesions in patients with von Recklinghausen's disease should raise the suspicion of a duodenal somatostatinoma. The diagnosis of the somatostatinoma syndrome requires the demonstration of increased concentrations of somatostatin-like immunoreactivity in the plasma and the resected tumor. However, other tumors outside the pancreas or intestine, such as small cell lung cancer, medullary thyroid carcinoma, pheochromocytomas, and paragangliomas, may also have elevated concentrations of somatostatin-like immunoreactivity. Somatostatinomas can be imaged using somatostatin receptor scintigraphy or, if needed, other conventional imaging studies to assess the tumor's location.

TREATMENT Rx

Treatment with octreotide or lanreotide can improve symptoms. Surgery, if possible, or chemotherapy, hepatic chemoembolization, or hepatic embolization may be of value.

PROGNOSIS

Patients with intestinal somatostatinomas, which uncommonly cause the somatostatinoma syndrome and are less malignant, have an excellent prognosis (5-year survival rate, >80%), whereas those with pancreatic somatostatinomas, which frequently cause the somatostatinoma syndrome and present with metastatic disease (>70%), have a much reduced 5-year survival rate (<50%).

GRFomas

DEFINITION

GRFomas are endocrine tumors that frequently originate in the pancreas but also occur in other extrapancreatic locations and ectopically release growth hormone–releasing factor (GRF). The GRF causes acromegaly that is clinically indistinguishable from that caused by a pituitary adenoma.

PATHOBIOLOGY

GRFomas most commonly occur in the lung (54%). Most of the remainder occur in the gastrointestinal tract, including 30% in the pancreas. Pancreatic GRFomas are usually large (mean, 6 cm), 39% are metastatic at diagnosis, 40% occur in combination with ZES, and 33% are in patients with MEN1.

DIAGNOSIS

GRFomas are an uncommon cause of acromegaly. These tumors occurred in none of 177 unselected patients with acromegaly in one study. However, any patient with acromegaly and abdominal complaints, with acromegaly but no pituitary tumor, or with acromegaly and hyperprolactinemia (which occurs in 70% of GRFomas) should be suspected of having a GRFoma. The intra-abdominal features of GRFomas result from its metastases and are typical of any malignant PET. The diagnosis is confirmed by performing a plasma assay for GRF and growth hormone.

TREATMENT Rx

The effects of the GRF can be controlled with octreotide or lanreotide in more than 90% of patients. Treatment should be directed at the GRFoma per se, as described for the other more common PETs.

Nonfunctional Pancreatic Endocrine Tumors

DEFINITION

Nonfunctional PETs are endocrine tumors that originate in the pancreas and either secrete no peptides or secrete products that do not cause clinical symptoms.

PATHOBIOLOGY

Frequently secreted, nonfunctional peptides include chromogranin A (100%), pancreatic polypeptide (60%), and the α-subunit (40%) and β-subunit of human chorionic gonadotrophin. Immunocytochemically, even higher percentages contain these peptides as well as insulin (50%), glucagons (30%), and somatostatin (13%).

CLINICAL MANIFESTATIONS

Nonfunctional PETs are frequently diagnosed only late in the course of disease after the patient presents with symptoms or signs of metastatic disease and a liver biopsy reveals metastatic PET. Any symptoms or signs result from the tumor per se and include abdominal pain (36 to 56%), abdominal mass or hepatosplenomegaly (8 to 40%), weight loss or cachexia (8 to 46%), and jaundice (27 to 40%). In 20% of asymptomatic patients, tumors are found incidentally at surgery.

DIAGNOSIS

Any patients with a long survival (>5 years) after a diagnosis of metastatic pancreatic adenocarcinoma should be suspected of having a nonfunctional PET. Most primary tumors are large (70% are >5 cm), and 70% occur in the pancreatic head. Liver metastases are frequent (38 to 62%) at presentation. An elevated plasma chromogranin A or pancreatic polypeptide level or a positive somatostatin receptor scintigraphic scan is strong evidence that a pancreatic mass is a PET. Malignancy correlates with vascular or perineural invasion, a proliferative index of more than 2%, a mitotic rate of 2 or higher, a size of at least 4 cm, capsular penetration, nuclear atypia, lack of progesterone receptors, and the presence of calcitonin immunoreactivity in the tumor.

TREATMENT Rx

Tumor localization, surgical resection, and, for advanced cases, chemotherapy with streptozotocin and doxorubicin, hepatic embolization, or chemoembolization are useful. Survival is better in patients with smaller tumors, patients who are asymptomatic at presentation, patients with no metastases, and patients in whom surgical resection can be performed.

Two novel agents have been recently found to prolong progression-free and probably overall survival in patients with advanced pancreatic neuroendocrine tumors, major proportions of which were nonfunctional. The multitargeted tyrosine kinase inhibitor sunitinib was administered by a daily oral dose of 37.5 mg; the oral inhibitor of mTOR, everolimus, was given at a dose of 10 mg once daily.

PROGNOSIS

The overall 5-year survival rate varies in different series from 30 to 70%, but it is heavily dependent on the extent of the disease at diagnosis, with survival rates of 96% in patients without metastases at presentation, decreasing to 30 to 50% for those with metastatic disease.

ACTHomas and Other Uncommon Tumors

PETs that ectopically secrete ACTH cause 4 to 16% of the cases of ectopic Cushing's syndrome. Cushing's syndrome (Chapter 234) occurs in 5% of all cases of ZES, but in patients with sporadic ZES, it is a late feature, occurring with metastatic liver disease. Its development is associated with a poor prognosis, and the response to chemotherapy is generally poor; however, occasional patients benefit from the use of long-acting somatostatin analogues (octreotide, lanreotide).

Paraneoplastic hypercalcemia (Chapter 186) can result from a PET that releases parathormone-related peptide or an unknown hypercalcemic

substance. Tumors are generally large with metastatic liver disease at diagnosis. Somatostatin analogues may help control the hypercalcemia, but surgery, chemotherapy, hepatic embolization, and chemoembolization are the mainstays of treatment.

PETs causing the carcinoid syndrome (Chapter 240) are usually large, and 68 to 88% are malignant. Octreotide may control the symptoms. Surgery, chemotherapy, or hepatic embolization or chemoembolization may be helpful.

A single case of a PET that secreted renin manifested with severe hypertension; the tumor was localized with somatostatin receptor scintigraphy, and the patient's symptoms improved significantly after tumor resection. A single case of an erythropoietin-secreting PET resulting in polycythemia and a single case of a PET secreting insulin-like growth factor II causing hypoglycemia have been described.

Two symptomatic cases of PETs that secreted luteinizing hormone have been described; virilization occurred in the female patient, whereas the male patient had increased acne and a skin rash. In both cases, the tumors were resectable, and symptoms improved postoperatively.

TABLE 202-1 LIVER AND BILIARY TRACT TUMORS

TUMOR	CHARACTERISTICS ON IMAGING
BENIGN TUMORS USUALLY REQUIRING OBSERVATION ONLY	
Cavernous hemangioma	Peripheral enhancement filling into the center on delayed contrast imaging
Focal nodular hyperplasia	Rapid arterial enhancement with return to isointensity in venous phase; possible central scar with feeding vessel
Simple cyst	Hypoechoic on ultrasound
Focal fatty change	Best characterized by in- and out-of-phase sequences on magnetic resonance imaging
Angiolipoma	Arterial enhancement on contrast imaging
BENIGN TUMORS REQUIRING FURTHER EVALUATION AND TREATMENT	
Hepatic adenoma	Heterogeneous lesion with rapid arterial enhancement
Nodular regenerative hyperplasia	Nonspecific and variable
Cystadenoma	Cystic lesion on ultrasonography with solid components, enhancement of cyst wall; possible septations
Hepatic abscess (Chapter 154)	Cystic lesion on ultrasonography
Inflammatory pseudotumor	Atypical enhancing mass on contrast imaging
Echinococcal cyst (Chapter 154)	Cystic mass with septations, calcified rims, daughter cysts
MALIGNANT TUMORS REQUIRING APPROPRIATE MANAGEMENT	
Hepatocellular carcinoma	Arterial enhancement with portal venous "washout"
Cholangiocarcinoma	Late arterial enhancement that persists in portal phase
Mixed hepatocellular-cholangiocarcinoma	Early to late arterial enhancement
Liver metastases	Peripheral arterial enhancement, usually bilobar, multifocal disease
Cystadenocarcinoma	Solid enhancing mass in cystic lesion
Sarcoma	Solid mass with arterial enhancement
Mixed hepatic tumor	Solid mass with arterial enhancement; possible areas of calcification
Non-Hodgkin's lymphoma (Chapter 191)	Less intense arterial enhancement than hepatocellular carcinoma; possibly diffuse or mimicking hepatocellular carcinoma with venous invasion

202 LIVER AND BILIARY TRACT TUMORS

LEWIS R. ROBERTS

Liver and biliary tract tumors are a diverse group of benign and malignant tumors that arise from the different epithelial and stromal tissues of the liver. Various malignant diseases of other tissues metastasize to the liver or extend into or metastasize to the vicinity of the biliary tract, but not all mass lesions of the liver and biliary tract are malignant (Table 202-1).

EVALUATION OF MASS LESIONS OF THE LIVER

Diagnostic Approach

Mass lesions of the liver can be classified as benign lesions usually requiring observation only, benign lesions requiring further evaluation and treatment, or malignant lesions requiring appropriate management (see Table 202-1). The clinical approach to liver mass lesions requires careful history taking, physical examination, appropriate laboratory and imaging studies, judicious use of liver biopsy for histologic confirmation, and optimal management that considers the patient's age and comorbidities (Fig. 202-1).

History and Physical Examination

Because of the increasing use of imaging techniques for the evaluation of abdominal symptoms, many mass lesions of the liver are discovered incidentally as a result of imaging performed to evaluate nonhepatic diseases, such as abdominal pain or discomfort (Chapter 134). Right upper quadrant discomfort is frequently nonspecific and unhelpful in the evaluation of liver masses. Nevertheless, large liver masses may distend the liver capsule and cause pain, which is occasionally referred to the right shoulder. Patients also may present with episodes of acute, severe pain, which results from bleeding into a hepatic adenoma, a primary hepatocellular carcinoma, or the liver surrounding the lesion. Patients with advanced malignant disease and regional lymph metastases may present with epigastric pain.

Patients with malignant liver disease, whether primary or metastatic, frequently present with constitutional symptoms, which include night sweats, low-grade fever, unintended weight loss, anorexia, and diarrhea. In the United States, the most common malignant lesions in the liver are metastases from other primary cancers, including the esophagus, stomach, colon, pancreas, breast, lung, neuroendocrine, kidney, bladder, and skin cancer. Patients with hepatocellular carcinoma often have symptoms related to their underlying liver disease, such as fatigue from chronic hepatitis or ascites, spontaneous bacterial peritonitis, variceal bleeding, or hepatic encephalopathy resulting from cirrhosis with portal hypertension. Patients with cholangiocarcinoma may present with jaundice from a dominant stricture or with episodes of acute cholangitis in the setting of primary or secondary sclerosing cholangitis (Chapter 158).

When available, previous imaging studies of the liver can be helpful in determining whether a liver lesion is new or enlarging. The patient's characteristics, including age, sex, history of oral contraceptive use (associated with an increased incidence of hepatic adenomas), geographic residence, travel history (relevant in cases of amebic liver abscess and hydatid cysts), alcohol

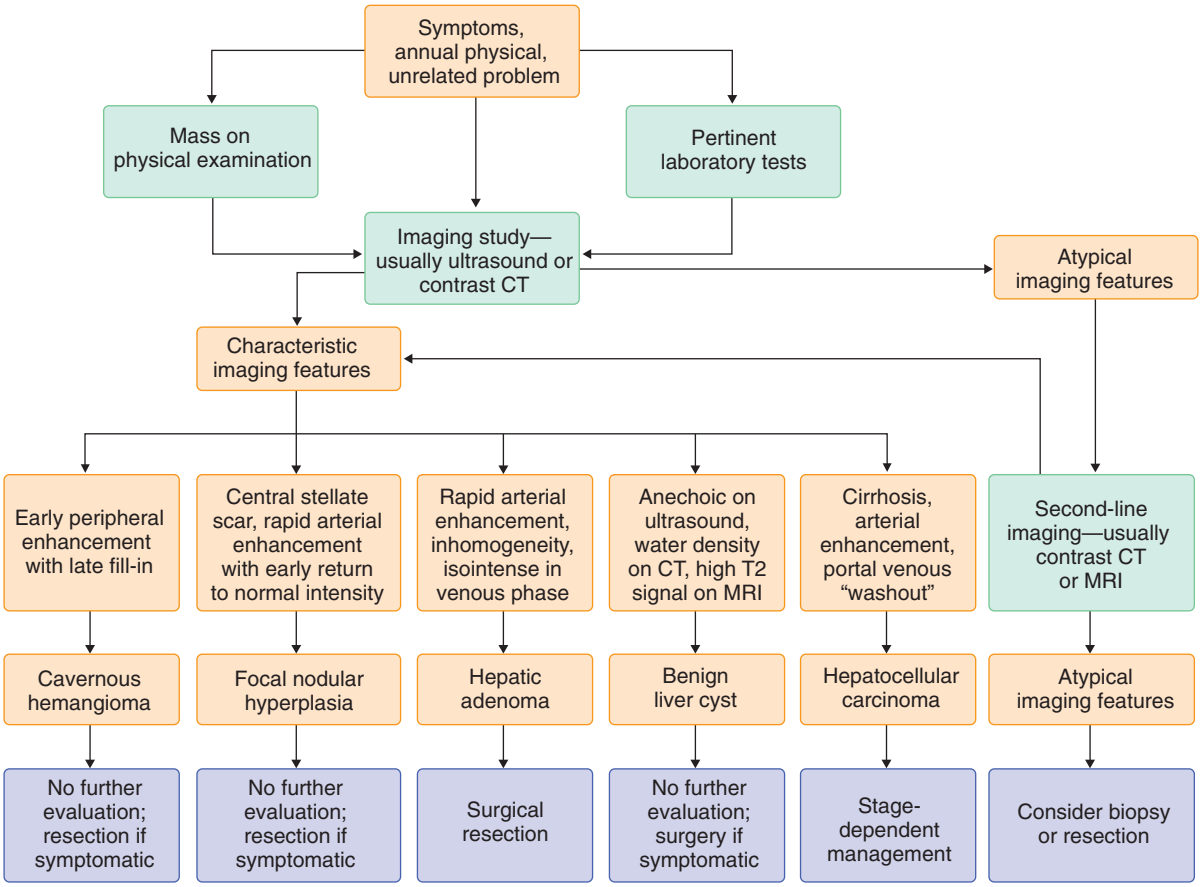

FIGURE 202-1. Approach to evaluating the patient with a mass lesion in the liver. Flow chart showing an algorithm for evaluating and managing common liver mass lesions. CT = computed tomography; MRI = magnetic resonance imaging.

consumption, and comorbid illnesses (e.g., association between chronic hepatitis or liver cirrhosis and hepatocellular carcinoma; association between ulcerative colitis or primary sclerosing cholangitis and cholangiocarcinoma) can also provide clues to the diagnosis.

On physical examination, patients with chronic liver disease typically have cutaneous stigmata (spider angiomas and palmar erythema), splenomegaly, and bilobar enlargement of the liver or caudate lobe hypertrophy. They may also have an abdominal bruit over a vascular hepatocellular carcinoma. Patients with metastatic disease may have peripheral or intra-abdominal lymphadenopathy or palpable peritoneal carcinomatosis. Jaundice, peripheral edema, and ascites are nonspecific features that may be related to benign or malignant liver disease.

Laboratory Findings

Laboratory studies are often useful in determining the nature of a liver mass or its underlying cause. Laboratory features of chronic liver disease include the following: thrombocytopenia; elevated levels of serum aminotransferase (elevated in active inflammatory liver disease or infiltrative neoplastic diseases), alkaline phosphatase, and bilirubin (markedly elevated in bile duct obstruction from biliary tumor or mass effect; Chapter 149); and low serum albumin levels and an elevated prothrombin time (abnormal in chronic liver disease). Viral markers (e.g., hepatitis B surface antigen and antibody, hepatitis B e antigen and antibody, hepatitis B virus DNA, and hepatitis C antibody and hepatitis C virus RNA), iron studies, and autoimmune markers (e.g., antimitochondrial antibody, antinuclear antibody, and anti–smooth muscle antibody) often help to determine the cause of chronic liver disease. Finally, tumor markers such as α-fetoprotein (AFP; hepatocellular carcinoma), CA-19-9 (cholangiocarcinoma), carcinoembryonic antigen (colorectal metastases or cholangiocarcinoma), and lactate dehydrogenase (lymphoma) have variable sensitivity and utility as screening tests but may be useful in confirming the diagnosis or in predicting prognosis.

COMMON BENIGN TUMORS OF THE LIVER

Cavernous Hemangioma

EPIDEMIOLOGY

Cavernous hemangioma, which is the most common benign tumor of the liver, is present in up to 7% of individuals in autopsy studies. There is a female predominance of 1.5 : 1 to 5 : 1, and hemangiomas are more common in multiparous women. Hemangiomas are multicentric in up to 30% of cases.

CLINICAL MANIFESTATIONS

Cavernous hemangiomas are usually asymptomatic, although large, subcapsular hemangiomas may cause abdominal pain or discomfort. Thrombosis of giant hemangiomas (>10 cm) may cause systemic features of inflammation such as fever, weight loss, and anemia.

Rarely, large hemangiomas are associated with the Kasabach-Merritt syndrome, which is local or disseminated intravascular coagulation with thrombocytopenia, hypofibrinogenemia, and increased fibrin degradation products, usually seen initially in infants (Chapter 178). Most cavernous hemangiomas remain stable over time, and malignant transformation does not occur. Rupture of cavernous hemangiomas is exceedingly rare, considering the high prevalence of hepatic hemangiomas.

DIAGNOSIS

Imaging

Hepatic cavernous hemangiomas have characteristic imaging features. On *ultrasound,* they appear as well-circumscribed, homogeneously hyperechoic lesions with smooth margins. Hemangiomas may also appear hypoechoic in fatty livers. Atypical features include hypoechoic lesions with a thin hyperechoic rim or a thick rind and scalloped borders.

On *dynamic contrast-enhanced multiphasic computed tomography* (CT), hemangiomas are hypoattenuating lesions on nonenhanced scans, with peripheral nodular enhancement during the arterial phase and later filling in

toward the center of the lesion. On *contrast magnetic resonance imaging* (MRI) *with gadolinium,* hemangiomas appear as homogeneous, low-intensity lesions on T1-weighted images and as sharply demarcated, hyperintense lesions on T2-weighted images. In the arterial phase, peripheral enhancement occurs and fills in toward the center of the lesion on delayed images.

Technetium-99m-labeled red blood cell scintigraphy is very specific for hemangiomas. It shows low perfusion on early images and a high concentration of isotope that completely fills the lesion on late images. Larger hemangiomas that are complicated by fibrosis, thrombosis, or bleeding may have incomplete filling in on contrast or technetium-99m studies.

Because the imaging features are often characteristic, biopsy is seldom needed to confirm the diagnosis. Biopsy is occasionally useful for small indeterminate lesions and for large lesions with scarring and atypical imaging features. Histologic examination shows a network of vascular spaces lined by endothelial cells and separated by a thin, fibrous stroma. Large hemangiomas may have areas of thrombosis, scarring, and calcification.

TREATMENT Rx

Observation is the optimal management for most patients with asymptomatic hemangiomas. Surgical enucleation or anatomic resection is recommended for hemangiomas that cause significant pain, enlarge over time, are of uncertain diagnosis, or are associated with the Kasabach-Merritt syndrome. Rarely, liver transplantation has been used for massive unresectable hepatic hemangiomas, particularly in the presence of Kasabach-Merritt syndrome.

Focal Nodular Hyperplasia

DEFINITION

Focal nodular hyperplasia is a benign reaction to a congenital arterial malformation within the liver. The lesion typically consists of a vascular stellate scar with connective tissue, bile ductules surrounded by proliferated hepatocytes, and Kupffer cells separated by fibrous septa.

EPIDEMIOLOGY

Focal nodular hyperplasia occurs predominantly in women of childbearing age. The relationship with oral contraceptive use is controversial; some studies suggest an association of long-term oral contraceptive use with focal nodular hyperplasia and with complications such as hemorrhage or infarction. However, discontinuation of oral contraceptive use usually does not lead to resolution of focal nodular hyperplasia. There is a female predominance of 2 : 1 to 4 : 1, and the lesions are typically diagnosed in women aged 20 to 50 years. Focal nodular hyperplasias are occasionally multiple (10 to 20%) or are associated with cavernous hemangiomas (20%).

CLINICAL MANIFESTATIONS

Most focal nodular hyperplasias are asymptomatic. Patients with large or subcapsular lesions may present with abdominal discomfort or an abdominal mass. In contrast to hepatic adenoma, presentation with acute abdominal pain from tumor bleeding or necrosis is very rare.

DIAGNOSIS

On *ultrasound,* focal nodular hyperplasias are variably hypoechoic, hyperechoic, or isoechoic. The lesions are most commonly hypoechoic except for the central scar. Doppler evaluation frequently shows blood flow within the central stellate scar.

On *dynamic CT,* focal nodular hyperplasias are isoattenuating or slightly hypoattenuating on noncontrast CT. One sees rapid, intense contrast enhancement in the arterial phase and rapid loss of contrast from the lesion, so it becomes isointense in the venous phase. An avascular central scar is often seen, sometimes with a feeding artery coursing into the middle of the lesion.

On *contrast MRI,* the lesions are isointense on T1-weighted images and remain isointense or are slightly hyperintense on T2-weighted images. The central scar is hypointense on T1-weighted images but hyperintense on T2-weighted images. As with contrast CT, rapid, intense contrast enhancement in the arterial phase quickly dissipates. Typically, the central scar has a low signal on T1-weighted images and enhances with contrast.

Technetium-99m-sulfur colloid scintigraphy is occasionally used to characterize focal nodular hyperplasias. Hyperintense or isointense uptake occurs in 50 to 70% of focal nodular hyperplasias because of uptake by Kupffer cells. In contrast, most hepatic adenomas do not have Kupffer cells and so do not take up technetium-99m-sulfur colloid. *Kupffer cell–specific MRI agents* such as ferumoxide are taken up by Kupffer cells and lead to significant signal intensity loss on ferumoxide-enhanced T2-weighted images, which may help to distinguish focal nodular hyperplasia from hepatic adenoma and hepatocellular carcinoma.

Diagnosis is usually made by radiologic studies, and biopsy is rarely needed. When a histologic diagnosis of focal nodular hyperplasia is needed, a core needle biopsy should be performed because fine-needle aspirates may only show benign-appearing hepatocytes in both focal nodular hyperplasia and hepatic adenoma. Histopathologic examination shows a benign hepatic parenchyma with bile ductules in septal fibrosis.

TREATMENT Rx

The management of asymptomatic focal nodular hyperplasias with characteristic imaging or biopsy features is observation because lesions usually do not enlarge, bleed, or undergo malignant transformation. Patients do not need to discontinue oral contraceptive use because no convincing evidence indicates that discontinuation leads to reduction in size of the lesions. Surgical resection is recommended for indeterminate or symptomatic lesions.

Hepatic Adenoma

EPIDEMIOLOGY

Hepatic adenoma is a benign liver tumor that occurs predominantly in the third and fourth decades of life. There is a female predominance of 2 : 1 to 6 : 1 as well as a strong association with oral contraceptive use. The relative risk of developing a hepatic adenoma is 2.5 after 3 to 5 years of oral contraceptive use and 25 to 40 after 9 years of use, resulting in an incidence of 4 per 100,000 versus 1 per million in the general population.

PATHOBIOLOGY

Hepatic adenomas also occur in users of androgenic steroids, in a familial pattern associated with diabetes mellitus, in the syndrome of maturity-onset diabetes of the young, and in patients with glycogen storage disease types 1A and 3 (Chapter 214), hemochromatosis (Chapter 219), and acromegaly (Chapter 231). Adenomas are multiple in 20% of cases, particularly in patients with glycogen storage disease.

CLINICAL MANIFESTATIONS

Hepatic adenomas are usually asymptomatic and are discovered on imaging studies, but patients may present with intermittent pain or discomfort in the upper abdomen or right upper quadrant of the abdomen. Adenomas also have a propensity to rupture, with intrahepatic hemorrhage and pain or rarely with hemoperitoneum and shock. They may decrease in size after withdrawal of oral contraceptives, but typically they do not, and sometimes they even increase in size.

DIAGNOSIS

On *ultrasound,* hepatic adenomas are variably homogeneous or heterogeneous (because of hemorrhage or necrosis within the tumor). On *dynamic CT,* adenomas, like focal nodular hyperplasias, are isoattenuating on nonenhanced scans; with intravenous contrast, they show early enhancement and then become rapidly isoattenuating in the portal venous phase. Adenomas are often hyperattenuating in a fatty liver. Adenomas typically have well-defined borders and are not lobulated. Approximately 40% of adenomas have intralesional hemorrhage with heterogenous regions of high attenuation. Approximately 5% of adenomas show coarse calcifications within the lesion.

On *contrast MRI,* adenomas are hyperintense or isointense on T1-weighted images and are slightly hyperintense on T2-weighted images. They show early enhancement in the arterial phase and become isointense on delayed imaging.

Technetium-99m-sulfur colloid scintigraphy shows no uptake in 70% of adenomas because of the absence of Kupffer cells. Overall, the relatively nonspecific imaging features make adenomas difficult to differentiate from other lesions.

Biopsy is often required for diagnosis, but a significant risk of misdiagnosis exists in differentiating hepatic adenomas from focal nodular hyperplasias, as well as a potential risk of hemorrhage from core biopsies. Histologic examination shows sheets of well-differentiated hepatocytes without bile ductules, fibrous septa, portal tracts, or central veins. Most adenomas do not contain Kupffer cells.

TREATMENT AND PROGNOSIS

Rx

Management of hepatic adenoma is usually by surgical resection because of the risks of hemorrhage (≤30% for large adenomas) and malignant transformation (the exact risk is unknown). Radiofrequency ablation is used in patients who are high surgical risks. Oral contraceptives should be discontinued, and patients should avoid pregnancy until the adenoma is resected because these lesions often grow during pregnancy. The risk of malignant transformation is small but real.

Benign Liver Cysts

EPIDEMIOLOGY

Benign liver cysts occur in approximately 4% of individuals. There is a female predominance of 4 : 1, and the prevalence increases with age. Liver cysts are often multiple and coexist with other mass lesions in the liver. The inherited autosomal dominant and recessive polycystic kidney diseases (Chapter 129) are both associated with the development of multiple liver cysts. Liver cysts are lined by cuboidal bile duct epithelium and are filled with isotonic fluid. Cysts are typically asymptomatic, but large cysts can cause pressure symptoms or biliary obstruction. Hemorrhage, infection, or rupture of cysts is rare.

DIAGNOSIS

Ultrasound is the best imaging test to confirm the fluid-filled nature of cysts, which are anechoic and show no vascular flow on color flow or duplex Doppler. They demonstrate through-transmission and well-defined posterior walls. Simple cysts may have thin echogenic septa. On *dynamic CT,* cysts appear as water-density lesions. On *contrast MRI,* cysts are hyperintense on T2-weighted images. Small cysts may be difficult to differentiate from a cavernous hemangioma or other small hepatic lesions on CT or MRI because of the volume averaging from adjacent tissue. Biopsy is typically unnecessary because of the classical imaging findings.

Lesions with Focal Fat or Fat Sparing

PATHOBIOLOGY

Fatty infiltration of the liver (Chapter 155) is increasingly common as populations increase in weight across the world. Focal fatty infiltration can look like a mass on imaging studies, as can focal sparing in a liver that is diffusely infiltrated by fat. Associations with fatty change in the liver include obesity, diabetes mellitus, high alcohol consumption, and altered nutritional status as a result of chemotherapy.

CLINICAL MANIFESTATIONS

Patients with focal fatty infiltration are typically asymptomatic. The lesions are usually discovered incidentally and are sometimes mistaken for more sinister masses.

DIAGNOSIS

The characteristic imaging feature of focal fat is that it does not distort the contour of the liver, so normal vessels, especially veins, can be seen coursing through the lesion. Focal fat usually occurs in vascular watersheds such as the region around the falciform ligament. Fat sparing usually occurs adjacent to the gallbladder fossa, in subcapsular areas, and in the posterior aspect of segment IV. On ultrasound, fat is usually hyperechoic. On dynamic CT, fatty liver is hypodense compared with the spleen, but not as low in density as adipose tissue. Venous structures can be seen in the lesion on venous phase studies. On contrast MRI, fatty liver is occasionally hyperintense on T1-weighted and T2-weighted images. The decreased signal intensity on out-of-phase gradient imaging is diagnostic of focal fat.

Biopsy is occasionally useful to rule out other lesions. On histologic examination, areas of fatty infiltration show fat-laden cells.

PRIMARY MALIGNANT TUMORS OF THE LIVER AND BILIARY TRACT

Hepatocellular Carcinoma

EPIDEMIOLOGY

Hepatocellular carcinoma, the third most common cause of death from cancer worldwide, accounts for approximately 700,000 deaths annually. There is a male preponderance of 2 : 1 to 4 : 1. The major predisposing factor for the development of hepatocellular carcinoma is cirrhosis of the liver (Chapter 156). The risk factors for the development of hepatocellular carcinoma include chronic hepatitis B or C virus infection (Chapter 151), alcoholic cirrhosis, nonalcoholic steatohepatitis (Chapter 155), hereditary hemochromatosis (Chapter 219), α_1-antitrypsin deficiency (Chapter 153), primary biliary cirrhosis (Chapter 158), and autoimmune hepatitis (Chapter 151). The hepatitis B virus almost always integrates into the host genomic DNA and can lead to development of hepatocellular carcinoma in the absence of cirrhosis. The availability of an effective vaccine against hepatitis B has reduced the incidence of hepatitis B–related hepatocellular carcinomas in high-prevalence regions. Long-term exposure to fungal aflatoxins in the diet significantly increases the risk of hepatocellular carcinoma. The fungi are ubiquitous and invade and grow in grains, legumes, and peanuts when they are stored in conditions of high humidity and temperature. The aflatoxin-producing fungal species, *Aspergillus flavus* and *Aspergillus parasiticus,* produce at least 13 different types of aflatoxin, with aflatoxin B1 the most potent. In most parts of the world, the most rapidly increasing groups of patients with hepatocellular carcinoma includes those with chronic hepatitis C virus infection. More than 90% of individuals with hepatitis C virus infection develop chronic infection, and up to 20% of patients with chronic hepatitis C develop cirrhosis. Hepatocellular carcinoma then develops in up to 20% of individuals with cirrhosis from chronic hepatitis C virus, at a rate of 2 to 6% per year. More recently, there has been a progressive increase in obesity-related nonalcoholic fatty liver disease (Chapter 155), which can progress to steatohepatitis, cirrhosis (often previously considered to be of unknown origin or "cryptogenic"), and hepatocellular carcinoma. Diabetes, also obesity related, has recently been shown to be an independent risk factor for the development of hepatocellular carcinoma.

PATHOBIOLOGY

Like most other malignant diseases, hepatocellular carcinoma develops as a result of a combination of the activation of cellular oncogenic pathways and abrogation of tumor suppressor pathways. Chronic hepatic injury resulting from viruses, alcohol, and metabolic or autoimmune mechanisms leads to repeated cycles of liver cell death, regeneration, and repair that ultimately lead to premature senescence of the liver.

Cellular senescence is characterized by a progressive decrease in length of the telomeric regions that protect the ends of chromosomes, with resulting development of chromosomal and genetic instabilities that are recognized by cellular stress response pathways and that trigger the apoptosis of senescent cells in a process known as *telomeric crisis.* In some senescent cells, apoptosis is avoided, and the cells become immortal, either through activation of the cellular telomerase enzyme complex, which maintains telomere ends, or through non-telomerase-dependent mechanisms. These genetically unstable, immortal cells are then prone to the development of additional genetic and epigenetic alterations that result in the cancer phenotype of unconstrained cell proliferation, resistance to apoptosis, enhanced cell migration and invasion, and activation of new vessel formation (angiogenesis).

Many oncogenic pathways normally have intrinsic tumor suppressor activities that limit their growth-promoting procarcinogenic effects; during carcinogenesis, mutations or epigenetic alterations lead to loss of the intrinsic tumor suppressing activity of the oncogenic pathways and result in unconstrained cellular proliferation and the secondary development of the other characteristics of the tumor phenotype. This hypothesis is well illustrated by the phenomenon of aflatoxin-induced mutation of the p53 tumor suppressor. During metabolism of aflatoxin in the liver, an aflatoxin B1-8,9-exo-epoxide intermediate is formed, and it interacts with cellular DNA to mediate formation of specific mutations, most frequently leading to a G-to-T transversion in codon 249 of the *p53* tumor suppressor gene. This mutation leads to loss of the p53 tumor suppressor function. Oncogenic pathways that normally activate p53 and limit proliferation are left without their natural "brake" on proliferation and result in an increased tendency to carcinogenesis. It is well known that aflatoxin B1 has a synergistic effect with the hepatitis B virus in the development of hepatocellular carcinoma.

Another important concept in the pathogenesis of malignant liver diseases is that of the development of malignant diseases within the epithelial stem cell compartment. Progenitor oval cells from the canals of Hering in the liver are capable of differentiating into both the hepatic and biliary lineages during liver regeneration. The development of a neoplastic phenotype within this compartment can result in the formation of cells that subsequently mature partially into more differentiated tumor cells and lead to the formation of a cancer with a "parent" clone of more immature progenitor cells and "daughter" clones of more mature cells. The existence of a tumor stem cell compartment (Chapter 185) has important implications for the development of anticancer therapy because agents that are active against carcinogenic pathways in the daughter cells but not in the parent clones may be capable of suppressing or arresting tumor growth but will not be curative unless they also target the growth pathways within the tumor stem cell compartment.

Integration of hepatitis B virus into host hepatocyte genomic DNA can lead to the development of hepatocellular carcinoma in the absence of cirrhosis. The pathogenic mechanisms include activation of oncogenic pathways through the activity of hepatitis B virus enhancer sequences and mutational inactivation of tumor suppressor genes by insertional mutagenesis. Certain proteins encoded by the hepatitis viruses have been shown to have oncogenic effects; these include the hepatitis B virus X protein, a truncated carboxy terminal variant of the hepatitis B virus S protein, the hepatitis C virus core protein, and NS5A protein.

Specific tumor suppressor and oncogenic molecules and pathways that have been shown to be important in liver carcinogenesis include the p53/$p21^{WAF1}$ pathway, the $p16^{INK4a}$/CDK4/RB1/E2F pathway, the Wnt/β catenin signaling pathway, transforming growth factor-α, c-myc, the transcription factor NFκB, insulin/insulin-like growth factor I, and the receptor tyrosine kinases (fibroblast growth factor, hepatocyte growth factor, and vascular endothelial growth factor) and their downstream activators.

CLINICAL MANIFESTATIONS

Most patients are asymptomatic except for symptoms of chronic liver disease at cancer diagnosis because ultrasound surveillance in high-risk patients detects cancer in asymptomatic patients. Symptomatic presentation such as abdominal pain often suggests advanced stage cancer. Mild decompensation of cirrhosis can be observed from the replacement of functioning liver tissue with tumor. The sudden onset of severe abdominal pain from hemorrhage within the tumor mass is a rare presentation. Signs on physical examination may include a palpable liver mass and a vascular bruit over the tumor. Hepatocellular carcinomas occasionally cause a variety of paraneoplastic syndromes, including hypoglycemia mediated by insulin-like growth factors, erythrocytosis from erythropoietin generation by the tumor, hypercalcemia related to production of a parathyroid-like hormone, and watery diarrhea from tumor production of vasoactive intestinal peptide and other neuroendocrine hormones (Chapters 186 and 187).

DIAGNOSIS

Approximately 80 to 90% of hepatocellular carcinomas occur in a cirrhotic liver, so the early diagnosis of most hepatocellular carcinomas depends on rigorous efforts of intermittent long-term surveillance for cancer in patients with cirrhosis. Surveillance is usually performed using liver ultrasound every 6 months in patients with any cause of cirrhosis. In patients with chronic hepatitis B who are at increased risk of hepatocellular carcinoma (family history of hepatocellular carcinoma; high viral load or transaminases; Africans older than 20 years; Asian males older than 40 years; Asian females older than 50 years), ultrasound surveillance is indicated even in patients without liver cirrhosis. Any suspicious nodules found by ultrasound are then examined with additional contrast imaging studies.

A serum AFP level is a specific tumor marker for hepatocellular carcinoma. A level greater than 200 ng/mL has a 95 to 100% specificity for hepatocellular carcinoma, and lesions larger than 2 cm with AFP greater than 200 ng/mL is diagnostic for hepatocellular carcinoma; but at the cutoff value of 200 ng/mL, the sensitivity of AFP is only about 20%. Therefore, use of AFP alone for hepatocellular carcinoma surveillance is not recommended.

Contrast imaging studies are diagnostic modalities of choice once suspected nodules are detected during surveillance. On contrast imaging studies, including contrast CT, MRI, ultrasound, and angiography, hepatocellular carcinomas are characterized by bright enhancement in the arterial phase, followed by a loss of enhancement as contrast washes out of the arterial circulation, and a characteristic decreased intensity below that of the surrounding liver during the portal phase, when the surrounding liver is perfused by contrast to a higher intensity than that of the tumor nodule. This feature, referred to as *washout,* is highly specific for hepatocellular carcinomas occurring in a cirrhotic liver (Fig. 202-2). In patients with cirrhosis, almost all hepatocellular carcinomas 2 cm or larger can be confidently diagnosed using noninvasive imaging criteria. When lesions are between 1 and 2 cm in a cirrhotic liver, characteristic imaging findings should be present in two dynamic imaging studies to diagnose hepatocellular carcinoma.

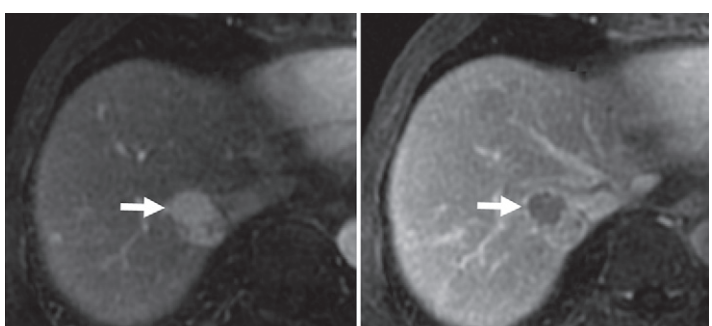

FIGURE 202-2. Hepatocellular carcinoma. A T1-weighted magnetic resonance image is shown during the arterial (**A**) and portal (**B**) phases after the administration of intravenous gadolinium contrast. The tumor *(arrows)* shows contrast enhancement in the arterial phase and washout in the portal phase.

Lesions smaller than 1 cm should be closely followed at an interval of 3 to 6 months for up to 2 years. Should a lesion not change, the patient can return to routine surveillance.

The diagnosis of small equivocal lesions in a noncirrhotic liver or any lesions in noncirrhotic liver can be established by needle biopsy of the lesion. However, because of the small but real risks of tumor seeding (0.5 to 2%), hemorrhage, and false-negative results from biopsy, many centers avoid biopsy, particularly in patients who may be candidates for liver transplantation and instead rely on imaging characteristics for the diagnosis of hepatocellular carcinoma.

PREVENTION

Universal vaccination against hepatitis B has been shown to reduce the incidence of hepatocellular carcinoma.[1] No vaccine is available against the hepatitis C virus. Individuals who have durable responses to treatment for hepatitis B and C appear to have a reduced risk of developing hepatocellular carcinoma.

TREATMENT

Rx

Patients who have early-stage hepatocellular carcinoma and who do not have significant underlying liver dysfunction can be treated by surgical resection. Liver transplantation (Chapter 157) of patients who meet the Milan criteria (one tumor mass lesion ≤5 cm or two to three lesions each ≤3 cm, with no evidence of extrahepatic spread or vascular invasion) provides long-term survival results no different from those of patients receiving liver transplants for nonmalignant indications. In patients who are not candidates for liver transplantation, local ablation of small tumors up to 3 to 4 cm is performed with percutaneous ethanol injection or radiofrequency ablation, which uses probes with small tines that can be deployed through the tumor and energized with high-frequency electrical current to produce coagulation of the tumor and a surrounding rim of benign tissue. Although surgical resection and the local ablative therapies are effective treatments for small hepatocellular carcinomas, patients with cirrhosis still have a residual molecular defect in the remaining liver that makes them susceptible to recurrent tumor, at a rate of approximately 50% by 3 years after surgical resection or local ablation.

Patients with tumors that do not meet the criteria for surgical resection, liver transplantation, or local ablation but that are still limited to the liver are considered to have intermediate-stage disease. Intermediate-stage disease is currently treated using transarterial chemoembolization with chemotherapeutic agents, such as doxorubicin, mitomycin C, and cisplatin, as well as polyvinyl alcohol (Ivalon) or absorbable gelatin (Gelfoam) particles, sometimes combined with iodized poppy-seed oil (Lipiodol or Ethiodol). Randomized trials and meta-analyses have confirmed that transarterial chemoembolization improves survival of patients with intermediate-stage hepatocellular carcinoma.[2] Radioembolization with yttrium-90-impregnated glass microspheres, which is an alternative to transarterial chemoembolization, can be used for patients with portal vein thrombosis because, unlike the Ivalon or Gelfoam particles used for chemoembolization, the 20- to 30-μg glass microspheres

used for radioembolization do not occlude the hepatic arterial vascular bed. However, radioembolization has not as yet been subjected to rigorous randomized trials.

Treatment using systemic chemotherapy is complicated by the presence of underlying chronic liver disease and a significantly increased risk of drug toxicity. Current efforts are focused on the use of targeted therapies directed against molecular pathways known to be involved in hepatocarcinogenesis, including receptor tyrosine kinases and the Wnt signaling pathway. Sorafenib, 400 mg twice daily, has been shown to increase median survival significantly in patients with advanced-stage hepatocellular carcinoma, typically by slowing progression but not by inducing remission.[3] Recently, sorafenib, 400 mg twice daily, combined with doxorubicin, 60 mg/m^2 intravenously every 21 days, was shown to be superior to doxorubicin alone in prolonging progression-free survival and overall survival among patients with advanced hepatocellular carcinoma.[4]

PROGNOSIS

Patients with early disease who undergo liver transplantation have an excellent outcome with a 5-year survival rate of 70 to 80% and 5-year recurrence rate of 10% or less. Patients who are ineligible for liver transplantation who undergo surgical resection or local treatment by radiofrequency ablation or percutaneous ethanol injection also have relatively high 5-year survival rates of 50 to 70%; however, because they still have a cirrhotic liver with a predisposition to cancer, these patients have a 3-year recurrence rate of approximately 50%. Patients with intermediate-stage disease who are treated with transarterial chemoembolization have a 1-year survival rate of 50 to 80% and a 2-year survival rate of 25 to 60%. Appropriate selection of individuals with preserved liver function is important for achieving the best outcomes with transarterial chemoembolization because it can decrease survival by inducing liver decompensation. Patients with advanced-stage disease who are currently candidates for treatment trials or symptomatic treatment have a median survival of only 6 to 8 months and a 1-year survival rate of 10 to 30%.

Cholangiocarcinoma

EPIDEMIOLOGY

Although the overall incidence of biliary cancers, or cholangiocarcinomas, is relatively low, these tumors are associated with perhaps the most rapidly rising incidence of any cancer in Western industrial nations. The reason for this trend is unknown. Most cholangiocarcinomas occur incidentally, but the known risk factors for cholangiocarcinoma include primary sclerosing cholangitis (Chapter 158), which is often associated with inflammatory bowel disease (Chapter 143); congenital choledochal cysts or other biliary tract abnormalities; Asian cholangiopathies secondary to liver fluke infections; and secondary chronic bacterial cholangitis, which frequently occurs in individuals who have had intrahepatic biliary stones or a prior biliary-enteric anastomosis. Chronic liver disease from viral or nonviral hepatitis is associated with cholangiocarcinoma, although the strength of association is weaker than with hepatocellular carcinoma.

PATHOBIOLOGY

The pathogenesis of cholangiocarcinoma is not well understood. Current concepts suggest that biliary inflammation results in impairment of DNA repair mechanisms, with the subsequent development of genomic instability and cancer. Genes in pathways shown to be involved in biliary carcinogenesis include *p53, K-ras, c-met, c-erbB2, mcl-1, Bcl-xl, p16^{INK4a}, p14^{ARF}, iNOS,* and *IL-6.*

CLINICAL MANIFESTATIONS

Patients with cholangiocarcinomas typically present with painless jaundice resulting from the presence of hilar or distal biliary strictures or with an intrahepatic mass causing abdominal pain, which may be referred to the shoulder. These patients often have associated pruritus, pale stools, and dark urine. Nonspecific symptoms such as weight loss and low-grade fever may also occur.

DIAGNOSIS

Cholangiocarcinomas are classified as intrahepatic or extrahepatic based on the location of the tumor within the biliary tree. The use of MRI with magnetic resonance cholangiography provides a noninvasive means of imaging the obstructed biliary tract before endoscopic retrograde cholangiopancreatography and allows the endoscopist and surgeon to plan an optimal approach for evaluation and therapy. Patients with unilateral biliary obstruction often have atrophy of the involved liver lobe and compensatory hypertrophy of the other lobe, referred to as the *atrophy-hypertrophy complex* (Fig. 202-3). Because of the presence of a dense fibrous stroma around a relatively sparse number of malignant glandular epithelial elements in many cholangiocarcinomas, cytologic examination from brushings of malignant strictures has a relatively low sensitivity, particularly in early cancers most amenable to successful therapy. However, the examination of biliary brush cytology specimens using advanced cytologic techniques such as DNA flow cytometry, digital image analysis, and fluorescence in situ hybridization with DNA probes for the detection of chromosomal polysomy has improved diagnostic accuracy (Fig. 202-4). These techniques can be applied in patients with primary sclerosing cholangitis who present with a new dominant stricture or clinical deterioration to improve the early detection of malignant transformation. Advanced endoscopic methods such as endoscopic ultrasound, intraductal ultrasound, and choledochoscopy also improve visualization and characterization of biliary strictures and associated metastatic lymphadenopathy.

The CA-19-9 marker is a commonly used tumor marker in cholangiocarcinoma. Although the sensitivity is modest and cholestasis and inflammation of the biliary tract can lead to false positive elevation, CA-19-9 is a tool for determining the effect of treatment or for monitoring recurrence after curative treatment.

TREATMENT Rx

The outcome after development of cholangiocarcinoma is generally poor because the tumor is relatively resistant to chemotherapy and also frequently results in biliary obstruction, which is complicated by episodes of bacterial cholangitis and cholestatic liver dysfunction. The treatment of biliary cancers depends on the extent of involvement of the biliary tree and on the presence of extrahepatic disease.

For disease limited to the liver and biliary tree, with malignant strictures that do not extend beyond the secondary branching of the right or left intrahepatic

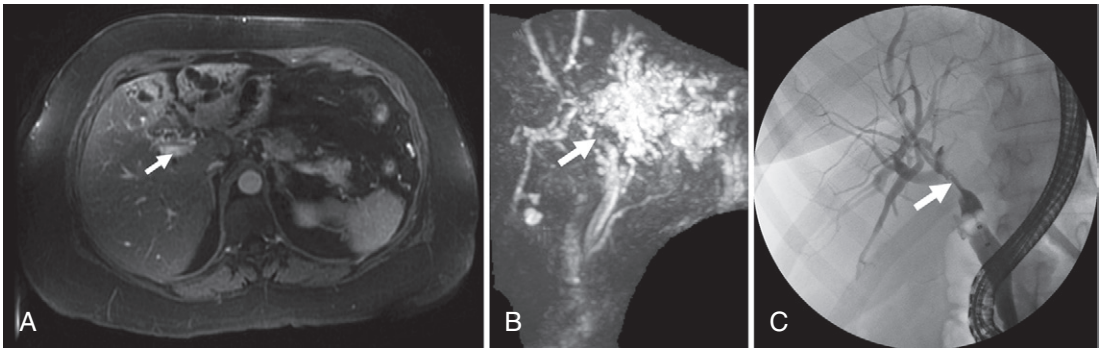

FIGURE 202-3. Cholangiocarcinoma. A, A T1-weighted magnetic resonance image during the arterial phase after the administration of intravenous gadolinium. The tumor *(arrow)* occludes the left hepatic duct, leading to marked dilation of the left biliary system and atrophy with enhanced contrast enhancement of the left lobe; the right lobe of the liver shows compensatory hypertrophy. This combination of features is called the *atrophy-hypertrophy complex.* **B,** Magnetic resonance cholangiopancreatography from the same patient showing narrowing of the common hepatic duct by the cholangiocarcinoma *(arrow)* and grossly dilated left biliary system. **C,** Endoscopic retrograde cholangiopancreatography showing filling of the right biliary system through the narrowed common hepatic duct *(arrow)*; the left biliary system is completely isolated and not filled during injection of contrast.

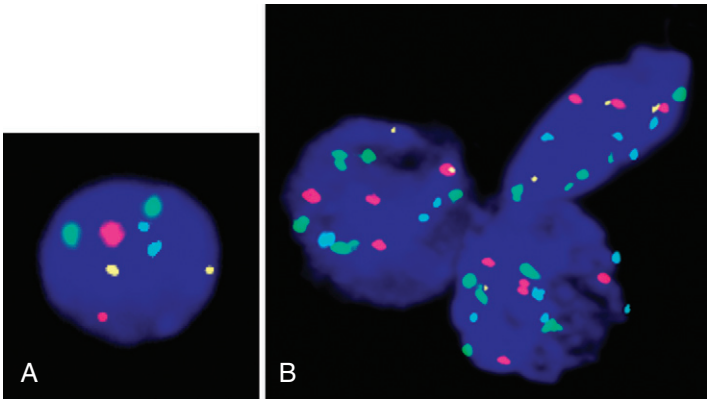

FIGURE 202-4. Fluorescence in situ hybridization for diagnosis of malignancy in biliary strictures. Fluorescent DNA probes for the centromeres of chromosomes 3 (red), 7 (green), 17 (aqua), and the p16 locus at chromosome 9p21 (yellow) are hybridized to brush cytology specimens obtained from biliary strictures at endoscopic retrograde cholangiopancreatography. The normal diploid cell (**A**) has two copies of each of the probes; the malignant polysomic cells (**B**) each have multiple copies of chromosomes 3, 7, and 17.

bile ducts, treatment by surgical resection results in a 5-year survival rate of approximately 20% after successful resection. Patients with distal biliary cancers without distant spread are usually treated by bile duct resection or by Whipple's pancreaticoduodenectomy.

Patients with unresectable disease are generally treated by palliative biliary stenting using plastic or metal stents. Effective stenting of approximately 25% of the total liver volume using the less affected lobe of the liver is usually sufficient to relieve cholestasis and is significantly less likely to result in repeated episodes of cholangitis.

Adjuvant chemotherapy and radiation, with staging laparotomy followed by liver transplantation for selected patients with early hilar cholangiocarcinomas, have resulted in a remarkable 5-year survival rate of 80% in patients who can successfully complete the treatment protocol. Photodynamic therapy with 630-nm laser light treatment administered using a fiber inserted across the biliary stricture after intravenous infusion of a photosensitizing porfimer, which is preferentially taken up by malignant cells, can preserve biliary patency and can improve survival in patients with unresectable malignant biliary strictures.■

In patients with locally advanced or metastatic cholangiocarcinoma, gallbladder cancer, or ampullary cancer, combination chemotherapy with cisplatin plus gemcitabine has been found to have survival advantage without the addition of substantial toxicity compared with gemcitabine alone.■

PROGNOSIS

Patients eligible for liver transplantation have the best prognosis with a 5-year rate survival of about 80%. Patients with curative resection have 5-year survival rate of about 20 to 40%. In patients with unresectable disease, biliary stenting, photodynamic therapy, and the use of chemotherapy regimens such as gemcitabine and cisplatin generally result in improvements in survival that are measured only in months.

TUMORS OF THE KIDNEY, BLADDER, URETERS, AND RENAL PELVIS

DEAN F. BAJORIN

RENAL CELL CARCINOMA

DEFINITION

Cancers of the kidney are a heterogeneous group of neoplasms, most of which are of epithelial origin and malignant. Renal cell carcinoma (RCC), classically referred to as clear cell carcinoma or hypernephroma, is not a single malignancy. Rather, RCC comprises a group of distinguishable entities, each with a strong relationship between its morphologic and genetic features. The World Health Organization recognizes these biologic and histologic differences in the classification system of kidney cancers (Table 203-1). The metastatic potential is dependent on the histologic subtype and ranges from the most virulent conventional clear cell carcinomas (75% of total tumors but accounting for 90% of the metastases), to the more indolent papillary and chromophobe carcinomas (20% of the total but only 10% of the metastases), to the benign oncocytomas (5% of all tumors).

EPIDEMIOLOGY

In the year 2009, it is estimated that there will be more than 49,000 new cases and approximately 11,000 deaths from kidney cancer in the United States. Since 1950, there has been a 126% increase in the incidence of renal cancer and a 36.5% increase in annual mortality. The increase in incidence of RCC may be in part related to early detection as a consequence of computed tomography (CT) and magnetic resonance imaging (MRI) of the abdomen for other medical conditions. The male-to-female ratio is approximately 2:1 to 3:1, and the increase in incidence is highest in African Americans and lowest in Asians and Pacific Islanders. The mean age at diagnosis is in the sixth to seventh decade of life. Aside from genetic predisposition, risk factors associated with RCC include cigarette smoking, obesity, hypertension, and the use of diuretics. Increased cigarette smoking has been associated with greater risk in both men and women. The risk may decrease after smoking cessation but requires about 20 years. Obese persons have an increased risk

TABLE 203-1 CLASSIFICATION OF RENAL CELL NEOPLASMS

BENIGN	MALIGNANT
Oncocytoma	Clear cell (conventional) renal cell carcinoma
Papillary (chromophil) adenoma	Papillary (chromophil) renal cell carcinoma
Metanephric adenoma	Chromophobe renal cell carcinoma
Nephrogenic adenofibroma	Collecting duct carcinoma
	Medullary carcinoma
	Mixed tubular and spindle cell carcinoma

Collecting duct	0.4	−18, −Y	−1q, −6p, −8p, −11, −13q, −21q c-*erB-1* oncogene expression	Renal medullary carcinoma

LOH = loss of heterozygosity; RCC = renal cell carcinoma; VHL = von Hippel-Lindau disease.
Modified from Zambrano NR. Histopathology and molecular genetics of renal tumors *J Urol.* 1999;162:1246-1258; and Klatte T, Pantuck AJ, Said JW, et al. Cytogenetic and molecular tumor profiling for type 1 and type 2 papillary renal cell carcinoma. *Clin Cancer Res.* 2009;15:1162-1169.

of RCC, and the risk rises with increasing body mass index. Although there is an elevated risk associated with diuretic use, this association is hard to distinguish from the increased risk associated with hypertension. RCC is more prevalent in patients with preexisting renal conditions such as polycystic kidney disease, horseshoe kidney, and chronic renal failure requiring hemodialysis.

PATHOBIOLOGY

The new classification system for RCC permits a better understanding of the cell of origin for the various subtypes and their chromosomal abnormalities (Table 203-2). The classic clear cell carcinoma constitutes approximately 65% of tumors and is believed to be derived from the proximal convoluted tubule. It is generally solitary and well circumscribed with a golden yellow color because of abundant cytoplasmic lipid. Higher-grade tumors contain less lipid and glycogen. About half of the tumors exhibit either a solid or acinar growth pattern characterized by solid sheets of tumor cells and accompanied by a rich capillary vascular network. Papillary RCCs represent approximately 15% of primary epithelial renal neoplasms. Multifocality, either bilateral or multifocal lesions in the same kidney, is present in about 45% of cases. Most of these tumors exhibit a broad morphologic spectrum, including papillary, papillary-trabecular, and papillary-solid areas; associated necrosis is a common finding. The classic papillary pattern is characterized by discrete papillary fronds lined by neoplastic epithelial cells and containing a central fibrovascular core, easily recognized on low magnification. These tumors are divided into type 1 and type 2 lesions, based on cytologic features and genetic differences. Chromophobe renal cancers make up 5% of renal epithelial tumors. Characteristically, these tumors are solitary and discrete but not encapsulated. The typical histology consists of large round-to-polygonal cells with well-defined cell borders and pale basophilic cytoplasm admixed with a smaller population of polygonal cells with eosinophilic cytoplasm. These tumors may be quite large at diagnosis, with resectable tumors reported as big as 23 cm.

Clear cell carcinoma is characterized by the loss of genetic material of the short arm of chromosome 3 (3p) and mutations in the von Hippel-Lindau *(VHL)* gene. In patients with von Hippel-Lindau disease, these losses and mutations occur in virtually all cases. The more common sporadic tumors also have somatic mutations or hypermethylation in the same region in approximately 75 to 80% of cases. Conventional clear cell tumors have a mutation in the *VHL* gene, which is inactivated by a point mutation or by epigenetic gene silencing by promoter methylation. The loss of *VHL*, responsible for ubiquination and degradation of hypoxia-inducible factor *(HIF)* genes, leads to upregulation of HIF-responsive genes responsible for angiogenesis and cell growth. Two of these upregulated genes are platelet-derived growth factor *(PDGF)* and vascular endothelial growth factor *(VEGF)*, which are angiogenic factors thought to induce the neovascularity seen in both primary and metastatic clear cell cancers. Patients with the VHL syndrome more commonly develop tumors at an earlier age and frequently have multiple tumors. Other tumors associated with the syndrome include central nervous system hemangioblastomas (Chapter 195), pancreatic neuroendocrine tumors (Chapter 201), pheochromocytomas, retinal angiomas, and epididymal cystadenomas.

Most sporadic papillary RCCs are characterized by trisomy of chromosomes 7 and 17 as well as loss of chromosome Y. Hereditary papillary renal cancer is a result of germline mutations and activation of the *MET* protooncogene, which is located on chromosome 7p. These cells have aberrant hepatocyte growth factor receptors that are unable to deactivate after binding by the growth factor. Somatic *MET* gene amplifications have also been observed in about 10% of sporadic papillary renal cancer. The syndrome of hereditary leiomyomatosis and papillary renal cancers is associated with the gene for fumarate hydratase. Birt-Hogg-Dubé syndrome is a rare disorder predominantly associated with the chromophobe renal cancers but in which clear cell tumors and chromophobe and oncocytic tumors can develop. The gene associated with the Birt-Hogg-Dubé syndrome has been mapped to 17p and expresses a novel protein, folliculin, whose function is not yet characterized. Chromophobe RCCs have genetic loss on chromosomes 1 and Y as well as combined chromosomal losses affecting chromosomes 1, 6, 10, 13, 17, and 21.

CLINICAL MANIFESTATIONS

Although RCC has a high propensity for metastases and has associated paraneoplastic syndromes, most patients are asymptomatic at presentation. Historically, RCC tumor was characterized by the presenting triad of hematuria, a palpable mass, and pain in as many as 10% of patients. However, there has been a migration to the detection of earlier-stage tumors with the increased use of abdominal imaging for unrelated medical conditions in modern series. Up to 48% of tumors may be discovered in this manner, and less than 5% of patients now have a palpable mass at presentation. The more common presenting symptoms are anemia, weight loss, malaise, and anorexia (Table 203-3). The presence of these symptoms has been associated with the disease-free survival after nephrectomy. Patients presenting with RCC frequently have associated paraneoplastic syndromes. Hypercalcemia (Chapter 186) has been observed in approximately 20% of patients and can be due to the secretion of parathyroid hormone, parathyroid hormone–like peptide, and interleukin-6, shown to stimulate osteoclastic bone resorption. Other associated syndromes include hypertension, erythrocytosis (from ectopic erythropoietin production) and the rare Stauffer's syndrome, which is the presence of liver dysfunction without the presence of hepatic metastases; the hepatic dysfunction resolves after surgical resection of the tumor.

DIAGNOSIS

The complete evaluation for patients with suspected RCC should include a complete blood count, chemistry profile, bone scan, and CT scan of the chest, abdomen, and pelvis. CT is the most reliable method for detecting and staging of RCC. The "ideal" CT scan for renal masses can be divided into four phases, including the precontrast images, the arterial phase (about 25 seconds after injection), the nephrographic phase (about 90 seconds into the injection), and the excretory phase. The most important phases for imaging renal tumors are the precontrast and nephrographic images because renal lesions appear low in density in contrast to the uniformly enhanced renal parenchyma. The arterial phase is helpful for identifying renal arteries and small hypervascular masses. The excretory phase aids in assessing the collecting system and the renal pelvis. The CT scan is also helpful in detecting regional

TABLE 203-3 PRESENTING SYMPTOMS AND SIGNS OF RENAL CELL CARCINOMA (BOTH LOCALIZED AND METASTATIC DISEASE)

Anemia	52%
Hepatic dysfunction	32%
Weight loss	23%
Hypoalbuminemia	20%
Malaise	19%
Hypercalcemia	13%
Anorexia	11%
Thrombocytosis	9%
Night sweats	8%
Fever	8%
Erythrocytosis	4%
Hypertension	3%
Chills	3%

metastases, and three-dimensional CT imaging is now possible in cases in which "nephron-sparing surgery" or partial nephrectomy is planned. The additional use of ultrasonography and MRI can help distinguish benign from malignant lesions of the kidney and in treatment planning. Ultrasound is used when distinguishing cysts from solid lesions. MRI has the advantage of imaging tumors in patients with poor renal function in which intravenous contrast may be contraindicated. MRI is also helpful for delineating any thrombi that may be extending into the renal vein or inferior vena cava, and magnetic resonance angiography can be used to determine the number and location of renal arteries in patients who are candidates for partial nephrectomy. Once the evaluation is complete, the clinical stage is assessed using the TNM (tumor, node, metastasis) system (Table 203-4).

TABLE 203-4 TNM STAGING OF RENAL CELL CARCINOMA

TUMOR, NODES, AND METASTASES CLINICAL CLASSIFICATION	
PRIMARY TUMOR (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor 7 cm or less in greatest dimension, limited to the kidney
T1a	Tumor 4 cm or less in greatest dimension, limited to the kidney
T1b	Tumor more than 4 cm but not more than 7 cm in greatest dimension, limited to kidney
T2	Tumor more than 7 cm in greatest dimension, limited to kidney
T2a	Tumor more than 7 cm but less than or equal to 10 cm in greatest dimension, limited to the kidney
T2b	Tumor more than 10 cm, limited to the kidney
T3	Tumor extends into major veins or the perinephric tissues but not into the ipsilateral adrenal gland but not beyond Gerota's fascia
T3a	Tumor grossly extends into renal vein or its segmental (muscle-containing) branches, or tumor invades perirenal and/or renal sinus fat but not beyond Gerota's fascia
T3b	Tumor grossly extends into the vena cava below the diaphragm
T3c	Tumor grossly extends into vena cava above the diaphragm or invades the wall of the vena cava
T4	Tumor invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland)
Regional Lymph Nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in regional lymph node(s)
Distant Metastasis (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
STAGE GROUPING	
Stage I	T1, N0, M0
Stage II	T2, N0, M0
Stage III	T1 or T2, N1, M0
	T3, N0 or N1, M0
Stage IV	T4, Any N, M0
	Any T, Any N, M1

From *AJCC Cancer Staging Manual*, 7th ed. New York: Springer-Verlag; 2010.

TREATMENT

Localized Disease

The historical standard of care for patients with an RCC is a radical nephrectomy. Kidney cancers routinely selected for radical nephrectomy include large and centrally localized tumors that have effectively replaced most of the normal renal parenchyma, tumors associated with regional adenopathy (of benign or malignant etiology), those with inferior vena cava or right atrial extension, and even those in which metastatic disease is evident. Nephrectomy can be performed through a flank, transperitoneal, or a transthoracic incision. The ipsilateral adrenal gland is also removed, but a regional lymph node dissection is optional and controversial. The increasing percentage of small tumors has resulted in a corresponding decrease in patients undergoing radical nephrectomy. Partial nephrectomy for tumors of 7 cm or smaller offers rates of local tumor control and survival similar to radical nephrectomy but also reduces the risk of renal insufficiency over time. Partial nephrectomy is further supported by the fact that approximately 35% of renal cortical tumors are the indolent papillary or chromophobe carcinomas. Laparoscopic nephrectomy offers a minimally invasive alternative to the classical radical nephrectomy. Both open and laparoscopic approaches can be used for partial nephrectomy to control disease and preserve renal function.

RCCs are resistant to both radiation therapy and traditional chemotherapy. Neither are used in either the neoadjuvant or adjuvant surgical setting. Immunotherapy with interferon and interleukin-2, used in the treatment of metastatic disease, have shown no benefit in the adjuvant setting after nephrectomy.

Metastatic Disease

About 30% of patients with RCC present with metastatic disease, and an additional 20 to 30% of patients with surgically resected primary tumors relapse with metastases. Complications of metastatic disease include pain from either an unresectable primary tumor or from skeletal metastases. Radiation therapy is frequently used for palliation of bone metastases and in patients with multiple brain metastases. Palliative nephrectomy is sometimes used to provide symptomatic relief of pain. Surgical resection of the primary tumor is considered a mainstay of treatment even in patients with metastatic disease and has been shown to extend survival in these patients. Surgical resection of metastatic sites of disease (i.e., "metastectomy") may also extend survival and even cure a subset of patients. The patients most likely to benefit from surgical resection of metastatic disease are those with a disease-free interval of greater than 1 year, those with a solitary site of metastases, and those with lung metastases. Long-term survival has been observed when the solitary site of resection was the lung (up to 45%) and even the brain (up to 20%). RCC is resistant to most conventional chemotherapy agents, with responses seen in less than 10% of patients.

Immunotherapy with either interleukin-2 or interferon-α (Chapter 35) has been the historical treatment for patients with metastatic disease. High-dose intravenous interleukin-2, a potentially curative treatment, requires a dedicated inpatient setting because of the severe toxicities associated with this therapy, including hypotension, pulmonary edema, renal failure, and central nervous system toxicity. However, most toxicities are reversible, and complete or partial responses are seen in approximately 15 to 20%; approximately 4% of patients achieve long-term, disease-free survival. Interferon-α therapy is given as three to five subcutaneous injections per week, is less toxic than interleukin-2, and has an overall response rate of approximately 15%. However, the number of patients achieving a complete response and long-term survival is substantially less than seen with interleukin-2. Reversible toxicities of interferon-α treatment include influenza-like symptoms such as fever, chills, myalgias, mild myelosuppression, and mild hepatic dysfunction.

RCC has been an ideal candidate for the development of new "targeted" therapies, exploiting the downstream effects of *VHL* mutations. Randomized trials have shown the benefit of tyrosine kinase inhibitors (TKIs), such as sunitinib and sorafenib, that block the actions of *VEGF* and PDGF, and

bevacizumab, an antibody that blocks the endothelial growth factor receptor. Sunitinib was found to be superior to interferon as initial therapy and is now a standard of care. Common side effects include fatigue, diarrhea, hypertension, and hand-foot-syndrome, a condition in which blisters appear at areas of contact. The addition of bevacizumab to interferon is superior to interferon alone, and this combination has been approved for first-line treatment as well. Side effects include hypertension and an increased risk of bleeding. Sorafenib was found to be superior to placebo in patients whose disease progressed after cytokine therapy. Side effects are similar to sunitinib. Two new drugs active in RCC target the mammalian target of rapamycin (mTOR) pathway and have also been approved for treatment. Temsirolimus, an intravenous mTOR inhibitor, improves survival of patients with untreated poor-risk disease (those with three or more risk factors; see later). Everolimus, an oral mTOR inhibitor, improves the outcomes of patients who have been previously treated with sunitinib, sorafenib, or bevacizumab. Common side effects include fatigue, skin rashes, and mouth sores.

PROGNOSIS

Survival rates for resected nonmetastatic renal cortical tumors range between 60 and 100% depending on the mode of presentation, tumor histology, tumor size, and pathologic stage (E-Fig. 203-1). The prognosis declines considerably for patients with more advanced disease, with long-term survival seen in only 20% of stage III patients and 5% or less of stage IV patients. Of the more common histologic subtypes of RCC, the prognosis of clear cell carcinoma is less favorable than papillary RCC; chromophobe RCC is the most favorable. For patients with metastatic disease, five clinical features associated with shorter survival are low performance status, high lactate dehydrogenase, low hemoglobin, high calcium, and absence of prior nephrectomy. Three groups have been defined using survival data from patients treated with immunotherapy: favorable (0 zero risk factors), with a median survival of 20 months; intermediate (one or two risk factors), with a median survival of 10 months; and poor (three or more risk factors), with a median survival of 4 months. Immunotherapy treatment of patients and surgical resection of metastases can result in long-term survival of a small percentage of RCC patients. New targeted drugs, a direct result of increased understanding of RCC biology, are now the standard of care for patients with metastatic disease.

BLADDER CANCER

DEFINITION

A spectrum of tumors arise from the urothelial lining of the bladder, renal pelvis, ureters, and urethra, of which transitional cell carcinoma is the most common. Most tumors arise from the bladder, with a minority arising from the upper tracts (renal pelvis and ureters) and even fewer from the proximal urethra. Although transitional cell cancers possess a variable natural history, they have a proclivity for multifocality, high recurrence rates, and progression to higher pathologic stages. These tumors are generally grouped into the three broad categories of superficial, muscle-invasive, and metastatic disease, each of which differs in clinical behavior, prognosis, and primary management. For superficial tumors, the aim is to prevent recurrences and progression to a more advanced stage. In muscle-invasive disease, the medical challenge is to integrate the modalities of surgery, chemotherapy, and radiation to optimize cure and minimize morbidity. For metastatic disease, chemotherapy is used to palliate the symptoms of most patients, but there is a subset of patients in whom combination chemotherapy may result in long-term cure. During the past 30 years, improvements in diagnosis, management, and therapies has resulted in a 5-year survival rate that has increased from 73% in the 1974 to 1976 time period to 82% for those patients diagnosed between 1998 and 2001.

EPIDEMIOLOGY

More than 68,000 estimated new cases of bladder cancer were diagnosed in 2008, of which 14,000 patients are expected to succumb to their disease. The male-to-female ratio of 3:1 is similar in all racial groups, making this disease the fourth most common cancer in men and the ninth in women. The combined bladder cancer incidence for men and women has remained stable from 1986 to 2001 after rising 0.7% per year from 1975 to 1986, whereas the death rate from bladder cancer continues to decline. Bladder cancer is twice as prevalent in whites as in African Americans and is less frequently observed in Asians. The median age at diagnosis is approximately 70 years, and the disease is rarely diagnosed before the age of 40 years.

Carcinogens or their metabolites implicated in the carcinogenesis of bladder cancer are believed to be excreted in the urine, where they can act directly on the urothelial lining. The latency period from initial exposure to the development of cancer is almost 20 years, making it difficult to establish a definitive cause-and-effect relationship between a putative carcinogen and the development of the disease. Cigarette smoking is the leading risk factor for bladder cancer, believed to contribute to 48% of the cancers in men and 28% of the cancers in women. A longer duration of exposure is associated with a higher risk than a more intense exposure (in cigarettes/day) over a shorter time period of time. Overall, smokers have a two- to four-fold higher relative risk of bladder cancer than nonsmokers. Smoking is associated with cellular atypia of the urothelium; individuals who never smoked show atypia in only 4% of cases, in contrast to a 50% incidence of atypia in smokers.

Polycyclic aromatic hydrocarbons such as 2-naphthylamine, 4-aminobiphenyl, and benzidine and benzene or exhausts from combustion gases are associated with an increased risk of bladder cancer. Occupations reported to be at higher risk include aluminum work, dry cleaning, manufacturing of preservatives and polychlorinated biphenyls, and pesticide application. Arylamines, also implicated in carcinogenesis, are metabolically activated to electrophilic compounds by *N*-hydroxylation in the liver by cytochrome P-450 IA2 and detoxified by *N*-acetylation; studies suggest that individuals with a fast oxidizer and slow acetylator phenotype are at highest risk. Patients with occupations associated with a higher exposure to arylamines, such as workers in the dye, rubber, or leather manufacturing industries, are believed to be at higher risk of bladder cancer. *Schistosoma haematobium* infection enhances formation of carcinogenic *N*-nitroso compounds and results in an increased risk of both squamous and transitional cell carcinomas of the bladder. An association has been observed between squamous cell carcinoma (but not transitional cell tumors) and the presence of chronic urinary tract infections seen in paraplegic patients and those with chronic bladder stones and indwelling Foley catheters. The chemotherapy agent cyclophosphamide can increase the risk of bladder cancer nine-fold, and phenacetin-containing compounds have been implicated in the development of renal pelvis and ureteral tumors.

PATHOBIOLOGY

Urothelial tumors can occur anywhere along the urinary tract, including the renal pelvis, ureters, bladder, and urethra. More than 90% of tumors originate in the bladder, 8% in the renal pelvis, and the remaining 2% in the ureter and urethra. Transitional cell carcinomas make up 90 to 95% of urothelial tumors; squamous cell (keratinizing) tumors (3%), adenocarcinomas (2%), and small cell tumors (1%) constitute the remainder. Mixed-histology tumors, consisting of predominantly transitional cell carcinoma with areas of squamous, adenocarcinomatous, or neuroendocrine elements, are frequently observed. Squamous cell tumors are more common in the distal urethra, and adenocarcinomas occur in the embryonal remnant of the urachus on the dome of the bladder and in periurethral tissues. In endemic areas of *S. haematobium* (Chapter 363) infections (such as Egypt), 40% of tumors are squamous cell carcinomas. Rare tumors of the bladder include lymphoma, sarcoma, and melanoma.

Most (70 to 80%) newly detected bladder cancers are classified as superficial tumors and include exophytic papillary tumors confined to the mucosa (Ta), tumors invading the lamina propria (T1), and carcinoma in situ (CIS, also called Tis). Superficial bladder tumors are typically graded according to the World Health Organization/International Society of Urologic Pathology (WHO/ISUP) grading system as low or high grade. If the grading system is not specified, a numerical system can be used: well differentiated (G1), moderately differentiated (G2), poorly differentiated (G3), and undifferentiated (G4). Grading is more important for noninvasive Ta tumors because almost all invasive bladder tumors (T1 or greater) are high grade. Primary CIS (or Tis) without a concurrent Ta or T1 tumor constitutes 1 to 2% of new bladder cancer cases. More frequently, CIS is found in the presence of multiple papillary tumors, either immediately adjacent to another lesion or involving remote mucosa in the bladder. CIS is, by definition, high-grade disease; it is regarded as a precursor to more invasive tumors because 60% of untreated tumors develop more invasive disease within 5 years. A T1 tumor is an aggressive, invasive malignancy. Virtually all T1 tumors are high grade, and 50% have associated CIS. Fifty percent of patients have disease recurrence by 1 year, and 90% within 5 years. A minority of primary tumors at diagnosis are found to invade the muscularis propria (T2), extend to perivesicular fat (T3), or extend into immediately adjacent organs (T4); all primary tumors stage T2 or higher are high grade.

The natural history of a urothelial tumor is to recur either at the same location or at a separate site in the urothelial tract and at the same or a more advanced stage. Several studies support the controversial concept that these recurrences are clonal in origin. Chromosome 9 deletions are the most commonly observed chromosomal changes in bladder cancer. Chromosomal deletions of 17p (the *TP53* locus), 18q (the *DCC* gene locus), and the *RB* gene locus are frequently observed in invasive tumors; deletions of 3p and 11p occur in both superficial and invasive tumors. Associations between specific gene deletions and prognosis have been attempted, particularly for the *TP53* and *RB* genes, but inconsistent findings among studies preclude their routine use in clinical management. The epidermal growth factor receptor is highly expressed (~80%) on bladder cancer tumors, and the Her-2/Neu growth factor receptor is less frequently expressed (~50%). Studies suggest that higher expression of these receptors on bladder cancers is associated with a more advanced and more aggressive phenotype of disease.

CLINICAL MANIFESTATIONS

Hematuria is the presenting symptom in 80 to 90% of bladder cancer cases, but others present with a urinary tract infection. Individuals older than 40 years who develop hematuria should have an evaluation for the presence of urothelial cancer that includes urinary cytology, cystoscopy, and imaging of the urinary tract by either an ultrasound or CT. Screening of asymptomatic subjects for hematuria increases the probability of diagnosing bladder cancer at an earlier stage but does not improve survival; thus, it is not routinely recommended. Urinary frequency and nocturia may be present as a consequence of either irritative symptoms or reduced bladder capacity. Pain, when present, typically reflects the location of the bladder tumor. Lower abdominal pain may occur as a result of a bladder mass, and rectal discomfort and perineal pain can result from tumors invading into the prostate or pelvis. Tumors of the renal pelvis, ureter, or bladder in which the ureteral orifice is obstructed can cause hydronephrosis, reduced renal function, and flank pain. Patients with more advanced disease can present with anorexia, fatigue, weight loss, or pain from a metastatic bone lesion. The physical examination is frequently unremarkable in patients presenting with bladder tumors because most patients have organ-confined tumors.

DIAGNOSIS

The mainstay of bladder cancer diagnosis and staging is the cystoscopic evaluation. The procedure includes the examination under anesthesia to determine whether a palpable mass (either mobile or not) is present. A nonmobile tumor mass is indicative of disease invading the pelvic sidewall, which is unlikely to be resectable. Urine is obtained to evaluate for the presence of malignant cells. A cystoscope is inserted to visually inspect the bladder and detail the size, number, location, and growth pattern (papillary or solid) of all lesions. All visible tumors undergo transurethral resection of the bladder tumor to determine the histologic subtype and depth of invasion. Adequate evaluation, particularly in large tumors that may be invasive, requires that muscle be identified in the pathologic specimen. Repeat biopsy of the resected area is occasionally required to ensure that no muscle invasion is present because invasion into muscle requires consideration of surgical removal of the bladder rather than just endoscopic resection of the tumor. Biopsies from any areas of erythema are performed to assess for CIS. The urethra is inspected during withdrawal of the cystoscope, and specimens are taken if clinically indicated. Patients with a positive cytology but no apparent tumor within the bladder undergo selective retrograde catheterization of the ureters up to the renal pelves to assess for upper tract disease.

The decision whether to image the abdomen and pelvis is based on the cystoscopy results and the pathology of the tumor. An intravenous pyelogram or CT urogram can evaluate the upper urinary tracts, and CT or MRI may distinguish whether a tumor extends to the perivesical fat (T3) or prostate or vagina (T4) and whether regional lymph nodes are involved. In the case of larger, invasive tumors, the presence or absence of distal metastases can be documented with physical examination, CT of the abdomen and pelvis, chest radiograph, and radionuclide bone scan.

All patients with carcinoma of the bladder or of related sites are staged using the TNM system advocated by the American Joint Committee on Cancer (AJCC) (Table 203-5). The TNM system categorizes the depth of invasion of the primary tumor, nodal metastases in the pelvis (or retroperitoneum for upper tract disease) on the basis of the number and size of regional nodes involved, other nonregional lymph node sites, and any visceral sites of disease.

TREATMENT

Rx

Superficial Disease

The standard treatment for superficial tumors is a complete endoscopic resection. Most patients develop new tumors, 30% of which progress to a higher stage, mandating vigilant surveillance at 3-month intervals with cystoscopy, urine cytology, and repeat transurethral resection when indicated. Additional treatment in the form of adjuvant intravesical therapy is dependent on the number of lesions, the size, the depth of invasion, and the number of prior tumors in that individual. Prophylactic or adjuvant intravesical therapy is typically instituted in the setting when a patient has shown either a repeated tendency to develop new lesions in the bladder or is at high risk for recurrence or progression de novo. Intravesical therapy is not warranted for the first Ta tumor that is low grade. Instances of high recurrence and progression warranting intravesical therapy include multifocal or large lesions, high-grade papillary lesions, T1 tumors, CIS, or a combination. It is never advised for muscle-invasive tumors because agents instilled in the bladder do not penetrate beyond a few layers of cells. After allowing sufficient time for healing after the endoscopic resection, intravesical therapy is most frequently initiated with the immunologic agent bacillus Calmette-Guérin (BCG) weekly for 6 weeks.■ Occasionally, other chemotherapy and cytokines are used when BCG is contraindicated. Treatment outcome is assessed at the 3- and 6-month evaluations following treatment to determine whether the bladder has been rendered tumor free. If disease persists, either a repeat course of BCG treatment or even an immediate cystectomy may be recommended. Bladder toxicity can result from urothelial irritation, including bladder irritability or spasms, hematuria, and pain on urination. A rare complication of BCG is development of a systemic tuberculosis infection requiring treatment with systemic antituberculosis agents. BCG is highly effective in eradicating CIS, with 70% of patients disease free at 1 year and 40% at 10 years. Selected tumors in the ureter or renal pelvis can be managed by ureteroscopic resection, in some cases by instillation of BCG through the renal pelvis, or nephroureterectomy. Tumors of the prostatic urethra are frequently managed by cystoprostatectomy, particularly if a complete resection cannot be accomplished.

Muscle-Invasive Tumors

For patients with tumors infiltrating the muscularis propria, the standard of care in the United States is a radical cystectomy and pelvic lymphadenectomy because of the high incidence of cancer extending into the perivesicular fat or into regional lymph nodes. A prostatectomy is also performed in men; in women, the urethra, uterus, fallopian tubes, ovaries, and anterior vaginal wall are removed. Urinary flow can be directed through either a conduit diversion or a continent reservoir. With a conduit diversion, urine is drained directly from the ureters to a loop of small bowel that is anastomosed to the skin surface with no internal reservoir. Urine is collected in an external appliance. Alternatively, a low-pressure continent reservoir can be created from a detubularized segment of bowel attached to the abdominal wall with a continent stoma that can be self-catheterized at regular intervals. Low-pressure reservoirs can also be anastomosed to the urethra, creating an internal orthotopic neobladder and permitting the patient to void through the normal urethra. The standard pelvic lymphadenectomy includes the distal common iliac, external iliac, obturator, and hypogastric nodes; improved survival and decreased local recurrence are associated with an increased number of lymph nodes removed. Complications of cystectomy include recurrent urinary infections, hyperchloremic acidosis (Chapter 120), oxalate stones (Chapter 128), incontinence, and impotence.

Neoadjuvant chemotherapy before cystectomy for muscle-invasive bladder cancer increases survival.■ This survival benefit is achieved only with cisplatin-based combinations, which require the patient to have normal renal function and a good performance status. Some physicians prefer immediate cystectomy followed by adjuvant chemotherapy if the pathologic evaluation demonstrates a high risk of recurrence, such as disease extending to either the perivesicular fat or the lymph nodes. Radical cystectomy is effective in providing long-term disease control in 75 to 80% of patients with organ-confined disease, approximately 50% of those with tumors extending into the perivesical tissues, and nearly one third of patients with regional lymph node involvement. Some patients prefer a bladder-sparing approach using radiation treatment rather than a cystectomy. The best candidates for this approach are patients with a solitary early-stage lesion and no evidence of hydronephrosis. This trimodality treatment for bladder preservation first requires a successful, near-complete transurethral resection of tumor followed by concurrent chemotherapy and radiation. External beam treatments are delivered in five daily fractions a week, starting with the whole pelvis to a total dose of 40 to 45 Gy followed by 20 to 25 Gy reduced volume to the bladder tumor. Toxicities include inflammation of the skin, impotence, fatigue, and irritative symptoms from the bladder and bowel; persistent proctitis is rare. In this approach, cystectomy is reserved for patients failing to achieve complete response. The 5-year disease-free survival rate with this approach is 50%, with most patients retaining a normally functioning bladder.

TABLE 203-5 TNM DEFINITIONS FOR CANCERS OF THE BLADDER, URETER, AND RENAL PELVIS

PRIMARY TUMORS OF THE BLADDER (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Noninvasive papillary carcinoma
Tis	Carcinoma in situ ("flat tumor")
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades muscularis propria
pT2a	Tumor invades superficial muscularis propria (inner half)
pT2b	Tumor invades deep muscularis propria (outer half)
T3	Tumor invades perivesical tissue
pT3a	Microscopically
pT3b	Macroscopically (extravesical mass)
T4	Tumor invades any of the following: prostatic stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumor invades the prostatic stroma, uterus, vagina
T4b	Tumor invades the pelvic wall, abdominal wall
REGIONAL LYMPH NODES FOR UROTHELIAL TUMORS OF THE BLADDER (N)	
Regional lymph nodes include both the primary and secondary drainage regions. All other nodes above the aortic bifurcation are considered distant lymph nodes.	
NX	Lymph nodes cannot be assessed
N0	No lymph node metastasis
N1	Single regional lymph node metastasis in the true pelvis (hypogastric, obturator, external iliac, or presacral node)
N2	Multiple regional lymph node metastases in the true pelvis (hypogastric, obturator, external iliac, or presacral node)
N3	Lymph node metastasis to the common iliac lymph nodes
PRIMARY TUMORS OF THE URETER AND RENAL PELVIS (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Ta	Papillary noninvasive carcinoma
Tis	Carcinoma in situ
T1	Tumor invades subepithelial connective tissue
T2	Tumor invades the muscularis
T3	(For renal pelvis only) Tumor invades beyond muscularis into peripelvic fat or the renal parenchyma
T3	(For ureter only) Tumor invades beyond muscularis into periureteric fat
T4	Tumor invades adjacent organs or through the kidney into perinephric fat

REGIONAL LYMPH NODES FOR UROTHELIAL TUMORS (N)* OF URETER AND RENAL PELVIS	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node, 2 cm or less in greatest dimension
N2	Metastasis in a single lymph node, more than 2 cm but not more than 5 cm in greatest dimension; or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node, more than 5 cm in greatest dimension

*Note: Laterality does not affect the N classification.

DISTANT METASTASIS FOR ALL UROTHELIAL TUMORS (M)	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

Metastatic Disease

Patients with metastatic disease are treated predominantly with chemotherapy. Cisplatin-based chemotherapy is the standard of care. The two most commonly used regimens are gemcitabine plus cisplatin (GC) and the four-drug regimen of methotrexate, vinblastine, doxorubicin, and cisplatin (MVAC); six cycles of therapy are given are over a 6-month period. The most frequently observed toxicities include anemia, thrombocytopenia, neutropenic fever, mucositis, and fatigue. The GC regimen is better tolerated and has less severe toxicities than MVAC. The median survival of patients treated with both regimens is approximately 14 months, and the 5-year survival rate is 15% or less. Patients with a good performance status and whose metastatic disease is limited to the lymph nodes (i.e., no visceral metastases) have the highest likelihood for response and a 20 to 33% chance of 5-year disease-free survival. Patients with impaired renal function are treated with carboplatin rather than cisplatin owing to less toxicity to the kidney with carboplatin. Carboplatin is administered with either gemcitabine or paclitaxel, and toxicities include myelosuppression and fatigue.

PROGNOSIS

Urinary bladder cancer is a common but heterogeneous disease with a decreasing mortality rate because of improvements in therapy. Superficial Ta G1 lesions, easily treated with endoscopic resection alone, almost never progress. At the other end of the spectrum of superficial disease, aggressive transitional cell CIS requires intravesical immunotherapy therapy with BCG in addition to endoscopic resection. This intravesical treatment can substantially reduce recurrence and progression, with a 5-year disease-free survival rate of 60%. Muscle-invasive disease is most frequently cured with an integrated approach of systemic chemotherapy for micrometastases followed by cystectomy and pelvic lymphadenectomy; cure rates for T2 tumors can be as high as 80% with this multimodality approach. Bladder-sparing approaches associated with an improved quality of life are possible using external beam radiation. Metastatic urinary bladder cancer is a fast growing and often lethal malignancy; despite aggressive chemotherapy, only a small proportion (~15%) of patients are disease free at 5 years.

CANCERS OF THE RENAL PELVIS AND URETERS

Approximately 10% of transitional cell carcinomas occur in the ureters and the renal pelvis. These tumors can arise either de novo or in the setting of prior tumors. The risk of developing an upper tract tumor in patients with multifocal CIS of the bladder approaches 25% by 10 years. These tumors are morphologically similar to the tumors in the bladder and behave in a similar manner. Hematuria is the most common presenting symptom, although patients with large tumors or ureteral obstruction can present with flank pain. An intravenous pyelogram, CT, or MRI is used to stage the extent of primary disease and to detect regional metastases. Low-grade tumors can be treated endoscopically, but high-grade tumors are most commonly treated

with a nephroureterectomy. In contrast to cystectomy, a regional lymphadenectomy is not routinely performed. In renal pelvis tumors, the ureter is removed in addition to a nephrectomy because of the high risk of multifocal tumors along the entire upper tract and the inability to monitor the ureteral stump with accuracy. Systemic chemotherapy is used for unresectable primary tumors, patients with regional adenopathy, or recurrent tumors. Upper tract transitional cell carcinomas are staged according to the TNM system (see Table 203-5). Treatment of advanced, nonsurgical disease is with chemotherapy, and these urothelial tumors have the same sensitivity to chemotherapy as bladder cancer, with similar response rates and 5-year survival rates. Cisplatin-based chemotherapy is used in patients with normal renal function. Carboplatin-based chemotherapy is considered if there is renal insufficiency either from obstruction, a prior nephroureterectomy, or medical comorbidity.

TABLE 204-1 RISK FACTORS FOR BREAST CANCER

RISK FACTOR	RELATIVE RISK
Any benign breast disease	1.5
Postmenopausal hormone replacement (estrogen with or without progestin)	1.5
Menarche at <12 yr	1.1-1.9
Moderate alcohol intake (two to three drinks/day)	1.1-1.9
Menopause at >55 yr	1.1-1.9
Increased bone density	1.1-1.9
Sedentary lifestyle and lack of exercise	1.1-1.9
Proliferative breast disease without atypia	2
Age at first birth >30 yr or nulliparous	2-4
First-degree relative with breast cancer	2-4
Postmenopausal obesity	2-4
Upper socioeconomic class	2-4
Personal history of endometrial or ovarian cancer	2-4
Significant radiation to chest	2-4
Increased breast density on mammogram	2-4
Older age	>4
Personal history of breast cancer (in situ or invasive)	>4
Proliferative breast disease with atypia	>4
Two first-degree relatives with breast cancer	5
Atypical hyperplasia and first-degree relative with breast cancer	10

204

BREAST CANCER AND BENIGN BREAST DISORDERS

NANCY DAVIDSON

Invasive breast cancer, the most common nonskin cancer in women in the United States, will be diagnosed in about 180,000 women in 2010 and will result in approximately 40,000 deaths. Incidence and mortality from breast cancer appear to be dropping in the United States and parts of western Europe. This decline is believed to reflect early detection by screening mammography and widespread use of adjuvant systemic therapy as well as decreased use of hormone replacement therapy.

BREAST CANCER

EPIDEMIOLOGY AND PATHOBIOLOGY

Multiple risk factors for the development of breast cancer have been identified (Table 204-1). The principal risk factor is gender. Breast cancer is largely a disease of women, although it does occur in men at an incidence of about 1% that seen in women. A second critical risk factor is age. About 75% of breast cancer cases in the United States are diagnosed in women older than 50 years of age.

Family history is a third critical risk factor. About 20% of breast cancer occurs in women with a family history of breast cancer; increased risk is associated with diagnosis of breast cancer in first-degree relatives younger than 50 years. Five to 8% of breast cancer cases occur in high-risk families. Several familial breast cancer syndromes with associated molecular abnormalities have been identified. Chief among them is the breast ovarian cancer syndrome, which is linked to germline mutations in the breast cancer susceptibility genes, *BRCA1* and *BRCA2*. These mutations are inherited in an autosomal dominant fashion and can therefore be transmitted through the maternal or paternal line. Extensive studies suggest that a germline mutation in either of these genes is associated with a 50 to 85% lifetime risk of developing breast cancer. Testing for *BRCA1* and *BRCA2* mutations is now viewed as a standard option for women with clinical features suggestive of a hereditary breast cancer syndrome; these include multiple family members with early-onset breast or ovarian cancer, bilateral breast cancer, or Ashkenazi Jewish heritage. Careful counseling about the implications of a positive or negative test and about the limitations of testing is a prerequisite for testing.

Other hereditary cancer syndromes (Chapter 184) include Li-Fraumeni syndrome, which is linked with germline mutations in the *p53* tumor suppressor gene, and Cowden's syndrome, which is associated with inherited mutations in the *PTEN* gene. Finally, in addition to these high-penetrance genetic susceptibility syndromes, recent results from genome-wide association studies have identified a number of low-penetrance genetic associations, including single nucleotide polymorphisms in a variety of genes. If or how to incorporate these low-penetrance traits into clinical practice remains to be established.

Reproductive risk factors include early menarche, late menopause, nulliparity, and late first pregnancy. In aggregate, these factors result in prolonged estrogen exposure of the breast. The emerging association between postmenopausal obesity and breast cancer likely reflects estrogen exposure as well. Certain types of breast pathology, including atypical hyperplasia and lobular carcinoma in situ, are also associated with increased risk. The possibility that increased breast density as assessed by mammography is a risk factor has also been raised. Finally, much interest has focused on the possibility that exogenous environmental factors predispose to breast cancer. Among the

factors that appear to enhance breast cancer risk are ionizing radiation during adolescence, prolonged use of hormone replacement therapy, ongoing use of oral contraceptives, and alcohol consumption. Large studies have failed to show any convincing association between exposure to estrogenic pesticides or a high-fat diet and breast cancer.

CLINICAL MANIFESTATIONS

Breast cancer usually presents as a mammographic abnormality or a physical change in the breast including a mass or asymmetrical thickening, nipple discharge, or skin or nipple changes. Two unusual clinical presentations include Paget's disease of the nipple and inflammatory breast cancer. The former is a form of adenocarcinoma involving the skin and ducts and is manifested as nipple excoriation. The latter is recognized as a constellation of redness, warmth, and edema that often reflects tumor cell infiltration of dermal lymphatics of the breast; it should not be mistaken for a simple mastitis.

Nipple discharge may be associated with breast malignancy. Although milky discharge is seldom associated with a malignant diagnosis, patients with a clear or bloody nipple discharge require breast examination and mammography and often excisional biopsy of any suspicious area. Ductography and sometimes ductoscopy may be used to identify the inciting lesion. A bloody discharge is frequently caused by an intraductal papilloma.

Breast pain is common, especially as a premenstrual symptom in premenopausal women. But it may also be associated with an underlying malignancy. Patients with localized noncyclic breast pain should undergo breast examination and bilateral mammography. If these are normal, ultrasound or magnetic resonance imaging (MRI) may be used to exclude the small probability of a malignancy.

DIAGNOSIS

Diagnostic evaluation is generally triggered by suspicious findings on screening mammogram or detection of a palpable breast abnormality by the patient or health care provider. For both clinically occult and clinically apparent lesions, pathologic evaluation is mandatory to establish a diagnosis. Today, fine-needle aspiration and core needle biopsy have replaced incisional or excisional biopsy as the standard diagnostic measures. These procedures can be performed in the office in patients with suspicious palpable lesions. For women with nonpalpable lesions, biopsy guided by mammography, ultrasonography, or MRI is now standard. A recently published systematic review showed that stereotactic- or ultrasound-guided core needle biopsies are almost as accurate as and associated with lower complication rates than open surgical biopsy. These technologies permit an accurate diagnosis that can be followed by definitive treatment planning. It is axiomatic, however, that further evaluation must be undertaken for suspicious lesions that give an equivocal diagnosis after needle aspiration or core biopsy. Finally, bilateral breast imaging is always recommended to identify any unsuspected lesions in the contralateral breast that may also require evaluation.

Staging and Prognostic and Predictive Markers

Although staging originally reflected the clinical assessment of tumor size, nodal status, and evidence of metastatic disease, pathologic staging is the most accurate estimate of tumor involvement and prognosis. The staging system for breast cancer was revised in 2002 (Tables 204-2 and 204-3).

Most patients with breast cancer present with stage I or II disease in the absence of symptoms. In these patients, laboratory studies can be limited to blood counts, chemistry panel, and chest radiograph, and more extensive radiologic evaluation is not warranted because of low yield. In contrast, women with clinical evidence of stage III or IV disease should undergo more intensive evaluation of common sites for metastases, including lung, liver, and bone, through computed tomography and radionuclide scanning.

The two most important determinants of prognosis for early-stage breast cancer are pathological lymph node status and tumor size. Other factors that contribute to prognosis are the expression of the estrogen receptor-α (ER), progesterone receptor (PR), and HER2 proteins; these are conventionally measured by immunohistochemistry, although fluorescence in situ hybridization (FISH) for *HER2* gene amplification is also employed. Poor prognosis is associated with high lymph node burden, poor histologic grade, large tumor size, absence of ER and PR expression, and overexpression of HER2.

Recently, the focus has been on the development of predictive markers to guide selection of therapy. There are three established predictive markers for breast cancer—ER, PR, and HER2—and these should be routinely evaluated in every invasive cancer. Most tumors that express ER or PR, or both, are responsive to endocrine therapy, whereas those that lack ER and PR expression seldom respond to such therapy. Overexpression of the HER2 protein by immunohistochemistry or *HER2* gene amplification by FISH is associated with response to the HER2-targeted monoclonal antibody, trastuzumab, or the receptor tyrosine kinase inhibitor, lapatinib. Evidence that links expression of ER, PR, or HER2 to chemotherapy efficacy is equivocal.

Modern molecular techniques have provided further insight into molecular classification of breast cancer. Transcriptional profiling has suggested that breast cancers can be divided into at least five molecular subsets—normal mammary, luminal A and B, HER2, and basal. The luminal subtypes frequently express ER, but luminal A appears to be associated with a better

TABLE 204-2 STAGING OF BREAST CANCER: TNM SYSTEM

TUMOR SIZE: T (LARGEST DIAMETER)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis Tis (DCIS) Tis (LCIS) Tis (Paget's)	Carcinoma in situ Ductal carcinoma in situ Lobular carcinoma in situ Paget's disease of the nipple NOT associated with invasive carcinoma and/or carcinoma in situ (DCIS and/or LCIS) in the underlying breast parenchyma. Carcinomas in the breast parenchyma associated with Paget's disease are categorized based on the size and characteristics of the parenchymal disease, although the presence of Paget's disease should still be noted.
T1	Tumor ≤20 mm in greatest dimension
T1mi	Tumor ≤1 mm in greatest dimension
T1a	Tumor >1 mm but ≤5 mm in greatest dimension
T1b	Tumor >5 mm but ≤10 mm in greatest dimension
T1c	Tumor >10 mm but ≤20 mm in greatest dimension
T2	Tumor >20 mm but not ≤50 mm in greatest dimension
T3	Tumor >50 mm in greatest dimension
T4	Tumor of any size with direct extension to chest wall or skin (includes inflammatory carcinoma)
NODAL INVOLVEMENT: N (NODAL STATUS)	
NX	Regional lymph nodes cannot be assessed (e.g., previously removed, not removed)
N0	No regional lymph node metastases histologically
N1	Metastases to movable ipsilateral level I, II axillary lymph node(s)
N2	Metastases in ipsilateral level I, II axillary lymph nodes that are clinically fixed or matted; or in clinically detected* ipsilateral internal mammary nodes in the *absence* of clinically evident axillary lymph node metastases.
N3	Metastases in ipsilateral infraclavicular (level III axillary) lymph node(s) with or without level I, II axillary lymph node involvement; or in clinically detected* ipsilateral internal mammary lymph node(s) with clinically evident level I, II axillary lymph node metastases; or metastases in ipsilateral supraclavicular lymph node(s) with or without axillary or internal mammary lymph node involvement
N3a	Metastases in ipsilateral infraclavicular lymph node(s)
N3b	Metastases in ipsilateral internal mammary lymph node(s) and axillary lymph node(s)
N3c	Metastases in ipsilateral supraclavicular lymph node(s)
METASTASES: M	
M0	No clinical or radiographic evidence of distant metastases
cM0(i+)	No clinical or radiographic evidence of distant metastases, but deposits of molecularly or microscopically detected tumor cells in circulating blood, bone marrow, or other nonregional nodal tissue that are no larger than 0.2 mm in a patient without symptoms or signs of metastases
M1	Distant detectable metastases as determined by classic clinical and radiographic means and/or histologically proven larger than 0.2 mm

**Clinically detected* is defined as detected by imaging studies (excluding lymphoscintigraphy) or by clinical examination and having characteristics highly suspicious for malignancy or a presumed pathologic macrometastasis based on fine-needle biopsy with cytologic examination.

TABLE 204-3 TNM STAGE AND SURVIVAL

STAGE	TNM CATEGORY*	RECURRENCE FREE AT 10 YEARS (NO SYSTEMIC ADJUVANT THERAPY)
0	TisN0M0	98%
I	T1N0M0	80% (all stage I patients)
	T < 1 cm	90%
	T > 1-2 cm	80-90%
IIA	T0N1M0; T2N0M0	60-80%
IIA	T1N1M0	50-60%
IIB	T2 N1M0	5-10% worse than IIA and based on node status
IIB	T3N0M0	30-50%
IIIA	T0 or T1 or T2N2M0; or T3N1 or N2M0	10-40%
IIIB	T4N0 or N1 or N2M0	5-30%
IIIC	Any T, N3M0	15-20%
IV	Any T, any NM1	<5%

*See Table 204-2 for TNM definitions.

TABLE 204-4 CARCINOMA IN SITU: DUCTAL VERSUS LOBULAR

FEATURE	LOBULAR CARCINOMA IN SITU	DUCTAL CARCINOMA IN SITU
Age	Younger	Older
Palpable mass	No	Uncommon
Mammographic appearance	Not detected on mammography	Microcalcifications, mass
Immunophenotype	E-cadherin negative	E-cadherin positive
Usual manifestation	Incidental finding on breast biopsy	Microcalcifications on mammography or breast mass
Bilateral involvement	Common	Uncertain
Risk and site of subsequent breast cancer	25% risk for invasive breast cancer in either breast over remaining lifespan	At site of initial lesion; 0.5% risk/yr of invasive breast cancer in opposite breast
Prevention	Consider tamoxifen or raloxifene	Consider tamoxifen or raloxifene if estrogen receptor positive
Treatment	Yearly mammography and breast examination	Lumpectomy ± radiation; mastectomy for large or multifocal lesions

prognosis and higher likelihood of response to endocrine therapy than luminal B. The basal subtype is dominated by tumors that lack expression of ER, PR, and HER2—the so-called triple-negative breast cancer that lacks a readily identified molecular target. Multigene assays that evaluate these gene expression patterns are under investigation, and several multigene assays are available in clinical practice. One such assay, Oncotype Dx, may assist in the identification of women with early-stage steroid receptor–positive breast cancer who would benefit from the addition of chemotherapy to tamoxifen. A second assay, Mammaprint, may be useful to identify young women with breast cancer with poor prognosis. A number of other assays are under development, and both the Oncotype Dx and Mammaprint assays are the subject of large randomized trials to refine the conditions for their optimal use.

TREATMENT

Rx

Local Treatment of Early-Stage Breast Cancer

In Situ Carcinoma

Thanks to heightened breast cancer awareness and use of screening mammography, in situ carcinomas now account for 20 to 25% of newly diagnosed cases of breast cancer (Table 204-4). Most of these are ductal carcinoma in situ (DCIS). These lesions are associated with about a 30% risk for subsequent invasive breast cancer in the same breast. The risk for metastatic breast cancer with a diagnosis of DCIS is extremely small. As a consequence, management decisions are centered on the involved breast, and axillary lymph node evaluation is not routinely performed. Total mastectomy, the traditional therapy, has a high likelihood of cure, but studies suggest that breast conservation is appropriate for many women with DCIS. The major contraindications include poor cosmesis, extensive disease, or patient preference. Several models have suggested that size and grade of lesion and surgical margin status are important determinants of local outcome. Excision to obtain tumor-free margins is critical. Careful mammographic examination of the specimen and postexcision mammography of the breast are crucial to confirm that the DCIS has been adequately excised. A large randomized trial showed that radiotherapy plus lumpectomy decreased the likelihood of in situ or invasive recurrence when compared with lumpectomy alone. Other data sets suggest that some women with favorable histology who are willing to undergo close surveillance are candidates for local excision alone. In addition, the use of tamoxifen for 5 years can reduce ipsilateral breast cancer recurrence and contralateral breast cancer diagnosis by about 50%.

Controversy continues over whether lobular carcinoma in situ (LCIS) is truly a malignant lesion. LCIS is usually an incidental finding on a breast biopsy done for other indications, and it appears to be associated with a 25% risk for development of invasive breast cancer in either breast. Women with LCIS are generally managed expectantly with regular breast examination and mammography. Bilateral total mastectomy is sometimes considered for women with LCIS who have other risk factors or extreme anxiety. Finally, these women are candidates for tamoxifen or raloxifene as a risk-reduction strategy based on the results of several large breast cancer chemoprevention trials.

Invasive Breast Cancer

Surgery

Although radical mastectomy (removal of the breast, axillary contents, and underlying chest musculature) was the mainstay for breast cancer treatment for many years, it is seldom performed today. Multiple randomized trials have consistently shown that breast conservation therapy (BCT) with lumpectomy plus radiotherapy provides identical survival rates to modified radical mastectomy (removal of the breast and lymph nodes) for women with stages I and II breast cancer. Medical contraindications to BCT include multifocal disease, previous radiotherapy, ongoing pregnancy that precludes the timely use of radiotherapy, poor cosmesis, and patient preference. Although the number of patients who receive BCT has increased substantially, there are wide geographic differences within the United States. Patients who undergo mastectomy should be counseled about the availability of a number of autologous tissue and implant options for reconstruction, either at the time of surgery or anytime thereafter.

Because the likelihood of distant micrometastatic spread is highly correlated with the number of pathologically involved axillary lymph nodes, axillary dissection has traditionally been used to provide prognostic information. A drive toward limiting axillary surgery to minimize the incidence of postoperative lymphedema (see later) has led to the development of sentinel node techniques. Here a radioactive tracer or blue dye or both are injected into the area around the primary breast tumor. The injected substance tracks rapidly to the dominant axillary lymph node—the sentinel node—that can be located and removed by the surgeon. If the sentinel node is tumor free, the remaining nodes are likely to be tumor free as well, and no further axillary surgery is required. Currently, women with palpable axillary nodes and those with a histologically involved sentinel node are counseled to undergo axillary dissection. For women with small tumors and a clinically negative axilla, large randomized trials of sentinel node management and traditional axillary dissection suggest similar outcomes.

Adjuvant Radiotherapy

Radiotherapy has been a cornerstone in BCT because women who undergo lumpectomy alone have a breast cancer recurrence rate of up to 40%, whereas the rate of recurrence is less than 10% with whole-breast radiotherapy. Attempts to identify women whose tumors are so favorable that radiotherapy can be withheld are ongoing. One large trial suggested that women older than 70 years with small ER-positive tumors who receive tamoxifen gain little with radiotherapy. Current research is also focused on the possibility that radiotherapy can be delivered safely and effectively to a smaller field (partial breast radiotherapy) or over a shorter period of time.

The role of postmastectomy radiotherapy continues to be a matter of debate. Based on the results of individual randomized trials as well as a meta-analysis suggesting a survival advantage, many radiation oncologists recommend postmastectomy radiation to women with more than three involved nodes and discuss its use for those with involvement of one to three nodes.

Adjuvant Systemic Therapy for Early Breast Cancer

Adjuvant systemic therapy is defined as the use of chemotherapy, endocrine therapy, or biological therapy, or a combination of these, after definitive

local therapy for early breast cancer. Its goal is to suppress or eradicate clinically occult micrometastases. Because current testing does not permit the definitive identification of the patient with micrometastases, recommendations for adjuvant systemic therapy are based on menopausal status, lymph node status, tumor size, and the extent of expression of the ER, PR, and HER2 proteins in breast cancer cells. The treatment algorithms that are currently used are the result of more than 50 years of clinical trials[1]; the results of these trials have been compiled in sequential overview analyses that have evaluated the worldwide experience with use of endocrine therapy and chemotherapy. These analyses have shown that adjuvant therapy results in a proportional reduction in risk of recurrence across all patients regardless of risk of recurrence; this implies that the absolute benefit of adjuvant systemic therapy is greatest for individuals with the greatest risk of recurrence. Tools to assist the clinician and patient to make decisions about the use of adjuvant therapy include guidelines based on evidence and expert consensus such as the National Comprehensive Care Network (NCCN) and St. Gallen conference guidelines, as well as web-based algorithms like Adjuvant Online (Table 204-5).

Adjuvant Endocrine Therapy

Tamoxifen (20 mg/day for 5 years) has been the most widely used endocrine therapy. It improves outcomes in women of all ages with ER- or PR-positive breast cancer. Its side-effect profile includes an increased risk for thromboembolic events and uterine cancer, especially in postmenopausal women, because of its estrogen agonist properties. Potential benefits include promotion of bone density and lowering of cholesterol. The effects of altered activity of the tamoxifen metabolizing enzyme, CYP2D6, by coadministration of pharmacologic inhibitors or single-nucleotide polymorphism variants in the *CYP2D6* gene on outcome with tamoxifen is an area of active research.

In recent years, the role of estrogen deprivation has been the subject of intense scrutiny—ovarian suppression or ablation for premenopausal women and aromatase inhibition for postmenopausal women. Ovarian ablation through surgery or radiotherapy is the oldest form of systemic therapy for breast cancer. More recent work has focused on the use of luteinizing hormone-releasing hormone (LHRH) agonists as a means of effecting a temporary and reversible ovarian suppression. Two large meta-analyses have sought to define the role of these approaches. A meta-analysis of trials addressing the efficacy of LHRH agonists in women with early-stage ER-positive breast cancer suggested the following: (1) monotherapy with LHRH agonist has significant activity; (2) the efficacy of LHRH monotherapy is similar to that of certain chemotherapy regimens; and (3) LHRH agonists appear to add benefit to adjuvant chemotherapy, especially in women younger than 40 years, who are less likely than older women to become postmenopausal as a consequence of adjuvant chemotherapy. Unfortunately, these trials did not routinely include tamoxifen because its value in premenopausal breast cancer was recognized only after accrual for these ovarian suppression studies was completed. In sum, however, it appears that ovarian ablation or suppression is a viable strategy for premenopausal women with steroid receptor–positive breast cancer.

In postmenopausal women, the primary source of estrogen is the conversion of androgens synthesized by the adrenal glands to estrogen through the activity of CYP19 or aromatase in peripheral tissues such as the mammary and adipose tissues. The aromatase inhibitors (anastrozole, letrozole, and exemestane) specifically inhibit this conversion, leading to further estrogen deprivation in older women. Randomized trials have shown that efficacy of aromatase inhibitors is similar or superior to that of tamoxifen and that these drugs have an acceptable side-effect profile.[3] Multiple trials have compared monotherapy with tamoxifen or aromatase inhibitor or sequential therapy; in aggregate, they suggest that the use of an aromatase inhibitor at some point should be considered for most postmenopausal women with steroid receptor–positive invasive breast cancer. Side effects include postmenopausal symptoms, osteoporosis and fractures, and arthralgias. Aromatase inhibitors are not useful for receptor-negative breast cancer, nor should they be used as monotherapy in premenopausal women. The simultaneous administration of tamoxifen plus aromatase inhibitor does not improve outcome over aromatase inhibitor alone. In premenopausal women, the combination of LHRH agonist plus aromatase inhibitor is no better than LHRH agonist plus tamoxifen in initial studies.

Duration of endocrine therapy appears to be quite important. Direct evidence suggests that at least 5 years of adjuvant endocrine therapy is associated with better outcomes than shorter periods. Whether longer durations will be more useful remains uncertain.

Adjuvant Anti-HER2 Therapy

Increased understanding of growth and death pathways of breast cancer has led to the identification of critical nonendocrine pathways that are potential targets for therapy. The transmembrane HER2/neu protein is overexpressed in about 20% of breast cancers, generally because of gene amplification. The efficacy and safety of the monoclonal antibody, trastuzumab, in the treatment of women with HER-overexpressing metastatic breast cancer laid the foundation for several adjuvant trials that in aggregate showed that the addition of 1 year of trastuzumab to chemotherapy reduced the risk for recurrence by about 50% in women with high-risk early breast cancer. Thus, use of trastuzumab is considered for many women with HER2-positive tumors. Important questions remain regarding long-term risks and benefits, optimal duration of therapy, use of trastuzumab in the absence of chemotherapy, and role of other anti-HER2 agents such as lapatinib in addition to or in place of trastuzumab.

TABLE 204-5 ADJUVANT TREATMENT GUIDELINES FOR PATIENTS WITH EARLY-STAGE INVASIVE BREAST CANCER*

PATIENT GROUP*	TREATMENT
FAVORABLE HISTOLOGY (TUBULAR OR COLLOID)	
ER- and/or PR-Positive Breast Cancer	
<1 cm	No adjuvant therapy
1-2.9 cm	Consider adjuvant hormonal therapy†
≥3 cm or node-positive	Adjuvant hormonal therapy ± adjuvant chemotherapy†
ER- and PR-Negative Breast Cancer	
<1 cm	No adjuvant therapy
1-2.9 cm	Consider adjuvant chemotherapy
≥3 cm or node-positive	Adjuvant chemotherapy
HORMONE RECEPTOR–POSITIVE (ER- AND/OR PR-POSITIVE) BREAST CANCER	
Lymph Nodes Negative	
≤0.5 cm	No adjuvant therapy
0.6-1.0 cm well differentiated and no unfavorable features‡	Consider adjuvant hormonal therapy
0.6-1.0 cm moderate or poorly differentiated or unfavorable features	Adjuvant hormonal therapy ± adjuvant chemotherapy
>1 cm	Adjuvant hormonal therapy ± adjuvant chemotherapy
Lymph Nodes Positive	
	Adjuvant hormonal therapy + adjuvant chemotherapy
HORMONE RECEPTOR–NEGATIVE (ER- AND PR-NEGATIVE) BREAST CANCER	
≤0.5 cm	No adjuvant therapy
0.6-1.0 cm	Consider chemotherapy
>1 cm or lymph-node positive	Adjuvant chemotherapy
HER2 POSITIVE	
	Trastuzumab should be added to the suggested treatment above for all node-positive patients; trastuzumab not recommended for tumors ≤1 cm for most node-negative patients; for tumors >1 cm, trastuzumab should be considered for most patients

*Data are insufficient to make chemotherapy recommendations for patients 70 years and older. Treatment should be individualized for these patients based on life expectancy and comorbidity.
†In ER-positive or PR-positive patients, decisions regarding the added value of chemotherapy in addition to hormonal therapy alone can be aided by accurately assessing the added value of chemotherapy in individual patients using a web-based model: *www.adjuvantonline.com* or Oncotype Dx assay.
‡Unfavorable characteristics include high-grade tumor, blood vessel or lymphatic invasion by tumor, and high tumor proliferation rate (high S phase by flow cytometry or high Ki-67 value by immunohistochemistry) or HER2-positive status.
ER = estrogen receptor; PR = progesterone receptor.
Modified from National Comprehensive Cancer Network Guidelines. Available at www.nccn.org.

Adjuvant Chemotherapy

Individual trials and the Early Breast Cancer Trialists Collaborative Group meta-analysis have shown the benefit of adjuvant chemotherapy. Benefit varies by age and nodal status such that, in the meta-analysis, the absolute benefit is greatest in women younger than 50 years, in whom 15-year breast cancer mortality decreased from 42% to 32%, whereas it decreased from 50% to 47% for women aged 50 to 69 years.

These trials have established several principles that guide chemotherapy use. Combination therapy appears to be more effective than single-agent chemotherapy. Effective agents include anthracyclines, taxanes, antimetabolites, and cyclophosphamide.[4] Randomized trials have shown that 3 to 6

months of therapy is preferred over longer durations. Dose reduction below the standard level was associated with inferior outcome, but dose escalation through the use of colony-stimulating factors or autologous stem cell support led to excess toxicity without improved outcome. Regimens that use colony-stimulating factors to accelerate schedule of chemotherapy administration have been more successful.

Increased use of adjuvant chemotherapy and longer survival have led to concerns about toxicity. Acute side effects of therapy are nausea and vomiting, bone marrow suppression, and hair loss; all are reversible, and the first may be mitigated by the use of modern antiemetics. Careful use of colony-stimulating agents can minimize complications of neutropenia, but current evidence argues against the use of erythroid-stimulating agents for chemotherapy-induced anemia. Induction of menopause is a common concern for premenopausal women. Its likelihood is related to the type and duration of chemotherapy and the age of the patient; most women older than 40 years will suffer drug-induced menopause. Doxorubicin-related cardiomyopathy is noted in about 1% of women who received doxorubicin-containing adjuvant chemotherapy. Use of standard adjuvant chemotherapy regimens results in a very small incidence of acute leukemia, but there is no evidence of increased incidence of other second tumors. Concerns about cognitive impairment are under evaluation.

Sequencing of Adjuvant Therapy

Women frequently receive several adjuvant interventions, including chemotherapy, radiotherapy, endocrine therapy, or anti-HER2 therapy. A logical question is how best to sequence these therapies. A randomized trial showed no clear difference between the sequence of chemotherapy to radiotherapy and radiotherapy followed by chemotherapy. Concurrent chemoradiotherapy requires that certain drugs be omitted during the radiotherapy to limit toxicity. A common algorithm is surgery followed by chemotherapy followed by radiotherapy. Radiotherapy can be safely administered with endocrine or anti-HER2 therapy.

Because a large randomized trial showed that concurrent chemotherapy plus tamoxifen led to worse outcome than chemotherapy followed by tamoxifen, most practitioners delay the administration of endocrine therapy until after completion of chemotherapy. Conversely, the benefit of trastuzumab appears to be greater when it is coadministered with taxane chemotherapy rather than following completion of taxane.

A number of trials have tested the concept that administration of systemic therapy before primary surgery would improve outcome over the standard sequence of surgery followed by systemic therapy. Together they suggest that, compared with adjuvant therapy, preoperative (also termed *neoadjuvant*) systemic therapy improves the rate of breast conservation but does not enhance disease-free or overall survival. The possibility that preoperative therapy can provide an in vivo assessment of tumor response to therapy is suggested by the correlation between the finding of a pathologic complete response (absence of invasive cancer in the surgical specimen) and long-term disease-free survival in some studies.

Follow-up of Early Breast Cancer Survivors

A critical question is how longitudinal medical follow-up should be conducted in women who have received appropriate local and systemic therapy for early breast cancer. Randomized trials have addressed the question of the value of serial laboratory and radiology testing as well as the role of primary care versus oncology specialist follow-up. On the basis of these and other studies, the American Society of Clinical Oncology has published evidence-based guidelines for follow-up of asymptomatic survivors of early-stage breast cancer. These guidelines are summarized in Table 204-6.

Stage III Breast Cancer

Locally advanced or inoperable stage III breast cancer accounts for about 10% of breast cancers. It is characterized by large primary tumor or fixed tumor or lymph nodes or neoplastic invasion of the skin or chest wall. Inflammatory breast cancer falls into this category. It has a clinical presentation of breast swelling, warmth, and erythema and may or may not be associated with a mass. Because as many as one third of women with locally advanced breast cancer have distant metastases at the time of diagnosis, many oncologists perform an evaluation for distant disease even in asymptomatic patients. Diagnosis is usually established by fine-needle aspiration or core biopsy, and combined-modality therapy is used to maximize control of local disease and distant micrometastases. Several months of preoperative endocrine therapy or chemotherapy results in tumor regression in most patients, thereby allowing definitive breast surgery of some type to be performed. Postoperative radiotherapy is generally employed to enhance local control, and some studies suggest that administration of further chemotherapy, hormone therapy, anti-HER2 therapy, or a combination thereof (depending on the features of the cancer) is then desirable. Multimodality therapy results in a 5-year disease-free survival rate of about 50%.

Stage IV or Metastatic Breast Cancer

Although seldom curable, advanced breast cancer is a highly treatable illness. Palliation or prevention of symptoms without excess toxicity is the primary goal of treatment. The median survival after diagnosis of metastatic breast cancer is 2 to 3 years, although the range is great, and a small cadre of long-term survivors has been described. Several recent clinical trials have documented small improvements in survival with some of the newer therapies.

Most women with metastatic breast cancer present with symptoms or abnormalities on physical examination. Less than 10% of women present with metastatic disease; rather advanced disease is normally diagnosed in women with a previous diagnosis of early breast cancer for which they received treatment. Common sites for metastases include bone, soft tissues, lung, liver, and brain. If metastatic disease is suspected, relevant hematologic, biochemical, and radiographic evaluation is indicated to assess location and severity of involvement. Because of the import of the diagnosis, pathologic confirmation is preferred. This permits verification of recurrent disease, exclusion of other diagnoses, and reassessment of biologic features such ER, PR, and HER2. Elevation of tumor markers (e.g., CA-2729, carcinoembryonic antigen) or the presence of circulating tumor cells is not diagnostic of recurrent disease, although these markers may be useful adjuncts in the assessment of the effects of therapy.

The role of surgery in metastatic breast cancer is limited. It is useful in certain circumstances such as resection of a chest wall nodule or solitary brain metastasis or orthopedic stabilization to treat or prevent a long-bone fracture. Radiotherapy is a mainstay in the management of advanced disease. It may be used at any time during the patient's course to treat localized disease such as chest wall recurrence, brain metastases, or painful bony metastases. Systemic treatment is the primary mode for management of disseminated disease. Key principles for selection of therapy include maximal palliation of symptoms, minimization of treatment-related toxicity, and prevention of disease complications. An algorithm for treatment of stage IV breast cancer is shown in Figure 204-1.

Endocrine Therapy

Endocrine therapy is preferred as the first intervention for metastatic breast cancer whenever feasible because of its favorable therapeutic index. Factors that support the use of endocrine therapy include the expression of hormone receptors, a long disease-free interval, and absence of symptoms or visceral disease. More than half of the women who meet these criteria respond to an initial course of hormone therapy, with a median response duration of 9 to 12 months. Length of response is a good predictor for the likelihood of response to a second course of endocrine therapy when the first agent fails. A second course of endocrine therapy is less likely to be successful, and the duration of response is shorter; again, duration of response predicts for likelihood of success with third-line therapy. Successful application of this algorithm can result in good disease control with little toxicity for several years in some women.

A number of types of hormone therapy are now available. These include the selective estrogen receptor modulator (SERM) tamoxifen; the selective estrogen receptor–degrading agent, fulvestrant; the aromatase inhibitors; and ovarian suppression by oophorectomy or LHRH agonists. Selection is usually made on the basis of efficacy, toxicity, and menopausal status. Serial

TABLE 204-6 FOLLOW-UP GUIDELINES FOR PATIENTS WITH EARLY-STAGE BREAST CANCER: AMERICAN SOCIETY OF CLINICAL ONCOLOGY GUIDELINES*

PROCEDURE OR TEST	FREQUENCY
History and physical examination* (eliciting of symptoms of breast cancer)	Every 3-6 mo for first 3 yr, every 6-12 mo for next yr, then yearly
MAMMOGRAPHY	
Mastectomy patients	Yearly
Lumpectomy patients	Yearly
Pelvic examination	Yearly
Breast self-examination	Monthly
Complete blood cell counts and chemistry studies	The literature does not support the use of these tests
Chest radiography, bone scans, PET scans, breast MRI, liver imaging, and tumor marker studies	Not recommended for routine follow-up in asymptomatic patients
Patient education regarding signs and symptoms of recurrence	Each visit

*Limited evaluation: assess for pain, dyspnea, weight loss, and other major changes in function. The limited examination should include an assessment of nodes, axillae, lumpectomy or mastectomy site, chest, and abdomen. Patients should be instructed regarding symptoms of recurrence.
Modified from Khatcheressian JL, Wolff AC, Smith TJ, et al. American Society of Clinical Oncology 2006 update of the breast cancer follow-up and management guidelines in the adjuvant setting. *J Clin Oncol.* 2006;24:5091-5097.

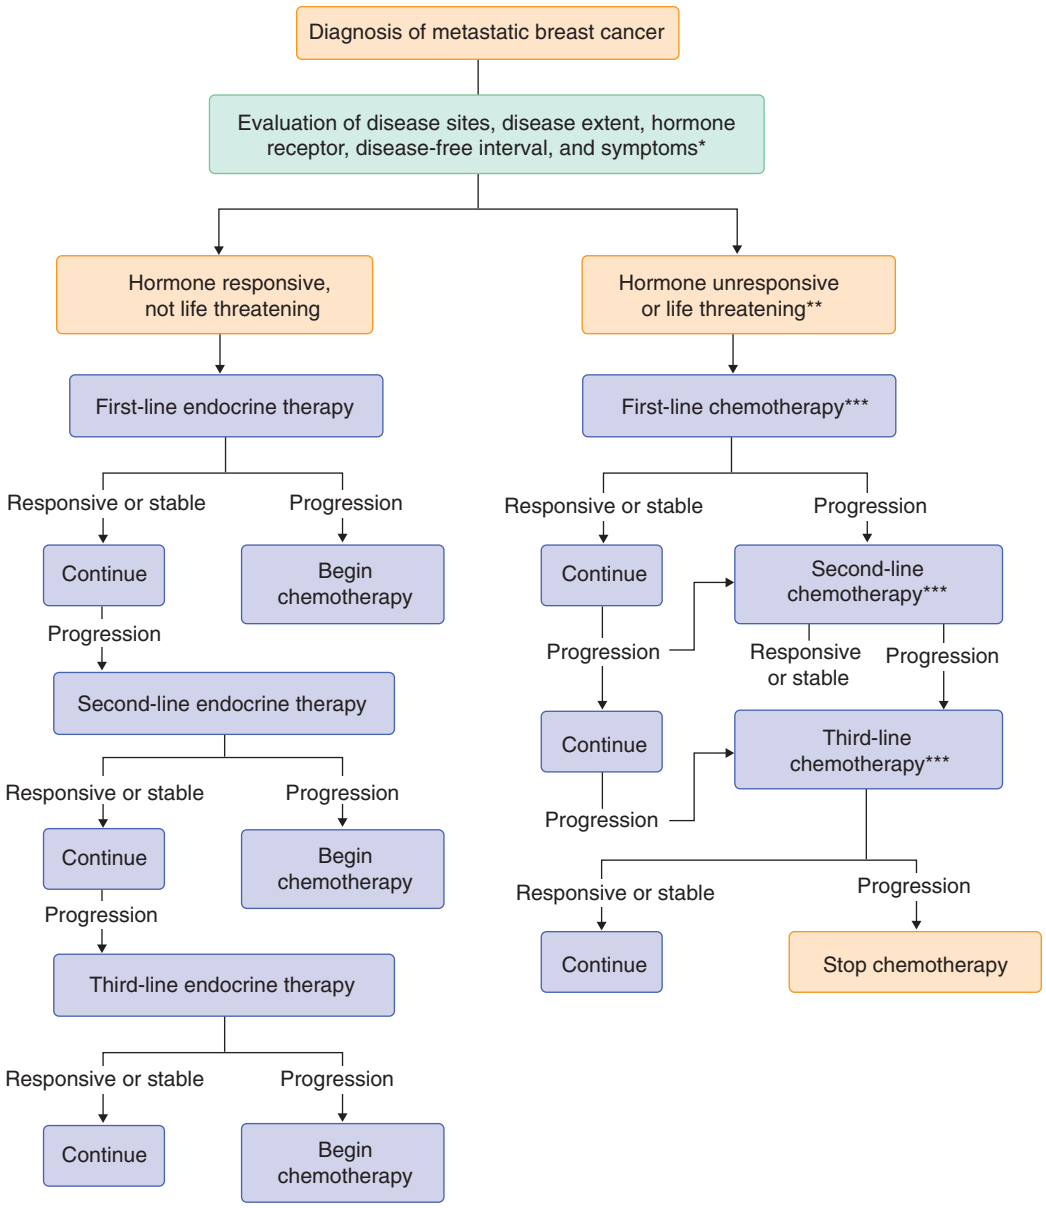

FIGURE 204-1. An algorithm used for the systemic treatment of stage IV breast cancer. *Consider role of bisphosphonate if bone involvement. **Consider integration of anti-HER2 therapy if tumor is HER2 overexpressing. ***Consider using bevacizumab.

administration of agents is the norm; combination therapy (with the possible exception of ovarian suppression plus tamoxifen) does not improve outcomes.

Several months of therapy are needed before the efficacy of a newly introduced endocrine therapy can be assessed. Patients and clinicians should be aware of the possibility of treatment-related tumor flare—a syndrome of worsening symptoms and increased circulating tumor markers—that can occur within the first few weeks of treatment. This response is usually of short duration and should not be confused with disease progression.

Chemotherapy

Most women with advanced breast cancer experience endocrine-unresponsive disease at some point and become candidates for palliative chemotherapy. Serial chemotherapy is the norm. Patients receive two to four cycles of therapy and then are evaluated for disease stabilization or improvement. Duration of therapy is variable for those who are responding to therapy. Several trials compared the approach of continuing therapy until time of disease progression with the approach of administering therapy, followed by a "drug holiday," with resumption of therapy at the time of disease progression. In sum, these studies suggest that survival is the same with these two approaches but that quality of life, as judged by the patients, is often better with continued therapy. Thus, decisions about continuation or cessation of a therapy are driven by perception of side effects and benefits by the patient and clinician.

Many active agents for breast cancer are now available. These include well-established drugs such as cyclophosphamide, doxorubicin, and methotrexate as well as newer agents like paclitaxel, docetaxel, vinorelbine, capecitabine, gemcitabine, carboplatin, ixabepilone, pegylated doxorubicin, and nanoalbumin-bound paclitaxel. All these agents are active individually and in combination. There is considerable debate about the value of combination therapy compared with sequential single-agent therapy for metastatic breast cancer. In addition, much attention has been focused on schedule of administration. For example, weekly paclitaxel regimens appear to be more effective and better tolerated than every-3-week regimens for many women. As with endocrine therapy, response rates and duration diminish with each successive change in therapy. As with early breast cancer, high-dose chemotherapy combined with autologous stem cell or bone marrow support has not shown benefit. A difficult question for patient and doctor is when to stop chemotherapy. No fixed rules exist, but many patients and physicians move to a program of supportive care if two successive chemotherapy regimens fail to produce a tumor response or disease stabilization.

Biological Agents

Enhanced understanding of breast cancer biology has resulted in the identification of new targets for therapy beyond the estrogen receptor pathway. The first agent brought into clinical practice was the monoclonal antibody, trastuzumab (Herceptin), which is active against the transmembrane HER2/neu protein. Administration of trastuzumab monotherapy to women with metastatic HER2-overexpressing breast cancer led to partial or complete tumor regression in about 30% of untreated women. Concurrent trastuzumab with paclitaxel increased response rate and duration and survival compared with paclitaxel alone for women with newly diagnosed metastatic breast cancer. Similar results were seen with concurrent administration of trastuzumab and doxorubicin, but this combination was associated with a 20% incidence of congestive heart failure. This unexpected finding demonstrates the need for careful evaluation of new biological agents as they enter the clinic. Dose and schedule of trastuzumab have been studied, and it appears that every-3-week administration is active with less patient inconvenience. One unanswered question has been how long to continue trastuzumab in

advanced breast cancer because discontinuation of a therapy at the time of progression has been the norm. A small provocative study suggests that patients who develop progressive disease while taking paclitaxel and trastuzumab fare better if they are changed to a regimen of trastuzumab and capecitabine rather than capecitabine alone.

Another molecular target of interest is the epidermal growth factor receptor (EGFR, or HER1). Small molecules that target the EGFR tyrosine kinase, gefitinib and erlotinib, or the monoclonal antibody against EGFR, cetuximab, have shown little activity as monotherapy in women with advanced breast cancer. But the dual HER1 and HER2 receptor inhibitor, lapatinib, has been shown to improve outcome for women with advanced HER2-overexpressing breast cancer when added to capecitabine. Further, clinical trials have suggested that addition of lapatinib to trastuzumab at the time of progression on trastuzumab gives superior results to lapatinib alone. Studies of both these agents suggest that their benefit is most marked in women whose tumors overexpress HER2 protein. Other agents that target the HER family members are in clinical testing.

Strategies to block tumor angiogenesis are also employed. One such agent is bevacizumab, a monoclonal antibody that targets the vascular endothelial growth factor. This agent has only modest activity as monotherapy in metastatic breast cancer, but its addition to taxane-based chemotherapy for women with newly diagnosed stage IV breast cancer appears to improve progression-free survival without a major impact on survival. Other studies suggest that it has similar effects when added to subsequent chemotherapy regimens as well. Its use in concert with standard adjuvant chemotherapies is under evaluation.

Multiple other targeted agents are also under development. Of recent interest are the poly-ADP-ribose polymerase (PARP) inhibitors. These small molecule inhibitors of DNA repair show particular activity in women with *BRCA* mutant breast cancer in early studies. In addition, early information suggests that coadministration of PARP inhibitor with chemotherapy improves outcomes over chemotherapy alone for women with stage IV triple-negative breast cancer. More definitive testing is in progress.

Supportive Care

Bone Health

Because palliation of symptoms and prevention of complications of metastatic disease are the primary goals of treatment for advanced breast cancer, careful attention to supportive care is vital. Bone is the most common site of metastasis in breast cancer, and bone disease can be a source of significant morbidity. Several studies have shown that regular administration of a bisphosphonate such as zoledronate or pamidronate in addition to endocrine therapy or chemotherapy can reduce pain and lower the incidence of skeletal complications of disease. Although such therapy is now the norm, several issues remain unaddressed, including the optimal treatment interval and duration of therapy.

Given the propensity of breast cancer therapy to lead to estrogen deprivation and osteopenia or osteoporosis (Chapter 251), the use of bisphosphonates in the adjuvant setting is under evaluation. Small trials have raised the possibility that bisphosphonates might prevent or delay the development of metastases in women with early-stage breast cancer, and the results of large randomized trials are awaited.

Postmenopausal Symptoms

Postmenopausal symptoms as a consequence of therapy or natural aging are common in breast cancer survivors. In general, hormone replacement therapy should be avoided in women with a history of breast cancer. A short course of treatment can be considered in patients with early-stage breast cancer who have truly disabling symptoms. Topical estrogens are considered for women with vaginal dryness that does not respond to lubricants. Vasomotor symptoms may be reduced with the use of certain antidepressants of the selective serotonin release inhibitor family. Multiple studies have failed to show consistent benefit from many alternative therapies.

Lymphedema

Lymphedema develops in the ipsilateral arm in up to 15% of women after treatment for early breast cancer. Its incidence is lower with sentinel lymph node procedures and meticulous radiotherapy planning. Prevention includes avoidance of trauma and possibly exercises. Early recognition of symptoms is key. Affected patients should be referred to specialists for consideration of treatment such as manual drainage or the use of compression stockings or pumps.

Special Circumstances

The risk for breast cancer is slightly increased during and just after pregnancy. Suspicious breast findings during pregnancy should be investigated vigorously. Surgical therapy for breast cancer can be safely performed after the first trimester of pregnancy, but radiotherapy should be delayed until after delivery. Current data suggest that certain adjuvant chemotherapy regimens can be safely administered in the second and third trimesters of pregnancy, and development is normal in children of mothers who receive this chemotherapy. Administration of antimetabolites should be avoided because of the potential for damage to the placenta. Initiation of endocrine therapy is generally delayed until after delivery. Pregnancy after a diagnosis of early breast cancer does not appear to increase the risk for metastatic disease in limited data sets. The major considerations for women contemplating pregnancy should be its timing with regard to endocrine therapy, which may require 5 or more years to complete, as well as the underlying risk for disease recurrence.

Men account for not more than 1% of breast cancer cases. Failure of the patient or health care provider to diagnose the disease means that it may be diagnosed at a later stage. Most breast cancers in men express ER, and treatment recommendations for these men are generally similar to those for postmenopausal women.

PREVENTION AND SCREENING

There is enormous interest in the development of breast cancer prevention strategies. Currently these include surgical, chemopreventive, and lifestyle modification approaches.

Prophylactic Mastectomy and Oophorectomy

Prophylactic mastectomy appears to reduce the risk of developing breast cancer by about 90% in individuals who are at high risk because of a strong family history or carriage of a germline *BRCA1* or *BRCA2* mutation. Prophylactic oophorectomy in *BRCA* mutation carriers has also been shown to decrease breast cancer incidence by about 50%, presumably because of reduction in ovarian steroids. It is critical that women who opt for prophylactic mastectomy be counseled about the possibility that cancer may develop in remnants of breast tissue that remain after prophylactic mastectomy.

Chemoprevention

The observation that adjuvant endocrine therapy with the SERM tamoxifen also decreased contralateral breast cancer led to evaluation of tamoxifen as a chemopreventive for well women who are at high risk for breast cancer. Meta-analysis of four randomized trials of tamoxifen versus placebo for high-risk women confirmed a 38% reduction in invasive breast cancer with tamoxifen. The largest trial, NSABP P01, randomized 13,388 high-risk women to receive either tamoxifen or placebo for 5 years. Risk factors used to determine eligibility were age ≥60 years, a diagnosis of LCIS, or age 35 to 59 years with a constellation of risk factors that, when combined, resulted in a 1.67% or greater risk for breast cancer within 5 years. This study showed a 50% decrease in the diagnosis of breast cancer across all age groups at a cost of increased risk for endometrial cancer and thromboembolic events in women older than 50 years. These data led to the approval of tamoxifen to reduce incidence of breast cancer in women at high risk as defined by the eligibility criteria for this prevention trial.

Other SERMs have been studied as chemopreventive agents. Two trials have documented the utility of raloxifene as a breast cancer risk-reduction strategy.■ In one trial, raloxifene administration reduced the incidence of breast cancer in postmenopausal women of average breast cancer risk and elevated cardiovascular risk. A second trial showed that raloxifene was as effective as tamoxifen in preventing invasive breast cancer in postmenopausal women at high risk for breast cancer. Raloxifene use was associated with fewer uterine cancers than tamoxifen but carries the same risk for thromboembolic events. It is approved by the U.S. Food and Drug Administration (FDA) for risk reduction in high-risk postmenopausal women. A vitamin A derivative, fenretinide, showed some impact as a chemopreventive agent for secondary prevention in premenopausal breast cancer survivors but has not found a place in routine practice. Finally, large epidemiologic studies have raised the possibility that aspirin or certain statins might also decrease breast cancer risk, but these agents have not been prospectively tested.

Lifestyle Modification

Prevention strategies that involve lifestyle alterations have been suggested. The Women's Health Initiative did not show a clear role for a low-fat diet as a means of breast cancer prevention. Regular exercise, especially during adolescence, may be associated with reduced breast cancer risk. By extrapolation from the epidemiologic studies mentioned previously, abstinence from alcohol might slightly reduce the risk for breast cancer.

Screening

Screening strategies for breast cancer have traditionally included the triad of breast self-examination (BSE), clinical breast examination (CBE) by a health

TABLE 204-7 BREAST CANCER SCREENING

TEST	ACS	USPSTF
Mammography		
40-49 yr	Annual	Insufficient evidence to support
>49 yr	Annual if healthy	Every 2 yr, 50-75 yr
Clinical breast examination	Every 3 yr, 20-39 yr Annually, ≥40 yr	Insufficient evidence to support
Breast self-examination	Optional	Not recommended

ACS = American Cancer Society; USPSTF = U.S. Preventive Services Task Force.

care professional, and screening mammography in well women. Although widely promulgated as an important component of early detection, two large randomized trials of conventional BSE versus observation failed to show any clinical advantage with BSE. As a result, many experts now promote breast awareness rather than regular BSE. The independent value of CBEs has not been rigorously assessed. Rather, it has been studied in conjunction with screening mammography, in which case the two interventions appear to decrease mortality from breast cancer by 25 to 30% in women older than 50 years. Considerable controversy continues over the value of screening mammography in women 40 to 50 years of age and those over 70 years of age as well as the optimal interval between mammograms for women aged 50 to 70 years. Currently, the American Cancer Society and the National Cancer Institute recommend annual screening mammography for women older than 40 years of age who are at standard risk for breast cancer. In contrast, the U.S. Preventive Services Task Force, advising the Department of Health and Human Services, recommended in 2009 that women between 40 and 50 years of age be counseled about the risks and benefits of screening mammography and that screening mammography can be used at 2-year intervals for women aged 50 to 75 years (Table 204-7). A study of digital versus conventional film screen mammography failed to show an overall advantage for digital mammography but suggest that digital mammography may be more useful for women with dense breasts.

The knowledge that screening mammography fails to diagnose about 10 to 15% of breast cancers has led to the evaluation of other imaging modalities. Of these, MRI is the most mature. MRI has been promoted as a useful screening tool for women at high risk by virtue of the *BRCA* mutation; indeed, the American Cancer Society has recommended consideration of screening MRI for women whose predicted risk for breast cancer exceeds 20%. MRI has been shown to detect breast cancer in the contralateral breast in 3% of women with a newly diagnosed breast cancer whose contralateral mammogram showed no abnormality. Use of MRI in the general population is limited by the fact that it is highly sensitive but lacks specificity. Insufficient information exists about other breast imaging modalities such as ultrasound and radionuclide imaging to support their use in screening asymptomatic women.

BENIGN BREAST LESIONS

Benign breast disease includes *mastalgia* (pain and tenderness), mastitis (including infectious and noninfectious inflammatory conditions), trauma, and benign tumors. In addition, mastalgia can be caused by extramammary conditions, such as myocardial ischemia, pneumonia, pleural irritation, esophageal spasm, costochondritis, rib fracture, and varicella-zoster virus (preceding the skin eruption). After these conditions have been ruled out, mastalgia is considered to be a benign condition that is self-limited. It can be cyclical or noncyclical in timing (where it is thought to be related to hormonal activity), and it may occur in postmenopausal women, even in the absence of hormone replacement therapy.

Mastitis is due to breast inflammation or infection, and it can occur in either nonlactating or lactating women. The typical presentation in nonlactating women is occurrence in their 40s with the acute onset of severe breast pain and tenderness followed by erythema and swelling that tends to be localized in the nipple-areolar area. The cause in most cases is considered to be rupture of dilated subareolar ducts that leads to an inflammatory response to leakage of intraductal contents into periductal tissue. Infection is difficult to rule out, and, in practice, patients are often treated with empirical antibiotics; if symptoms do not resolve within 7 to 10 days on antibiotics, ultrasound is required to rule out abscess. If the latter is found, incision and drainage are required. The most important differential diagnosis with mastitis is inflammatory carcinoma, as noted previously. Therefore, failure to improve with antibiotics or to find an abscess should lead to evaluation by a breast surgeon. Mastitis in lactating women is often due to infection caused by a break in the skin of the nipple or milk stasis. *Staphylococcal aureus, Staphylococcus albus,* and sometimes *Escherichia coli* or streptococci are the most common pathogens. Treatment requires antibiotics and milk removal.

Nonproliferative and Proliferative Benign Breast Lesions

Nonproliferative benign breast lesions include (1) inflammatory fat necrosis, which follows surgical or blunt trauma, and generally resolves spontaneously; (2) lymphocytic mastitis, which may be seen in diabetic patients; and (3) granulomatous mastitis, associated with foreign body reactions (e.g., silicone and paraffin for breast augmentation and reconstruction after cancer surgery), sarcoid, or certain infections. Other nonproliferative benign breast lesions appear as tumor-like processes, including (4) fibroadenoma, a very common (about 25% of women), usually solitary, sharply demarcated, smooth lesion in younger age groups; (5) phyllodes tumor (previously known as cystosarcoma phyllodes); (6) intraductal papilloma, solitary lesions that may be accompanied by bloody nipple discharge; (7) fibrocystic breast disease, which is now more appropriately called "fibrocystic changes" because it is observed clinically in up to 50% and histologically in 90% of women, composed of varying amounts of fibrosis and cysts sometimes associated with calcifications and inflammation; and (8) simple or complex cysts, which should be aspirated with ultrasound guidance and, when the fluid is not clear, sent for cytologic analysis.

Proliferative benign breast lesions include ductal or lobular hyperplasia; atypical hyperplasias are associated with increased risk for breast cancer.

Breast Cancer Risk

The increasing use of mammography has increased the frequency of breast biopsies, which, in turn, has increased the finding of benign breast lesions, the most common findings on biopsy. The benign breast lesions listed in the previous section encompass the general histologic spectrum of (1) nonproliferative lesions, (2) proliferative lesions without atypia, and (3) atypical hyperplasia, listed in ascending order of risk for breast cancer. A large number of retrospective and prospective studies have shown an overall relative risk for breast cancer of 1.5 to 1.6 for women with biopsy-proven benign breast disease compared with women in the general population. A study of 9087 women with all types of benign histology, followed for a median of 15 years at the Mayo Clinic, found that 707 of them developed breast cancers. Increased risk for cancer persisted for at least 25 years after the original biopsy. Of the three broad histologic categories, the relative risk for cancer development was 4.24 associated with atypia, 1.88 with proliferative changes without atypia, and 1.27 with nonproliferative lesions. It is not known if the finding of a benign breast lesion with atypical histology represents an actual precursor lesion for cancer or if it is only a marker for a general tendency to develop breast cancer. The observations that about half of breast cancers in these patients arise in the contralateral breast suggests the latter hypothesis.

GYNECOLOGIC CANCERS

MAURIE MARKMAN

CERVICAL CANCER

Worldwide there are more than 450,000 cases of invasive cancer of the cervix each year, leading to 250,000 deaths. Overall, this malignancy is the second most common cancer (after breast cancer) in women and the third most common cancer overall.

However, owing to the availability of a highly effective screening strategy (Pap smear), the incidence of invasive cervical cancer and deaths from this illness have decreased substantially in the developed world over the past several decades, with the majority of cases (and deaths) found in the developing world. For example, in the United States it is anticipated that there will be approximately 11,000 new cases accounting for 4000 deaths each year, making cancer of the cervix the 12th most common malignancy in women in this country.

EPIDEMIOLOGY

It is well established that essentially all cases of cervical cancer result from persistent infection (transmitted through sexual exposure) by oncogenic types of human papillomavirus (HPV; Chapter 381). Risk factors for cancer include early age of first sexual encounter; history of other sexually transmitted illnesses (Chapter 293), such as herpes simplex, chlamydia, and human immunodeficiency virus (HIV); multiple sexual partners and pregnancies; extended duration of oral contraceptive use; history of cigarette smoking; and chronic immunosuppression (e.g., renal transplantation, HIV).

Epidemiologic surveys demonstrate that as many as 50% of women will be exposed to HPV within 4 years of their initial sexual encounters. However, the large majority of individuals can spontaneously clear the infection, with subsequent cervical cytologic abnormalities being observed in only 5 to 10% of women experiencing an HPV infection.

The strongest association with cervical cancer involves HPV types 16 and 18, which together are implicated in approximately 70% of cases of the malignancy worldwide. An additional 30 types of HPV have been documented to be oncogenic, and another 70 have been described that are not known to have the potential to lead to cancer of the cervix. Besides types 16 and 18, other relatively common oncogenic HPV types that are responsible for varying percentages of cases in different regions of the world are 45, 31, 33, 52, 58, and 35.

PATHOBIOLOGY

It is important to note that the current level of understanding of the pathogenesis of cervical cancer from the time of viral infection to the development of invasive disease is greater than for any other human malignancy. Evidence suggests that once an oncogenic HPV successfully incorporates into the host genome (becoming a "persistent infection"), viral proteins (E6, E7) are produced that bind to and inactivate essential tumor suppressor proteins (RB1, TP53), leading to a cascade effect that ultimately results in a malignancy.

CLINICAL MANIFESTATIONS

Most cancers of the cervix are of squamous cell histology, although adenocarcinomas currently account for as many as one quarter of all cases of this malignancy. Other less common histologies include neuroendocrine and carcinoid tumors, lymphomas, and sarcomas.

The most common symptoms of invasive cervical cancer are abnormal vaginal or postcoital bleeding and vaginal discharge. These complaints are certainly not specific for cancer, but if they persist or another obvious cause is not evident, the diagnosis of cancer should be considered. A negative Pap test should not preclude further examination of the cervix as a possible site of malignancy in the appropriate clinical setting, because one half of women with documented invasive cervical cancer have a negative test.

With more advanced disease, pelvic pain and difficulty with both defecation and urination may be noted. Finally, with locally advanced cancer or metastatic spread, the patient may complain of back pain, leg swelling (from direct interference with blood flow to the region or development of deep venous thrombosis), or neuropathic pain (from nerve involvement).

DIAGNOSIS

Common diagnostic testing for cervical cancer includes physical examination (which may reveal a mass lesion or friable or necrotic tissue), laboratory testing (revealing possible renal dysfunction due to urethral obstruction), and radiographic imaging. In general, magnetic resonance imaging (MRI) is more sensitive than computed tomography in defining tumor size and extent of disease. Recent data have revealed the superiority of positron emission tomography in determining the presence or absence of nodal involvement in cancer of the cervix.

Screening for Preinvasive Disease

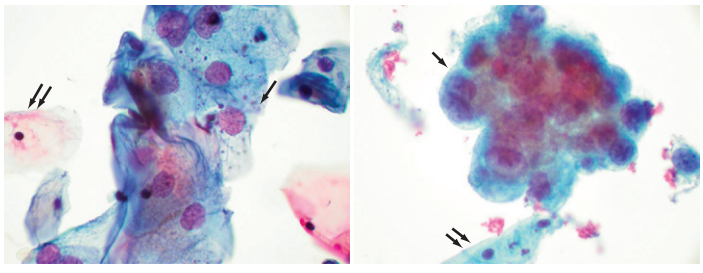
It would not be hyperbole to state that the initial development and subsequent routine use of Pap smears constitute one of the most important public health advances of the past 50 years (Fig. 205-1). It has long been recognized that preinvasive cervical abnormalities precede the development of invasive cancer by many years, permitting highly effective (essentially 100%, if correctly applied) and relatively nonmorbid local interventions.

Liquid-based cytologic testing procedures and HPV testing have improved both the sensitivity and the specificity of screening. However, the basic principle of screening remains the same: early discovery and removal of preinvasive lesions that, if left untreated, would have a substantial risk of developing into invasive cancer. The magnitude of this risk is highlighted by data revealing that as many as one third of documented, untreated carcinoma in situ abnormalities may progress to frank invasive cancer of the cervix over a 10-year period.

Patients with a concerning Pap smear result should be referred to undergo colposcopy and directed biopsies. Subsequent treatment and follow-up are based on the findings from this evaluation.

Recently revised guidelines from the American College of Obstetricians and Gynecologists for routine screening for cervical cancer are as follows:

- Screening should begin at age 21.
- Screening is recommended every 2 years for women aged 21 to 29.
- Either conventional or liquid-based cytology is acceptable.



A B

FIGURE 205-1. Cervical abnormalities on Pap smear. A, Low-grade squamous intraepithelial neoplasia. Note the group of mildly dysplastic cells with an increased nuclear-to-cytoplasmic ratio *(single arrow)* contrasted with a normal squamous epithelial cell *(double arrows)* (Papanicolaou stain, × 400). **B,** Cervical adenocarcinoma. Note the three-dimensional cluster of pleomorphic cells with a markedly increased nuclear-to-cytoplasmic ratio, dense nuclear chromatin, and macronucleoli *(single arrow)* contrasted with a normal squamous epithelial cell *(double arrows)* (Papanicolaou stain, × 400).

- Women 30 years of age and older with three consecutive negative results for intra-epithelial lesions can change to an every-3-year screening schedule.
- Women with any of the following risk factors may require more frequent screening: (1) HIV infection; (2) receiving immunosuppressive medication; (3) history of exposure to diethylstilbestrol in utero (see the section on vaginal cancer); (4) prior treatment for cervical intra-epithelial neoplasia (CIN) 2, CIN 3, or cancer.
- Women older than 65 to 70 years with three or more consecutive negative test results over the preceding 10 years can discontinue routine screening.
- Women who have had a total hysterectomy performed for a nonmalignant condition can discontinue routine screening.

TREATMENT

Localized Disease

Following evaluation for the extent of disease involvement, patients with localized cancer of the cervix can be managed with a variety of approaches, including (1) simple hysterectomy (if pretreatment clinical characteristics suggest the risk of lymph node involvement is very low), (2) radical hysterectomy (with removal of pelvic and para-aortic lymph nodes), (3) surgery plus external beam radiation, or (4) external beam radiation plus concurrent chemotherapy (so-called chemo-radiation).

Invasive Disease

Several randomized trials have revealed the superior outcome associated with radiation plus cisplatin-based chemotherapy, compared with radiation alone, in the management of locally advanced, invasive cervical cancer.[1] In patients with nonmetastatic, invasive cervical cancer, long-term disease-free survival is strongly influenced by a number of factors (most prominently, initial tumor stage) and ranges from as high as 95% (early-stage disease without lymphovascular space invasion) to less than 20% for stage IV cancer.

In the presence of metastatic cancer at diagnosis, or if the cancer has recurred following initial management, currently available treatment options provide quite modest palliative benefits. Cisplatin is the single most active antineoplastic agent in cancer of the cervix (20% objective response rate). Patients with an adequate baseline performance status that permits a more intensive approach may be treated with a cisplatin-based combination chemotherapy regimen.[1] Responses in this setting are generally limited in duration (3 to 4 months) and are more likely to occur in areas not previously radiated. In this difficult clinical setting, the limited potential for therapeutic benefit must be weighed against the risk of toxic effects that may negatively impact the quality of a patient's remaining life.

PREVENTION

Two recently licensed vaccines based on HPV types 16 and 18 are highly effective in reducing the risk of developing persistent HPV infection and type-specific cervical dysplasia *if administered before evidence of sexual exposure to the virus.*[2,3] In the large randomized trials conducted to obtain regulatory approval of these preparations, and in extensive post-marketing surveillance evaluations, few serious vaccine-related side effects (e.g., hypersensitivity reactions) have been documented.

There is no convincing evidence of the utility of HPV vaccination in an individual already infected with HPV. These data emphasize the importance of vaccination before an individual's first sexual contact.

Unanswered questions and unresolved issues regarding HPV vaccination include the following: (1) the duration of protective immunity following a single vaccination series (current evidence suggests that sufficient concentrations of antibody persist for more than 5 to 6 years in individuals receiving the complete vaccination regimen); (2) the utility of strategies consisting of fewer than three individual shots (initial vaccination followed by two booster injections) delivered over several months; (3) the benefit of approaches designed to increase the effectiveness of vaccination by adding other oncogenic types (in addition to 16 and 18); (4) the impact on cervical cancer prevention associated with the vaccination of males; and (5) cost, religious, and other societal objections to vaccine use (e.g., mandated vs. voluntary vaccination).

ENDOMETRIAL CANCER

Endometrial cancer is the most common female pelvic malignancy in the United States; approximately 40,000 new cases are diagnosed each year, resulting in almost 8000 deaths. Overall, endometrial cancer accounts for almost 50% of all female pelvic malignancies and is the fourth most common cancer type in women. The reported high incidence of endometrial cancer is likely due to several factors, including longer life expectancies, earlier diagnosis, and the reduced incidence of cervical cancer. Worldwide, endometrial cancer trails only cervical cancer as the leading cause of malignant disease in women.

EPIDEMIOLOGY

The major recognized risk factor for the development of endometrial cancer is estrogen exposure, either endogenous or exogenous. Case-control studies conducted more than 20 years ago demonstrated that women exposed to long-term unopposed estrogen have a 4- to 15-fold increased risk of developing this malignancy. In contrast to the impact of unopposed estrogens, the past use of oral contraceptives containing a progestin (either high or low potency) has been shown to reduce the risk for the development of endometrial cancer.

Other risk factors include obesity (an increased mass of fatty tissue is associated with greater aromatization of androstenedione to estrone), nulliparity, eating a "Western-type" (i.e., high-fat) diet, the documented presence of endometrial hyperplasia, a history of hereditary nonpolyposis colorectal cancer, and prior or current treatment with tamoxifen (used to treat or prevent breast cancer, leading to a 3- to 7-fold increased risk for this pelvic malignancy). There is also a documented greater risk of endometrial cancer in women with diabetes (3-fold higher) and in those with hypertension (1.5-fold higher), likely due to these conditions' association with obesity. This is the likely explanation for the "classic triad" frequently used to characterize the endometrial cancer patient: overweight, diabetic, and hypertensive.

For as many as 75% of all patients with endometrial cancer (type 1), it is possible to identify a clinical factor suggesting excessive estrogen exposure (e.g., replacement therapy, obesity). The malignancy in these individuals often begins as endometrial hyperplasia, is well differentiated (grade 1) and of low stage, and has a very favorable prognosis.

Conversely, 25% of patients with this cancer (type 2) have no evidence of excessive estrogen exposure. These women frequently have an atrophic endometrium, the malignancies are of higher grade (grade 3 or undifferentiated) and stage, and their overall survival is poorer.

CLINICAL MANIFESTATIONS

Endometrial cancer is seen predominantly in the postmenopausal population, although in some series as many as one quarter of patients were premenopausal. It is uncommon for endometrial cancer to be diagnosed in a woman younger than 40 years.

The most common presenting symptom is postmenopausal bleeding (80 to 90% of cases), which should lead to a formal gynecologic evaluation (with biopsy). In more advanced cases, pelvic pressure or pain may be noted.

Approximately 90 to 95% of all endometrial cancers are adenocarcinomas. Fortunately, most tumors are low grade and stage I (80%) at diagnosis. However, as previously noted, patients with type 2 endometrial cancer are more likely to present with both a higher-grade and higher-stage malignancy.

Endometrial sarcomas (e.g., uterine leiomyosarcomas) are far less common than adenocarcinomas and have a different natural history. Even in the setting of stage I cancer, as many as half of these patients experience subsequent disease progression.

Uterine carcinosarcomas (mixed müllerian tumors) are another uncommon subtype that frequently demonstrates rapid progression. Despite its name, this tumor is currently considered to be a poorly differentiated epithelial malignancy rather than a true sarcoma.

TREATMENT

Surgical resection is the standard initial treatment for the large majority of women with endometrial cancer, and it is generally considered sufficient therapy for patients with early-stage, low-grade disease. The role of routine postoperative adjuvant therapy is controversial. There is evidence that pelvic radiation decreases the risk of local recurrence, but the impact on overall survival is uncertain.

In patients with disease documented in the upper abdomen (stage III), phase III trial data have revealed the superiority of combination chemotherapy compared with whole abdominal radiotherapy.[4] Despite these data, many oncologists favor a multimodality strategy in the management of high-risk

endometrial cancer patients (e.g., those with completely surgically resected disease in the upper abdomen or locally advanced grade 3 cancer), which might include several cycles of systemic chemotherapy followed by pelvic radiotherapy (to reduce the chance of relapse in this region). Unfortunately, phase III trial data are not available to definitively prove the benefits of this approach. Vaginal brachytherapy appears to be as good as external beam radiotherapy.[5]

A number of chemotherapeutic agents have demonstrated biologic activity (objective response rates >20%) in endometrial cancer, including doxorubicin, paclitaxel, cisplatin, and carboplatin. In metastatic disease or in the setting of recurrent cancer, such agents are frequently administered as a combination strategy (e.g., carboplatin plus paclitaxel, cisplatin plus doxorubicin plus paclitaxel), and response rates greater than 50% have been reported. An optimal treatment regimen in this setting has not been defined.[6]

It is also known that patients with low-grade advanced or metastatic endometrial cancer may exhibit clinically meaningful and prolonged responses to high doses of progestational agents (anticipated 15 to 30% response rate). There is no evidence of an added benefit obtained by combining chemotherapy with hormonal therapy in patients with endometrial cancer, and high-grade tumors rarely (if ever) respond to progestational drugs.

Overall 5-year survival in patients with endometrial cancer varies, based on tumor stage. It ranges from greater than 80% for stage I cancer to approximately 25% for individuals who present with metastatic disease. Other factors that influence survival include patient age, evidence of vascular invasion, hormone receptor status (the presence of which suggests a more indolent clinical course), tumor grade, and histologic subtype (papillary, serous, and clear cell morphology being associated with poorer outcomes).

Management of both endometrial sarcoma and carcinosarcoma includes surgical staging and frequently an attempt at maximal surgical cytoreduction. Owing to the substantial risk of recurrence, adjuvant radiation and/or chemotherapy may be employed, but the utility of such treatment is uncertain. Chemotherapy of metastatic disease may prolong survival and favorably impact cancer-related symptoms.

EPITHELIAL OVARIAN CANCER

Epithelial ovarian cancer is the sixth most common cancer in women in the United States, accounting for approximately one quarter of all female pelvic malignancies. However, far more significant than its incidence is the disturbing fact that the majority of women (>70%) initially present with advanced cancer, and overall survival is inferior to that observed in other female pelvic malignancies.

EPIDEMIOLOGY

In rather striking contrast to cancers of the endometrium and cervix, there is no unifying hypothesis or etiologic factor that defines either the epidemiology or the risk of developing this malignancy. Perhaps the most widely accepted theory is that carcinogenesis is initiated during the normal process of damage and repair associated with a woman's monthly ovulatory cycle. This hypothesis is supported by population-based data revealing a lower incidence of ovarian cancer in women with a history of multiple pregnancies, lactation, extended use of oral contraceptives, and late menarche or early menopause. Each of these clinical features is associated with fewer lifetime ovulatory cycles. Conversely, women with a history of infertility, early menarche, or late menopause have a statistically increased risk of experiencing this malignancy.

Overall, an individual woman has a 1 in 70 lifetime risk for the development of ovarian cancer. The single well-established risk factor for ovarian cancer is a family history of either ovarian or early-onset breast cancer, which appears to account for approximately 5 to 15% of all cases of the malignancy. Existing data reveal that the large majority of women with such a family history have either a *BRCA1* or *BRCA2* mutation, which results in a lifetime ovarian cancer risk of 40 to 50% or 10 to 20%, respectively.

CLINICAL MANIFESTATIONS

The large majority of epithelial ovarian cancers are adenocarcinomas. Until recently, the specific ovarian histologic subtypes were not thought to have major prognostic relevance beyond that identified by tumor grade, but it has become evident that both mucinous and clear cell cancers respond poorly to standard ovarian cancer chemotherapy and have a much worse prognosis (when found in an advanced stage) compared with the more common papillary, serous, or endometrioid types.

Unfortunately, symptoms of ovarian cancer are quite nonspecific (abdominal bloating, discomfort, and pain; loss of appetite; early satiety; fatigue) and in the large majority of cases are an indication of advanced disease. Many women present with abdominal fullness and early satiety due to ascites and omental tumor implants. Ascites is commonly observed in patients with advanced disease. There is no evidence that any particular symptom or symptom complex is more suggestive of ovarian cancer in contrast to other equally (or more) common conditions that may be the cause of the reported complaints.

TREATMENT

Rx

Standard treatment of suspected or documented epithelial ovarian cancer includes surgical staging and a reasonably aggressive attempt to resect all macroscopic disease (including disease present in the upper abdomen) before the administration of cytotoxic chemotherapy. Extensive published retrospective experience supports the utility of this basic management approach, with superior outcomes anticipated for women who initiate chemotherapy with small-volume macroscopic or only microscopic cancer.

However, it is relevant to note the complete absence of evidence-based data from randomized, controlled trials documenting the superiority of surgery followed by chemotherapy compared with a primary chemotherapy approach (after histologic confirmation of malignant disease) in the treatment of stage III or IV epithelial ovarian cancer. A recently reported international phase III trial demonstrated equivalent survival and reduced morbidity for individuals managed by primary chemotherapy followed by an attempt at surgical resection compared with "standard" cytoreductive surgery followed by chemotherapy.[7] This provides important support for the concept that in certain settings it may be most appropriate for initial treatment to focus on cytotoxic drug delivery.

Ovarian cancer is a highly chemotherapy-sensitive malignancy, with major objective response rates to combination platinum-taxane chemotherapy exceeding 70 to 80%.[8] Prolonged disease-free survival (>5 years) is a realistic possibility for a minority of women who present with advanced (stage III and IV) disease. In women with small-volume residual intraperitoneal disease following surgical cytoreduction, direct delivery of cisplatin into the peritoneal cavity has been shown to improve survival in several randomized trials.

Unfortunately, the majority of responding patients ultimately experience a relapse of the malignancy. Although a number of second-line treatment approaches have been shown to favorably impact symptoms of recurrent disease and improve overall survival, there is no evidence that any such approach can cure the malignancy.

There may also be a role for secondary cytoreductive surgery at the time of documented recurrence of ovarian cancer. In general, patients who have experienced relatively long disease-free intervals (>12 months) following completion of the primary treatment program are the best candidates for surgery designed to remove all visible macroscopic cancer before the initiation of second-line chemotherapy.

It is important to note that carefully considered surgical procedures designed to palliate distressing cancer-related symptoms (e.g., colostomy for large bowel obstruction) may be reasonable therapeutic options, even in the setting of progressive cancer. External beam radiation may also play an important role in the palliation of painful masses in the setting of chemotherapy-resistant disease. Despite encouraging early results, the intraperitoneal administration of chemotherapy has not been incorporated into the mainstream management of advanced ovarian cancer.

PREVENTION

Currently, there is no indication that any screening strategy (e.g., tumor markers such as CA-125, radiographic imaging) can detect recurrent[9] or "early-stage" ovarian cancer, although several such approaches have been proposed. Although it may be tempting to suggest that women at high risk (those with known genetic abnormalities) for the development of ovarian cancer may benefit from some form of routine screening (biomarker or imaging), it must be emphasized that no valid data support the utility of such an approach.

For women with a strong family history of ovarian cancer, particularly those documented to have a *BRCA1* or *BRCA2* genetic abnormality, available data support the conclusion that bilateral oophorectomies can reduce the risk of developing the malignancy by more than 80%. However, the actual extent of the absolute reduction in lifetime risk remains uncertain, because most series have followed individuals for less than 10 years following this cancer prevention surgery. For an individual woman with the appropriate genetic background who is considering undergoing such surgery, it is important to consider the negative aspects of this approach, including infertility, potentially distressing symptoms of early menopause, and the risk of accelerated bone loss.

NONEPITHELIAL OVARIAN MALIGNANCIES

Germ Cell Tumors of the Ovary

Ovarian germ cell cancers are uncommon malignancies observed in adolescent girls and young women. Like their male germ cell counterparts (Chapter 206), these malignances are extremely chemosensitive and have a high cure rate, even if discovered at an advanced stage. Both the diagnosis and the treatment of ovarian germ cell tumors are aided by the presence of two sensitive serum markers (human gonadotropin and α-fetoprotein).

Standard management of ovarian germ cell tumors includes surgical staging and an attempt to remove all gross macroscopic cancer (in the presence of metastatic spread). The majority of ovarian germ cell tumors are unilateral at presentation, permitting the performance of a salpingo-oophorectomy on the involved side and potentially preserving fertility in this young patient population.

Early-stage dysgerminomas can be managed with observation following surgical staging; less than 25% of such patients will experience a relapse. For more advanced disease, chemotherapy is indicated. However, the large majority of nondysgerminous germ cell tumors require chemotherapy because of the high recurrence rate (80% in stage I disease).

Stromal Ovarian Tumors

Granulosa cell and Sertoli-Leydig tumors are uncommon ovarian tumors characterized by being generally localized at presentation and exhibiting long natural histories, even when metastatic spread is documented. In contrast to epithelial ovarian cancer and germ cell tumors, this group of malignancies exhibits modest responsiveness to cytotoxic chemotherapy, which is usually employed only when disease progression has been documented.

VULVAR CANCER

Primary vulvar cancers account for less than 5% of cancers involving the female reproductive tract. As with cervical cancer, HPV has been strongly implicated in the pathogenesis of this malignancy (HPV DNA documented in 70 to 80% of cases).

The majority of patients are symptomatic at presentation (pain, local irritation, pruritus), and these complaints have commonly (>80% of cases) been present for more than 6 months before diagnosis. Most vulvar cancers are of squamous cell histology (Fig. 205-2), but malignant melanoma is also observed in this region.

Standard treatment is surgical excision of the primary tumor and dissection of inguinal lymph nodes. The risk of tumor recurrence is related to the size and extent of tumor involvement, the ability of the surgeon to achieve adequate surgical margins, and the documented presence of metastatic cancer in the inguinal nodes. With advanced local disease, concurrent external beam radiation and chemotherapy are generally employed. There is little evidence for the effectiveness of cytotoxic antineoplastic drugs in the setting of metastatic vulvar cancer.

FIGURE 205-2. Vulvar cancer. Invasive squamous cell carcinoma of the vulva.

VAGINAL CANCER

Vaginal cancers are uncommon malignancies associated with prior persistent HPV infection, and they are generally seen in an elderly population (older than 60 years). The large majority of primary cancers in this region are of squamous cell histology (80 to 90% of cases). Melanomas and sarcomas can also originate at this site.

Women who have undergone successful treatment for cervical cancer have an increased risk for the development of vaginal cancer. Although mainly of historical interest, there is a well-recognized association between in utero exposure to diethylstilbestrol and the development of very rare clear cell vaginal cancer.

The major presenting symptom is vaginal bleeding. Dysuria and vaginal discharge are also noted. In patients with advanced disease, pelvic pain is frequently described.

Depending on the clinical circumstances, standard treatment of vaginal cancers may focus on either radiation or surgical resection. Combined chemo-radiation therapy may be employed in locally advanced disease, but the overall experience with this strategy is limited. In a patient whose performance status is adequate, systemic chemotherapy may provide a modest level of benefit in recurrent or metastatic disease.

UTERINE FIBROIDS

Though not a malignancy, it is appropriate to discuss the management of uterine fibroids in this chapter because this condition is the most common female pelvic tumor (70 to 80% incidence in the female population by age 50). During the reproductive years, the incidence of fibroids may be as high as 40%.

The majority of fibroids are asymptomatic. When present, symptoms can range from mild inconvenience to heavy bleeding and pelvic pressure and pain.

In the past, the most common treatment was surgical removal of the fibroid or of the uterus itself. This procedure can be performed during laparotomy or through less invasive laparoscopic surgery. Over the years, a variety of invasive strategies have been introduced into routine medical practice for the treatment of symptomatic uterine fibroids, including uterine artery embolization, transvaginal temporary uterine artery occlusion, and MRI-guided focused ultrasound.

Noninterventional, hormonally based approaches (e.g., antiprogestins such as mifepristone) have been examined in the management of uterine fibroids. Although they are effective in relieving symptoms, these strategies are potentially limited by long-term drug-related side effects. However, these agents are clinically helpful in reducing the size of fibroids, decreasing dysfunctional uterine bleeding and pain, and improving overall quality of life.

TESTICULAR CANCER

LAWRENCE H. EINHORN

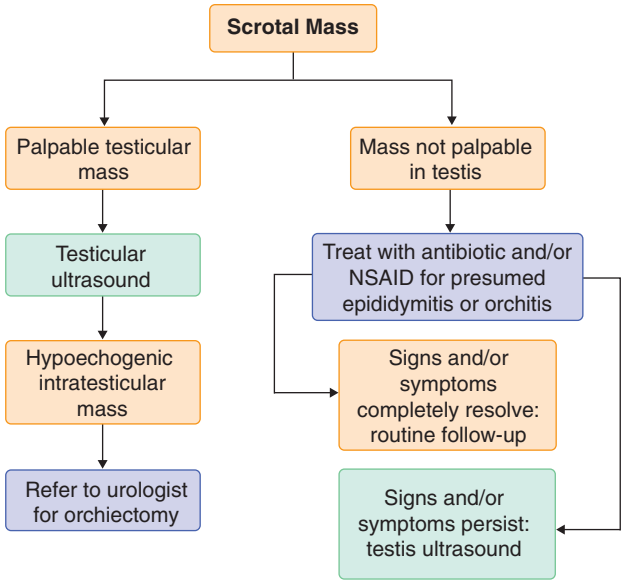

FIGURE 206-1. Management of a scrotal mass. NSAID = nonsteroidal anti-inflammatory drug.

EPIDEMIOLOGY

Testicular tumors are relatively uncommon and account for only 1% of male malignancies in the United States. The highest worldwide incidence occurs in Scandinavian countries; by contrast, testicular cancer is rare in African Americans and Asian Americans. The primary age group is 15 to 35 years for nonseminomatous tumors and a decade older for seminomas.

Male patients with a history of cryptorchidism have a 10- to 40-fold increased risk for the development of testicular cancer. The normally descended testis in these men is also at higher risk, suggesting a dysgenetic abnormality.

PATHOBIOLOGY

More than 95% of tumors of the testis originate from germ cells. Germ cell tumors can be seminomas or nonseminomatous germ cell tumors. Seminomas are more likely to be confined to the testis (stage I) and are exquisitely sensitive to radiation therapy. Pure seminomas never have elevated serum α-fetoprotein (AFP) levels. Nonseminomatous germ cell tumors consist of embryonal cell carcinomas, choriocarcinomas, yolk sac tumors, or teratomas, alone or mixed with other elements. Teratomas do not secrete human chorionic gonadotropin (HCG) or AFP and do not usually metastasize; they grow by local extension and are completely resistant to radiation therapy and chemotherapy.

Most germ cell testicular cancers in adults are associated with the cytogenetic abnormality i12p—an isochromosome of the short arm of chromosome 12—which is a highly specific finding in germ cell tumors. Sertoli cell tumors, Leydig cell tumors, and lymphomas are the most common non–germ cell tumors. In men older than 60 years, most tumors are non-Hodgkin's lymphoma (Chapter 191), with a predilection for bilateral involvement.

CLINICAL MANIFESTATIONS

Most patients with testicular cancer are initially evaluated because of testicular pain or because of a mass in or enlargement of one testis. Others are asymptomatic, and the cancer is first detected during a routine physical examination. Less commonly, the diagnosis is made during an evaluation for infertility, in part because testicular cancer can cause oligospermia.

Metastatic spread is either lymphatic or hematogenous. Lymphatic metastases usually go initially to the ipsilateral retroperitoneal lymph nodes, where they may be associated with flank pain. Lymphatic metastases may continue in a superior direction to the posterior mediastinum and eventually to the left supraclavicular lymph nodes. A large retroperitoneal mass or a supraclavicular lymph node may be palpable on physical examination. Hematogenous spread usually occurs first to the pulmonary parenchyma bilaterally. Pulmonary symptoms such as chest pain, shortness of breath, dyspnea on exertion, coughing, or hemoptysis are seen only with extensive pulmonary metastases. Other sites of hematogenous spread include the liver, bone, or brain. Significant elevation of the serum HCG level may produce gynecomastia.

DIAGNOSIS

Patients with a palpable mass in the testis should be suspected of having testicular cancer, especially if there is a history of cryptorchidism. Other causes of testicular and scrotal abnormalities may be included in the differential diagnosis. Acute pain in the testis suggests torsion. Painful enlargement may be due to a hydrocele, which may be caused by an underlying primary testicular malignancy. Pain and tenderness adjacent to the testis may be due to epididymitis or a varicocele. Tenderness of the testis itself on physical examination may reflect orchitis. However, an underlying neoplasm should always be considered.

Any testicular symptoms, including pain or a suspected mass, require evaluation. Testicular ultrasound is the test of choice in all suspicious cases. A hypoechogenic mass within the testis must be presumed to be testicular cancer and requires referral to a urologist (Fig. 206-1).

When orchiectomy reveals the diagnosis of testicular cancer, a staging evaluation is performed to determine the extent of disease and appropriate therapy. Clinical stage I disease is confined to the testis; stage II disease reflects spread to the retroperitoneal lymph nodes; and stage III is supradiaphragmatic disease, with either nodal metastases to the posterior mediastinum or supraclavicular region or hematogenous spread, especially to the lungs.

In addition to a full history and physical examination, serum HCG and AFP levels should be determined. Because the serum half-life is 1 day for HCG and 5 days for AFP, an AFP level of 1000 may take more than a month to normalize after orchiectomy, even if the tumor has been completely removed. Imaging studies to define the extent of disease include abdominal and pelvic computed tomography (CT) and a chest radiograph. If the chest radiograph does not show pulmonary metastases, a chest CT scan should be performed. Bone scans and head CT scans can be reserved for patients with symptoms suggestive of osseous and central nervous system metastases, respectively.

PREVENTION AND TREATMENT

A careful testicular examination is a mandatory part of the physical examination in men, especially young men (Chapter 14), and is the key means of detecting tumors at an early stage. With the patient lying supine or standing up, the testis is gently palpated with the thumb and second and third fingers; the entire anterior, posterior, and lateral surfaces of the testis should be examined.

Local and Regional Disease

Seminomas

About 70% of seminomas are initially diagnosed at clinical stage I. Although the cure rate with orchiectomy alone is 80 to 95%, treatment can also include 2000 cGy para-aortic irradiation■ or adjuvant carboplatin.■

Twenty percent of patients with seminoma are initially found to have stage II disease (positive abdominal CT scan). For these patients, radiation therapy has a 90% cure rate; in patients who are not cured by radiation therapy,

subsequent combination chemotherapy (cisplatin combined with etoposide, with or without bleomycin) is usually curative. If the transverse diameter of the tumor is greater than 3 cm, if there are multiple anatomic levels of nodal metastases, or if stage III disease is present, the preferred initial treatment is cisplatin combination chemotherapy without irradiation; the cure rate is 70 to 100%, depending on the extent of the disease.

Nonseminomatous Germ Cell Tumors

Management of clinical stage I nonseminomatous germ cell tumors begins with orchiectomy, which has a 70% cure rate. This is followed by either retroperitoneal lymph node dissection or close surveillance (which can detect metastases early and guide curative chemotherapy), with or without one course of bleomycin, etoposide, and cisplatin. Most relapses occur in the first year, during which meticulous surveillance should include history and physical examination, serum markers, and chest radiograph every 2 months and abdominal and pelvic CT scans every 4 months. All studies are performed every 4 months during the second year, every 6 months during the third to fifth years of surveillance, and annually thereafter. CT scans are discontinued after 5 years. The physical examination should include palpation of the remaining testis, because these patients have a 1 to 2% chance of developing a contralateral primary tumor. The major complication of retroperitoneal lymph node dissection is inadvertent severing of the sympathetic plexus, with resultant retrograde ejaculation or failure of ejaculation. Nerve-sparing retroperitoneal lymph node dissection can retain antegrade ejaculation in more than 95% of patients. Some centers advocate primary chemotherapy for high-risk clinical stage I disease (embryonal predominant or vascular or lymphatic invasion) with cisplatin combination chemotherapy.[3] However, surveillance is still an option in this patient population.

For clinical stage II disease with persistently elevated serum markers or a transverse tumor diameter greater than 3 cm, chemotherapy is preferred. Other stage II patients are treated with retroperitoneal lymph node dissection, often followed by close surveillance (as described earlier, but without abdominal CT scans) or adjuvant chemotherapy. Testicular cancer has a higher cure rate with surgery alone, despite nodal metastases, than any other cancer.

Chemotherapy for Disseminated or Persistent Disease

The combination of bleomycin, etoposide, and cisplatin repeated every 3 weeks for three to four courses cures 70% of patients with metastatic disease and is the standard chemotherapy for disseminated testicular cancer. Poor-risk disease (Table 206-1) has a 50 to 60% cure rate with standard three-drug therapy, intermediate-risk disease (HCG 5000 to 50,000 IU/mL or AFP 1000 to 10,000 ng/mL) has a 70% cure rate, and all other forms of metastatic disease (good risk) have a 90 to 100% cure rate.

In the 30% of metastatic germ cell tumors that are not cured by initial combination chemotherapy, the use of standard-dose salvage therapy (ifosfamide, cisplatin, and either vinblastine or paclitaxel) or high-dose carboplatin and etoposide therapy, followed by peripheral blood stem cell transplantation, can cure 25 to 70% of refractory cases, depending on patient characteristics.

TABLE 206-1 DEFINITION OF POOR-RISK DISEASE (ALL NONSEMINOMATOUS TESTICULAR CANCER PATIENTS)

Presence of any of the following:
Lactate dehydrogenase >10 times the upper limit of normal, human chorionic gonadotropin >50,000 IU/mL, or α-fetoprotein >10,000 ng/mL
Any primary mediastinal nonseminomatous germ cell tumor
Nonpulmonary visceral metastases (e.g., bone, liver, brain)

PROSTATE CANCER

ERIC J. SMALL

DEFINITION

Prostate cancer is the most common noncutaneous malignant neoplasm in men in the United States, where it results in about 32,000 deaths each year, making it the second most common cause of cancer death in men. Prostate cancer is a single histologic disease with marked clinical heterogeneity ranging from indolent, clinically irrelevant disease to a virulent, rapidly lethal phenotype.

EPIDEMIOLOGY

The incidence of clinically diagnosed prostate cancer reflects the effects of screening by the prostate-specific antigen (PSA) assay. Before PSA testing was available, about 19,000 new cases of prostate cancer were reported each year in the United States; this number reached 84,000 by 1993 and peaked at about 300,000 new cases in 1996. Since 1996, the reported annual incidence of prostate cancer in the United States has declined to about 190,000, a number that may more closely estimate the true incidence of clinically detectable disease. The death rate due to prostate cancer has declined by about 1% per year since 1990. The age-specific decrease in mortality has been greatest in men younger than 75 years. Men older than 75 years still account for two thirds of all prostate cancer deaths. Whether this decline is due to early detection (screening) or to improved therapy has not been proved.

Risk factors for prostate cancer include increasing age, family history, African American race, and dietary factors. Epidemiologic studies have suggested that nutritional factors such as reduced fat intake and increased soy protein may have a protective effect against the development of prostate cancer. The incidence of prostate cancer among African Americans is nearly twice that observed among white Americans. Prostate cancer is diagnosed in African Americans at a more advanced stage, and disease-specific survival is lower in African Americans. The relative contributions of biologic, genetic, and environmental differences, as well as differences in health care access, are not well established. Prior vasectomy and benign prostatic hypertrophy (Chapter 131) do not increase the risk. Prostatic intraepithelial neoplasia, particularly when it is high grade, is recognized as a premalignant lesion, so its presence on biopsy increases the likelihood of subsequent malignancy.

PATHOBIOLOGY

Prostate cancer appears to be common among relatives of men with early-onset prostate cancer. At the molecular level, there appears to be a susceptibility locus for the development of prostate cancer at an early age on chromosome 1, band q24; however, an abnormality at this locus occurs in less than 10% of patients with prostate cancer. Although many genetic abnormalities with both loss and gain of function have been identified, consistent patterns of changes associated with an increased likelihood for the development of prostate cancer have not been identified. Approximately half of prostate cancers demonstrate genetic rearrangements, with fusion of promoters or enhancers of androgen-responsive genes such as *TMPRSS2* (transmembrane protease, serine 2) with oncogenic *ETS (E-twenty six)* transcription factors such as *ERG (ETS-related gene)*. These fusions lead to overexpression of oncogenic transcription factors and appear to define a subset of tumors with more aggressive behavior.

Testosterone is required for maintenance of a normal, healthy prostatic epithelium, but it is also a prerequisite for the development of prostate cancer.

Prostate cancers express robust levels of androgen receptor, and signaling through the androgen receptor results in growth, progression, and invasion of prostate cancer. Inhibition of signaling, typically by the surgical or pharmacologic reduction of testosterone levels, results in prostate cancer apoptosis and involution. Ultimately, however, androgen-deprivation therapy loses clinical efficacy. The biologic events surrounding the clinical development of "androgen deprivation–resistant prostate cancer" are not well delineated, but amplification of the androgen receptor, which is a common event in these patients, presumably makes the cancer sensitive to minute levels of androgen or other ligands of the androgen receptor. The identification of androgen receptor splice variants that are constitutively active and ligand independent raises this as a potential mechanism by which true hormone resistance develops.

CLINICAL MANIFESTATIONS

Most patients with early-stage, organ-confined disease are asymptomatic. Obstructive voiding symptoms (hesitancy, intermittent urinary stream, decreased force of stream) generally reflect locally advanced disease with growth into the urethra or bladder neck, although these symptoms can be indistinguishable from benign prostatic hypertrophy (Chapter 131). Locally advanced tumors can also result in hematuria and hematospermia. Prostate cancer that has spread to the regional pelvic lymph nodes occasionally causes edema of the lower extremities or discomfort in the pelvic and perineal areas. Metastasis occurs most commonly to bone, where it is frequently asymptomatic, but it can also cause severe and unremitting pain. Bone metastasis can result in pathologic fractures or spinal cord compression. Although visceral metastases are rare as presenting features of prostate cancer, patients can have pulmonary, hepatic, pleural, peritoneal, and central nervous system metastases late in the natural history or after androgen-deprivation therapy fails.

DIAGNOSIS

More than 60% of patients with prostate cancer are asymptomatic, and the diagnosis is made solely because of an elevated screening PSA level. A palpable nodule on digital rectal examination, which is the next most common clinical presentation, generally prompts biopsy. Much less commonly, prostate cancer is diagnosed because of advanced disease that causes obstructive voiding symptoms, pelvic or perineal discomfort, lower extremity edema, or symptomatic bone lesions.

Although the digital rectal examination has a low sensitivity and specificity for the diagnosis of prostate cancer, biopsy of a nodule or area of induration reveals cancer 50% of the time, suggesting that prostate biopsy should be undertaken in all men with palpable nodules. The PSA level has a far better sensitivity but a low specificity because conditions such as benign prostatic hypertrophy and prostatitis can cause false-positive PSA elevations (Chapter 131). By use of a PSA threshold of 4 ng/mL, 70 to 80% of tumors are detected. Far greater accuracy is achieved with age-specific PSA thresholds. Thus, for men aged 40 to 49, a PSA greater than 2.5 is considered abnormal; for men 50 to 59, a PSA greater than 3.5 is abnormal; for men 60 to 69, a PSA greater than 4.5 should prompt further evaluation; and patients aged 70 to 79 should have a PSA of 6.5 or less. The positive predictive value for a single PSA level above 10 ng/mL is greater than 60% for cancer, but the positive predictive value for a PSA level between 4 and 10 ng/mL is only about 30%. Assays of the PSA fraction that circulates unbound (percentage of free PSA) may help distinguish prostate cancer from benign processes; in patients with PSA levels of 4 to 10 ng/mL, the percentage of free PSA appears to be an independent predictor of prostate cancer, and a cutoff value of free PSA less than 25% can detect 95% of cancers while avoiding 20% of unnecessary biopsies.

Transrectal ultrasonography with biopsies is indicated when the PSA level is elevated, when the percentage of free PSA is less than 25%, or when an abnormality is noted on digital rectal examination. Extended field specimens (preferably up to six biopsies on each side) are generally obtained. Seminal vesicles are sampled in high-risk patients. A bone scan is warranted only in patients with PSA levels above 10 ng/mL, and abdominal and pelvic computed tomography or magnetic resonance imaging is usually unrevealing in patients with a PSA level below 10 to 20 ng/mL.

The prognosis of prostate cancer correlates with histologic grade and extent (stage) of disease. More than 95% of prostate cancers are adenocarcinomas, and multifocality is common. The histologic (Gleason) grade ranges from 1 to 5, although in the modern era, Gleason grades of 1 and 2 are exceedingly rare; the Gleason score, which refers to the sum of the two most common histologic patterns seen on each tissue specimen, ranges from 4 (2+2) to 10 (5+5). In general, tumors are classified as well differentiated (Gleason score 2 to 6), of intermediate differentiation (Gleason score 7), or poorly differentiated (Gleason score 8 to 10).

Clinical stage is defined by the extent of disease based on the physical examination, imaging studies, and pathology. Stage T1 is nonpalpable prostate cancer detected only on pathologic examination, noted either incidentally after transurethral resection for benign hypertrophy (T1a and T1b) or on a biopsy specimen obtained because of an elevated PSA level (T1c, the most common clinical stage at diagnosis). Stage T2 is a palpable tumor that appears to be confined to the prostate gland (T2a in one lobe, T2b in two lobes), and stage T3 is tumor with extension through the prostatic capsule (T3a if it is focal, T3b if seminal vesicles are involved). T4 tumors are those with invasion of adjacent structures, such as the bladder neck, external urinary sphincter, rectum, levator muscles, or pelvic sidewall. Nodal metastases can be microscopic and detectable only by biopsy or lymphadenectomy, or they can be visible on imaging studies. Distant metastases are predominantly to bone, but occasional visceral metastases occur.

PREVENTION

The precise role for screening remains controversial. Currently, many organizations recommend screening with PSA, but the U.S. Preventive Services Task Force recommends against screening for men older than 70 years, and it is neither for nor against screening in younger men. Of two large randomized screening trials using PSA levels, one reported a reduction in prostate-cancer–specific mortality,[1] but neither found an overall reduction in mortality.[1,2] At best, an estimated 1410 men would need to be screened to prevent one prostate cancer death over a 10-year period. Randomized trials have shown that vitamins E and C and selenium are not effective at preventing prostate cancer. The use of 5a-reductase inhibitors (both finasteride and dutasteride) reduces the risk for development of prostate cancer.[3,4] However, this approach has not been widely adopted.

TREATMENT Rx

Localized Prostate Cancer

Principles of Therapy

The principal therapeutic options for men with localized prostate cancer include the following: active surveillance; androgen deprivation; retropubic or perineal radical prostatectomy, with or without postoperative radiation therapy to the prostate margins and pelvis; external beam radiation therapy; and brachytherapy (either permanent or temporary radioactive seed implants), with or without external beam radiation therapy to the prostate margins and pelvis.

Treatment options require individualization, taking into account the patient's comorbidity, life expectancy, likelihood of cure, and personal preferences based on an understanding of the potential morbidity associated with each treatment. A multidisciplinary approach to integrate surgery, radiation therapy, and androgen deprivation is increasingly recommended. For higher-risk patients with a greater likelihood of nodal micrometastases, androgen deprivation is often combined with radiation therapy encompassing both the prostate and the pelvis. In patients at extremely high risk of micrometastatic disease or with comorbidities, systemic therapy alone without concurrent local therapy may be appropriate.

PSA screening has led to the early detection of a large number of nonpalpable tumors, for which conventional clinical means of staging are inadequate. Thus, less emphasis is being placed on clinical stage and more emphasis is being placed on PSA values and other predictors of outcome. Careful risk assessment is required to identify patients who are appropriate candidates for definitive local treatment.

Several studies have confirmed that serum PSA level, clinical stage, and biopsy Gleason score can be used to predict the final pathologic stage after prostatectomy, and that these are independent predictors of survival without PSA elevation after external beam radiation therapy or radical prostatectomy. For example, in a radiation therapy series, clinical stage T3 or higher, PSA level above 10 ng/mL, and biopsy Gleason score of 7 or higher were risk factors for poor outcome (death or PSA elevation); 5-year survival without PSA elevation was 85% for patients with none of these adverse features (good risk), 65% for patients with one adverse feature (intermediate risk), and 35% for patients with two or three adverse features (poor risk). Similar statistics are cited in radical prostatectomy series. The percentage of biopsy specimens that are positive and the rate of increase in the PSA value are each independent predictors of outcome after radical prostatectomy and can be used to counsel patients about their therapeutic options. A number of multivariable prognostic models have been developed and validated and have been used to develop simple nomograms or online risk calculators.

Low- to Intermediate-Risk Disease

In a randomized trial of patients younger than 75 years with clinical stage T1b, T1c, or T2 prostate cancer, radical prostatectomy compared with no

therapy significantly reduced the relative risk of death due to prostate cancer by 50% (a 2% absolute risk reduction) and overall mortality by a similar absolute amount at 8.6 years.[5] Reductions in progressive disease and metastases were also significant. The adverse effects on quality of life differed between the two strategies—more sexual dysfunction and urinary leakage after radical prostatectomy, more urinary obstruction with active surveillance—but were of similar magnitude.[6] Nerve-sparing radical prostatectomy was not routinely performed in this study, and many patients already had palpable disease, so the implications for less advanced disease with newer surgical techniques are not known. Nonrandomized data suggest that active surveillance may be judiciously used in patients with low disease volume, Gleason score of 6 or lower, and slow PSA doubling times. Active surveillance is probably not appropriate for young, otherwise healthy men with high-risk features as described earlier (PSA >10 ng/mL, Gleason score of 7 or higher, clinical stage T3 or higher). Whether active surveillance is appropriate for men with intermediate-risk, nonpalpable tumors remains debated. Androgen deprivation has not been carefully studied as primary therapy for localized disease, but it is becoming a more common approach in men who wish to receive some therapy but are not suited for or decline to undergo prostatectomy or radiation therapy.

Men with T1 or T2 prostate cancer who otherwise have a life expectancy of more than 10 years and no significant comorbid illnesses usually should have definitive local therapy with either surgery or radiation therapy. Long-term survival is excellent. Men with T1 or T2 tumors with Gleason scores of 7 or less have 8-year survival rates of 85 to 95%. Patients with T1 or T2 tumors with Gleason scores of 8 to 10 have 8-year survival rates of about 70%.

Nerve-sparing procedures and careful dissection techniques have decreased the risk of postoperative urinary incontinence and impotence. Postoperative urinary incontinence is reported to occur in less than 10% of cases. Postoperative impotence is dependent on a variety of factors, including the patient's age, preoperative erectile function, extent of cancer, and whether a nerve-sparing procedure was performed. In general, impotence rates of 10 to 50% are cited. Robotic-assisted laparoscopic prostatectomies have gained popularity but have not been shown to result in better outcomes. After a radical prostatectomy, the PSA should become undetectable; a detectable PSA implies the presence of cancer cells, either locally or at a metastatic site. Immediate (adjuvant) postoperative radiation therapy improves biochemical progression-free survival and local control in patients with one or more pathologic risk factors (capsule penetration, positive surgical margins, invasion of a seminal vesicle) after radical prostatectomy.[7]

Conventional external beam radiation therapy is being replaced by three-dimensional conformal radiation therapy or intensity-modulated radiation therapy, which permits higher doses to the target tissue with less toxicity. Randomized trials suggest a benefit with higher doses of radiation. Brachytherapy, which is the placement of permanent or temporary radioactive seeds directly into the prostate, is adequate for intracapsular disease with no more than minimal transcapsular extension; otherwise, it should be combined with external beam radiation therapy.

High-Risk Disease

Patients with adverse risk features (Gleason score 8 to 10, PSA >10, stage T3) are at high risk of nodal and micrometastatic disease and are generally treated with aggressive local therapy in combination with androgen deprivation, which is synergistic with radiation therapy.[8] Taken in the aggregate, trials suggest that 4 months of androgen deprivation with radiation therapy can improve local control and prolong progression-free survival in patients with intermediate-risk features, whereas long-term androgen deprivation (up to 3 years) prolongs local control, progression-free survival, and overall survival in patients with high-risk features compared with radiation therapy alone.[8,9] Patients with stage T3 disease and Gleason scores of 7 have intermediate outcomes, with 8-year survival rates of about 70%; patients with stage T3 disease and Gleason scores of 8 to 10 have 8-year survival rates, after radiation therapy, of about 50%. Several randomized controlled trials suggest that patients with high-risk disease who are treated surgically and have capsule penetration, positive margins, or seminal vesicle involvement should receive immediate adjuvant radiation therapy.

Recurrent Disease

Between 30 and 50% of men treated with radiation therapy or prostatectomy have evidence of disease recurrence, as defined by a climbing PSA level. PSA doubling time is predictive of survival, and a short PSA doubling time (<3 to 6 months) is associated with a higher likelihood of systemic disease. For selected patients with clear local recurrences, low PSA levels, and prolonged PSA doubling times (generally), local salvage therapy (surgery for patients previously treated with radiation therapy, radiation therapy for patients previously treated with surgery,[10] and androgen deprivation) can be considered. Although androgen-deprivation therapy readily controls PSA levels, it is unknown whether it prolongs life in patients with PSA-only recurrent disease.

Advanced Disease

In patients whose radical prostatectomy surgery reveals microscopic involvement of lymph nodes, immediate androgen deprivation prolongs survival compared with deferment of androgen deprivation until osseous metastases are detected. Similarly, patients who are at high risk of nodal invasion and who undergo external beam radiation benefit from concurrent short-term hormonal therapy.[8]

In patients with newly diagnosed metastatic prostate cancer, androgen deprivation is the mainstay of treatment and results in symptomatic improvement and disease regression in approximately 80 to 90% of patients. Androgen deprivation can be achieved by orchiectomy or by medical castration with a luteinizing hormone–releasing hormone (LHRH) agonist (leuprolide acetate, goserelin acetate).

Some LHRH agonists cause a transient worsening of signs and symptoms during the first week of therapy as a result of a surge in luteinizing hormone and testosterone, which peaks within 72 hours; an antiandrogen (flutamide, bicalutamide, or nilutamide) should be given with the first LHRH injection to prevent a tumor flare. Medical castration occurs within 4 weeks. The duration of hormone sensitivity is 5 to 10 years for node-positive or high-risk localized (or recurrent) prostate cancer, but it is closer to 24 months in patients with overt metastatic disease. The most common side effects of androgen ablation are loss of libido, impotence, hot flashes, weight gain, fatigue, anemia, and osteoporosis. Bisphosphonates reduce bone mineral loss associated with androgen deprivation.

Castration-Resistant Prostate Cancer

Typically, the first manifestation of resistance to androgen deprivation is a climbing PSA level in the setting of anorchid levels of testosterone. In about 15% of patients, discontinuation of antiandrogen therapy (flutamide, bicalutamide, nilutamide) while continuing treatment with LHRH agonists results in a PSA decline that can be associated with symptomatic improvement and can persist for 4 months or more. If antiandrogen withdrawal fails, treatment with secondary hormonal manipulations, such as ketoconazole or estrogens, is appropriate. Sipuleucel-T is an autologous dendritic cell product that has been shown to prolong life[11] and is appropriate for patients with castration-resistant metastatic prostate cancer who do not have cancer-associated pain, visceral metastases, rapidly progressive disease, or the need for systemic steroids. Thereafter, treatment with chemotherapeutic regimens, such as docetaxel plus corticosteroids or mitoxantrone plus corticosteroids, may be effective. Randomized phase III trials have demonstrated a survival advantage of approximately 25% in patients receiving taxol-based therapy compared with mitoxantrone,[12,13] and docetaxol-prednisone is now considered a standard therapeutic approach in patients with metastatic, androgen deprivation–resistant prostate cancer. Following therapy with docetaxel, patients who remain candidates for further chemotherapy can be treated with cabazitaxel, an agent shown to prolong life in this group of patients. In general, serial PSA levels are the best (albeit imperfect) way to follow up patients, and a decline of 30 to 50% is associated with improved survival. Zoledronic acid or denosumab is indicated in castration-resistant prostate cancer patients with bone metastases, as each reduces the incidence of skeletal-related events.

Palliative Care

Many patients with advanced prostate cancer have bone pain or functional impairments that adversely affect quality of life, and the provision of appropriate palliative care is an integral component of their management. In addition to the usual analgesics, glucocorticoids serve as anti-inflammatory agents and can alleviate bone pain. For patients with widespread bone metastases and pain not easily controlled with analgesics or local irradiation, strontium-89 and samarium-153 can be administered intravenously; they are selectively concentrated in bone metastases and alleviate pain in 70% or more of treated patients.

The approach to the treatment of prostate cancer is detailed in Table 207-1.

PROGNOSIS

In general, the 10-year PSA progression-free survival is 70 to 80% with Gleason scores of 2 to 6, whether treatment is with radiation therapy or surgery; 50 to 70% for Gleason scores of 7; and 15 to 30% for Gleason scores of 8 to 10. For patients with a climbing PSA level after radical prostatectomy, time to detectable PSA, Gleason score at the time of prostatectomy, and PSA doubling time are important prognostic variables. The likelihood of bone metastases at 7 years ranges from 20% for good-prognosis patients to 80% for poor-prognosis patients.

For patients with microscopic nodal disease, 10-year survival approaches 80% in men treated with androgen deprivation. Median survival in men treated with androgen deprivation for established metastatic disease ranges

TABLE 207-1 APPROACH TO THE TREATMENT OF PROSTATE CANCER

EXTENT OF CANCER	THERAPEUTIC OPTIONS
Organ confined: low risk (usually T1 or T2, GS <7, PSA <10 ng/mL)	Surveillance Radical prostatectomy External beam radiation therapy to prostate Brachytherapy
Organ confined: intermediate risk (usually T2, GS = 7, PSA = 10-20 ng/mL)	Radical prostatectomy External beam radiation therapy to prostate, possibly to pelvis, with or without AD Brachytherapy
Organ confined: high risk (usually T3, GS >7, PSA >20 ng/mL)	Radical prostatectomy (with adjuvant radiation therapy, if needed) External beam radiation therapy to prostate and pelvis (usually with AD) Brachytherapy plus radiation therapy (usually with AD)
Climbing PSA level after local therapy	AD: antiandrogen monotherapy or combined AD Salvage radiation therapy (for patients with prior prostatectomy) Salvage radical prostatectomy (for patients with prior radiation therapy) Surveillance Investigational therapy
Node positive	Surveillance AD Pelvic or prostate radiation therapy + AD Investigational therapy
Metastatic: untreated hormone-refractory prostate cancer	AD Second-line hormones Sipuleucel-T immunotherapy Chemotherapy Investigational therapy

AD = androgen deprivation; GS = Gleason score; PSA = prostate-specific antigen.

from 3 to 5 years. The median survival for men with androgen deprivation–resistant disease ranges from 20 months if they are minimally symptomatic to 8 to 12 months if they are severely symptomatic.

FUTURE DIRECTIONS

Molecular markers can not only identify patients at risk for the development of progressive disease but also act as therapeutic targets. In addition, the genomic characterization of prostate cancer subtypes will lead to risk-adapted therapy. Enhanced understanding of androgen receptor biology may permit the development of specific hormonal therapies and guide the more rational use of existing agents.

PRIMARY AND METASTATIC MALIGNANT BONE LESIONS

ADAM LERNER AND KAREN H. ANTMAN

PRIMARY BONE TUMORS

DEFINITION

Primary bone malignancies are relatively uncommon tumors (0.2% of all neoplasms in the Surveillance, Epidemiology, and End Results [SEER] database, 1.8 new cases/100,000 population/year) that arise from cells that are normal components of bone tissues and that have the potential to metastasize. Malignant tumors are to be distinguished from a variety of more common benign bone lesions, such as osteochondromas and enchondromas, which lack the ability to metastasize.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Patients with primary malignant and benign bone tumors present with pain, swelling and occasionally pathologic fracture of the involved bone. If radiologic studies suggest a malignant primary bone tumor (see characteristics of each subtype described later), an orthopedic oncologist should be consulted before carrying out a biopsy because improper biopsy technique may compromise subsequent surgical care, particularly limb-sparing surgery. Staging of patients with bone tumors generally requires computed tomography (CT) scans of the chest, abdomen, and pelvis to assess for metastatic disease. Characterization of the primary bone tumor may benefit from magnetic resonance imaging (MRI) assessment of soft tissue extension or CT scan assessment of cortical bone involvement, or both.

MAJOR PRIMARY MALIGNANT BONE TUMORS

Myeloma, the most common primary bone malignancy, is covered in Chapter 193.

Osteosarcoma

Osteosarcoma is the most common malignant sarcoma of bone, representing about 35% of cases. It has a bimodal age distribution, with highest incidence in patients younger than 20 years, most likely related to the normal rapid bone growth that occurs during adolescence. In this age group, most

tumors arise in the metaphyseal areas of the long bones of the extremities, particularly around the knee. Males are affected more commonly than females at a ratio of 3:2. A second peak of incidence occurs in adults older than 60 years. The sites of origin in these older patients are somewhat more heterogeneous, with craniofacial and pelvic bones each accounting for 20% of tumors. Radiographically, osteosarcomas usually present as mixed osteoblastic and osteolytic lesions, although pure forms of either appearance can occur. Periosteal elevation (Codman's triangle), cortical destruction, and tumor extension into soft tissue are common on plain films or MRI.

The incidence of osteosarcoma is increased in families that carry germline deletion of retinoblastoma (*Rb*), *p53* (Li-Fraumeni), or *RecQ* DNA helicase (Rothman-Thompson, Werner, or Bloom syndrome) genes. Consistent with these observations, although most younger patients with osteosarcomas have no apparent predisposing factor or family history of bone tumors, alterations in the *p53* and *Rb* genes of such sporadic tumors occur in 40% and 60%, respectively. In older patients, a variety of conditions may predispose patients to osteosarcoma, most convincingly antecedent Paget's disease or prior radiation therapy.

TREATMENT Rx

Osteosarcoma is a highly proliferative neoplasm that metastasizes rapidly. As for most sarcomas, osteosarcoma spreads hematogenously, and the most common site of metastasis is the lung. Despite aggressive surgical resection of the primary bone tumor, the incidence of recurrence with metastatic disease is high in the absence of systemic treatment, consistent with the concept that most patients present with clinically inapparent micrometastatic disease. The development of effective systemic chemotherapy with doxorubicin (Adriamycin) and cisplatin, with or without methotrexate, has had a profoundly positive effect on treatment outcome, with 5-year disease-free survival rates exceeding 65% in patients younger than 40 years with nonmetastatic extremity tumors.[1] Most patients are managed with initial neoadjuvant chemotherapy, delayed resection of the primary tumor, and then further postoperative chemotherapy. Serum alkaline phosphatase levels, often elevated in osteosarcoma patients, can be used to monitor disease status.

Modern surgical techniques have allowed surgical resection of most extremity osteosarcomas without amputation. Although resection of lung metastases can be curative in about 20% of selected patients, detection of radiologically apparent metastatic disease at presentation significantly worsens prognosis. Long-term disease control in older adults with osteosarcoma is substantially lower than in younger patients, with a 5-year overall survival rate of 22% in one series of patients older than 65 years, most likely because of fundamental differences in the underlying molecular pathophysiology of tumors in older adults. Although osteosarcoma is generally considered to be relatively radiation resistant, radiation can play a palliative role in selected patients.

Chondrosarcoma

Chondrosarcoma, a malignant tumor characterized by hyaline cartilage differentiation, is the second most common sarcoma of bone, representing 25% of bone sarcomas. The peak incidence is in the fifth to seventh decades of life. The most common primary sites are in the pelvis, proximal femur, and proximal humerus. Patients present with long-standing complaints of swelling, pain, or both. Radiographically, chondrosarcoma is detected as an area of radiolucency with variable punctate mineralization, with frequent cortical bone erosion or thickening, sometimes with extension into adjacent soft tissue. Distinguishing low-grade chondrosarcomas from benign central enchondromas can be difficult: location in the axial skeleton and size greater than 5 cm favor malignancy.

Up to 15% of chondrosarcomas arise from preexisting peripheral osteochondromas and, like their benign counterparts, harbor mutations in the exostosin *(EXT)* genes. The remaining 85% of chondrosarcomas arise in a central location, some in preexisting enchondromas. Chondrosarcomas are divided into three grades, with higher-grade tumors characterized by greater cellularity and cellular atypia. In one series, 61% of patients had grade 1 tumors; only 4% of such patients developed metastases. In contrast, 36% of patients had grade 2 and 3% grade 3 tumors; among this combined group, 29% developed metastases.

TREATMENT Rx

Unlike osteosarcoma and Ewing's sarcoma, chondrosarcomas generally grow slowly, metastasize less commonly, and have an excellent prognosis after adequate surgical resection. Although chondrosarcomas are considered relatively radiation resistant, radiation therapy may provide palliation for patients with large or recurrent unresectable central chondrosarcomas.

Ewing's Sarcoma

Ewing's sarcoma and primitive neuroectodermal tumor (PNET) are a family of small round cell sarcomas that represent 16% of primary bone sarcomas. As with osteosarcoma, the peak incidence occurs during the second decade of life, but unlike osteosarcoma, the incidence of Ewing's is unimodal, being distinctly unusual in older adults and in nonwhites. Ewing's sarcoma tends to arise in the diaphyseal region of long bones, in the pelvis, or in ribs. Ewing's tumors are characterized radiologically by a permeative or "moth-eaten" appearance of the affected bone, with a multilayered "onion-skin" periosteal reaction. MRI studies frequently document a significant soft tissue mass associated with the bone lesion. Unlike other sarcomas of bone, Ewing's sarcoma may present with symptoms of an inflammatory systemic illness, with intermittent fevers, anemia, leukocytosis, and an increased sedimentation rate.

Eighty-five percent of patients with Ewing's family sarcomas contain a t(11;22)(9q24;q12) chromosomal translocation that juxtaposes the *EWS* gene on chromosome 22 with *FLI1*, an ETS family transcription factor. Another 15% contain a variant in which *EWS* is juxtaposed to *ERG*, another ETS family member on chromosome band 21q22. Because Ewing's sarcoma resembles other small round cell tumors microscopically, reverse transcription–polymerase chain reaction and fluorescent in situ hybridization studies that document such translocations play a critical role in confirming the diagnosis. Ewing's sarcoma/PNET cells characteristically express CD99/MIC2.

TREATMENT Rx

The development of effective systemic chemotherapy regimens has substantially improved long-term control of Ewing's sarcoma. After completion of staging procedures, patients are treated with neoadjuvant chemotherapy. One highly active regimen alternates cycles of vincristine, doxorubicin, and cyclophosphamide with ifosfamide and etoposide. After 3 months of chemotherapy, the primary tumor is resected, radiated, or both, depending on the location and extent of the primary tumor. Chemotherapy is then resumed for a total of up to 1 year of treatment. Using such an approach, the mean 5-year event-free survival rate for patients who present with nonmetastatic disease is 69%.[2] Insulin-like growth factor-1 receptor antagonists have demonstrated clinical activity in recent clinical trials for chemotherapy-refractory disease.

METASTATIC TUMORS TO BONE

Tumors metastatic to bone are important causes of cancer-related morbidity. Effective prevention and treatment of skeleton-related metastases are an important part of clinical care for many cancer patients. The most common tumors to metastasize to bone are breast in women and prostate in men, followed by lung, kidney, gastrointestinal tract, and thyroid.

Bone metastases typically present as localized or referred pain and less commonly as a fracture. Plain radiographs may demonstrate blastic or lytic lesions. Although prostate cancer is generally blastic and multiple myeloma usually lytic, most other tumors have a mixed appearance. In patients with one documented bone metastasis or in patients with widely metastatic disease and bone pain, a radiologic survey can identify bone metastases that may ultimately place the patient at risk for a pathologic fracture. Technetium diphosphonate bone scans are useful to delineate the extent of bony metastases and in following response to therapy. However, a negative study must be interpreted cautiously for tumors that are potentially purely lytic because these may be undetectable by bone scan. In such tumors (e.g., multiple myeloma), a skeletal survey is therefore preferable. Routine screening for bone metastases is not indicated for cancer patients with no symptoms or signs of bone involvement.

TREATMENT

Rx

In the absence of fracture or impending fracture, painful bone metastases are treated with external beam radiation therapy. In patients with numerous bone metastases, systemic chemotherapy or endocrine therapy can play an important palliative role. Pathologic fractures or imminent fractures are generally managed by operative internal fixation.

PREVENTION

In breast cancer, prostate cancer, and multiple myeloma patients, bisphosphonate therapy increases the time to a first skeletal event. Bisphosphonate therapy also appears to prolong survival in patients with metastatic breast cancer. The optimal schedule and duration of administration of bisphosphonates to maximize benefit and minimize potential complications remain to be established.

SARCOMAS OF SOFT TISSUE AND BONE, AND OTHER NEOPLASMS OF CONNECTIVE TISSUES

GEORGE D. DEMETRI

DEFINITION

Sarcomas are a very heterogeneous group of malignant neoplasms of connective tissues, including bone and soft tissue. Sarcomas, as well as other putatively "nonmalignant" neoplasms that affect soft tissue and bone, share a mesenchymal cell of origin with aberrant differentiation and growth potential. Mesenchymal cells (derived from mesoderm), as well as neural crest cells (from ectoderm), are critical for the normal structure and function of humans because they give rise to the connective tissues that hold the organism together and also provide critical functions such as support and nourishment of neural tissues. When the growth, differentiation, or survival of these cells is aberrant, tumors arise, and this is the family of neoplasms to which sarcomas belong. Sarcomas include a vast array of tumor types related to muscle, stromal tissue, adipose tissue, blood and lymphatic vessels, nerves and nerve sheaths, cartilage, bone, and other fibrous tissues.

Sarcomas are tumors with distinct histopathologic abnormalities; other forms of connective tissue neoplasms may also cause significant disease without being classified as sarcomas per se. For example, because of the histopathologically bland appearance of desmoid tumors, pathologists do not classify these myofibroblastic neoplasms as sarcomas, even though they can cause significant morbidity and even death if they are recurrent and unresectable. Similarly, the sarcoma known as gastrointestinal stromal tumor (GIST) was not considered a true sarcoma before 2000, although many GISTs certainly exhibit all the characteristics of aggressive malignancy. In brief, sarcomas represent a broad group of different diseases that can affect any anatomic location, and for this reason, they have puzzled clinicians and intrigued developmental biologists and fundamental researchers.

EPIDEMIOLOGY

True sarcomas represent a very uncommon subset of human malignancies, accounting for less than 1% of cancers in adults but a disproportionately large number of cancers in the pediatric population (approximately 15% of pediatric cancers). The overall incidence of sarcomas of soft tissue and bone is approximately 15,000 cases per year in the United States. Given the fact that there are no sarcoma-specific disease diagnostic codes, however, such numbers must be viewed as rough approximations at best. Nonetheless, it is clear that sarcomas are uncommon compared with carcinomas. The prevalence of sarcomas significantly exceeds the incidence, because sarcomas can be cured with expert multidisciplinary care. This makes it critical that the initial evaluation and management of patients suspected of having sarcomas be performed by an experienced team with relevant expertise and interdisciplinary capabilities (including pathology diagnostic capabilities, surgical specialization, and radiotherapeutic experience and judgment, as well as access to the latest systemic therapy agents and data on their use). Certain patients are at high risk of developing sarcomas, most notably individuals in families with Li-Fraumeni syndrome and those with neurofibromatosis (at risk for malignant peripheral nerve sheath tumors and GISTs) or familial polyposis (at risk for intra-abdominal desmoid tumors). Other risk factors include exposure to radiation (including radiation therapy for other cancers, such as patients with prior irradiated breast cancer or survivors of retinoblastoma). Chemical carcinogens can also increase the risk of sarcoma development, such as the increased risk of sarcomas in Vietnam veterans exposed to Agent Orange or the greatly increased risk of hepatic angiosarcomas associated with occupational exposure to polyvinyl chloride. However, the vast majority of sarcomas appear to be sporadic, with no evident inciting risk factors.

PATHOBIOLOGY

Sarcomas and other connective tissue neoplasms are an overwhelmingly complex and heterogeneous mixture of diseases with a wide range of clinical behaviors and outcomes. Some soft tissue neoplasms, such as localized tenosynovial giant cell tumors, can be cured by expert resection, whereas more advanced tumors of this type (referred to as pigmented villonodular tenosynovitis) often lead to debilitating amputations or even death due to metastatic disease. The bewildering array of polysyllabic names used by pathologists has caused confusion among clinicians and basic science investigators alike. In brief, expert pathologists strive to develop concise, systematic, and reproducible criteria for the diagnosis of specific sarcoma subtypes, but interobserver variability can plague the application of elegant diagnostic categories such as those promulgated by the World Health Organization. Increasing knowledge of the molecular pathways that drive sarcomas has provided more objective diagnostic tools with novel immunohistochemical staining patterns and genetic markers (e.g., pathognomonic chromosomal translocations have defined diseases such as Ewing's sarcoma or synovial sarcoma more objectively than any histopathologic appearance determined by simple light microscopy). In general, sarcomas may exhibit differentiation patterns consistent with defined connective tissues (e.g., well-differentiated liposarcoma may appear as only slightly bizarre fat cells under the microscope), or they may be absolutely unclassifiable. In fact, the terminology used by pathologists for very poorly differentiated sarcomas has also evolved: the current diagnostic category is "unclassifiable pleomorphic sarcoma," whereas 20 years ago most pathologists grouped such poorly differentiated tumors under the misnomer "malignant fibrous histiocytoma." In any case, as diagnostic tools have evolved, it has become possible to place such poorly differentiated tumors more accurately into certain histopathologic categories based on the expression of lineage-related proteins (e.g., smooth muscle actin expression may help categorize tumors as leiomyosarcomas) or on the basis of genomic markers (e.g., overexpression of chromosome 12 material or the *mdm2* gene locus is most consistent with a dedifferentiated liposarcoma).

It may be necessary to refer patient material to expert reference pathologists to accurately define the type of connective tissue neoplasm, and such referral can make an enormous difference in patient care (e.g., differentiating between a benign process that may self-resolve and a truly malignant sarcoma). The complexity of sarcoma and connective tissue tumor diagnosis cannot be overstated, and that is a major reason why all international clinical practice guidelines emphasize the importance of experienced diagnosticians and a low threshold for referral to expert pathology review for patients with connective tissue tumors.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Given the broad range of sarcomas, it is understandable that the clinical course can range from rapidly evolving and immediately life-threatening cancers (such as most Ewing's sarcomas) to indolent lesions that can take decades to evolve (such as atypical lipomatous tumors, also known as well-differentiated liposarcomas). Most patients with sarcomas present with a mass, often nontender, with a history of abnormal growth over time. For extremity tumors of soft tissues, it is important to note that many benign tumors (e.g., lipomas) cannot be easily distinguished from more worrisome neoplasms or even from frankly malignant sarcomas. Therefore, it is important to include sarcoma in the differential diagnosis of any mass.

The initial biopsy or surgical approach to a sarcomatous lesion is often the most important, and a poorly oriented biopsy or a suboptimal surgical procedure can make the difference between cure with full limb function and disease recurrence with the need for amputation or mutilating surgical re-resection. This lesson was first learned by orthopedic specialists with regard to bone sarcoma (osteosarcoma), but it is true for soft tissue sarcomas as well. The National Comprehensive Cancer Network (NCCN) has developed expert consensus guidelines for clinical practice that emphasize the importance of expert management from the moment a suspected sarcoma presents. The initial diagnosis includes appropriate imaging studies of relevant anatomic areas, including plain radiographs, computed tomography, or magnetic resonance imaging to define the anatomic area of the mass and surrounding tissue, as well as systemic staging because sarcomas can spread in well-defined patterns to distal sites such as the lung or liver. The decision to proceed to diagnostic biopsy, with optimal orientation, is an important one, and for certain lesions, forgoing incisional biopsy and proceeding directly to expertly planned surgical excision may be justified. The most important consideration is to make the correct diagnosis, and there must be sufficient amounts of properly prepared and expertly oriented tissues for optimal diagnostic analysis. In certain tumors with pathognomonic molecular markers (such as the translocation between chromosomes X and 18 that characterizes synovial sarcoma, or the balanced translocation between chromosomes 12 and 16 that defines myxoid and round cell liposarcoma), molecular analyses such as fluorescence in situ hybridization (FISH) may help make the diagnosis. New molecular subtypes of sarcomas enter the pathology literature on an annual basis, and this supports the need for expert pathology review of tumors of soft tissue and bone. These new diagnostic categories may lead to new molecularly targeted therapies. Nowhere has this been more evident than in the rapid evolution of effective therapy against the major pathobiologic cause of GISTs[1] (see later, under Treatment).

The diagnosis of a soft tissue or bone tumor is made by evaluating biopsy material in the clinical context, which includes understanding the tumor's anatomic location and imaging characteristics. Such contextual diagnostics are key to understanding whether a lesion may represent a primary sarcoma or whether it may be the first presentation of metastases from an occult primary tumor located elsewhere. Given the broad spectrum of sarcomas, the diagnostic considerations are quite far-reaching, especially because many benign pathophysiologic conditions can mimic sarcomas. For example, it may be very difficult for an inexperienced pathologist to distinguish among normal fat, inflammatory infiltrates, and liposarcoma. Similarly, certain fibroblastic neoplasms might simulate inflammation or scar. Therefore, a broad differential diagnosis is needed when considering any neoplasm of soft tissue or bone.

TREATMENT

Rx

The most important element of treatment is expert multidisciplinary care. The range of options is too broad to categorize simply, and the specific details of each patient's anatomy, comorbidities, functional status, and personal preferences must be taken into account when defining treatment options and management plans. Therefore, the care of virtually all sarcoma patients should be managed by an expert multidisciplinary team with expertise in advanced surgical and/or orthopedic oncology techniques, radiation therapy, reconstructive surgery, physical therapy and rehabilitation medicine, systemic therapies such as conventional cytotoxic chemotherapy, hormonal therapy, and modern molecularly targeted therapy with agents such as kinase inhibitors, as well as psychosocial support and specialized nursing care. Sarcomas represent such a complex family of diseases that referral to academic centers makes good sense for patients as well as for the health care system overall. Therefore, appropriate referral to obtain expert opinion and to define the diagnostic and treatment options for patients with suspected sarcomas is exceedingly important.

For most primary localized masses in which sarcoma is in the differential diagnosis, the first step is to obtain the correct diagnosis in a manner that does not compromise patient outcome or function. The need for biopsy must be considered first, because some small, localized sarcomas are best approached through definitive surgical excision following careful staging and expert review of imaging studies. For suspected sarcomas in deeper locations, such as deep within muscle compartments, or for large visceral lesions, biopsy may be necessary to ascertain that the process is in fact a sarcoma, as well as to fully characterize the histopathologic subtype. This may make the difference between initial management with chemotherapy, as might be appropriate for a highly chemosensitive disease such as Ewing's sarcoma, versus surgery, which might be appropriate for a less chemosensitive disease such as dedifferentiated liposarcoma. Expert opinion varies regarding the utility and timing of adjuncts to surgical resection, such as radiation therapy or systemic cytotoxic chemotherapy. This variation can best be appreciated by noting the variety of management options for extremity sarcomas in the NCCN's consensus practice guidelines.

In general, expert surgical resection is first-line therapy for localized sarcomas. Preoperative systemic chemotherapy is standard for most common forms of osteosarcoma, as well as for Ewing's sarcoma and certain rhabdomyosarcomas. Many expert teams favor preoperative radiation therapy for certain sarcomas; irradiation of a large primary tumor can deliver smaller doses to surrounding normal tissues preoperatively compared with postoperatively, but this is a matter of personal preference. A reasonably sized randomized trial of preoperative versus postoperative radiation therapy for large sarcomas of the extremity was performed in Canada, and outcomes were similar, with subtle differences: patients who received preoperative radiation had a higher incidence of serious postoperative wound complications, but the long-term functional outcomes were slightly more favorable.[2] Because of such subtleties in results, sarcoma care is based largely on expert opinion and personal experience, and the vast range of sarcoma diagnoses and clinical presentations adds to this complexity.

Many sarcoma centers disagree about the relative value of cytotoxic chemotherapy, although there is no doubt that chemotherapy has greatly improved disease control rates and cure rates of certain subtypes of aggressive sarcomas such as intermediate- and high-grade osteosarcomas, Ewing's sarcomas, and rhabdomyosarcomas. For other forms of sarcomas originating in bone (e.g., chondrosarcoma) or soft tissue (e.g., leiomyosarcoma, synovial sarcoma), there is no strong evidence that systemic chemotherapy increases cure rates or long-term clinical outcomes, although there may be some improvement in local disease control and recurrence-free survival. This has led to discordant expert opinion: many experts believe that the risks and toxicities of aggressive chemotherapy justify the benefit of longer disease-free survival, whereas others feel that such toxicities are not reasonable without a major improvement in overall survival. Limited series of postoperative adjuvant therapy are often contradictory owing to the relatively small patient groups under study, as well as divergent patient selection factors, such as the inclusion of those with a lower risk of recurrence or death from metastatic disease. Inclusion of a sizable percentage of sarcoma patients with low-risk disease no doubt dilutes the results of even a reasonably effective therapy and runs the risk of making the study result negative; this possibility has remained an irreconcilable point of controversy among sarcoma centers across the United States and around the world.

It is also critical to recognize that treatment may differ radically depending on the histologic diagnosis. The best example of this is GIST, a form of sarcoma that, in more than 95% of cases, is driven by aberrant tyrosine kinase signaling. Routine systemic chemotherapy is completely ineffectual against this disease once it has metastasized or become unresectable owing to extensive local disease. By understanding the pathobiology of the disease and the "short-circuits" of intracellular kinase signaling, it is now possible to use targeted tyrosine kinase inhibitor drugs (e.g., imatinib mesylate, sunitinib malate) to block the abnormally activated tumor cell signaling, leading to dramatic tumor regression and tumor control in more than 85% of patients. Therefore, correctly diagnosing GIST is critical for choosing the proper therapy, and it can have life-or-death consequences for patients. Fortunately, pathologists are increasingly able to recognize this histopathologically and molecularly defined sarcoma. Immunohistochemistry to detect antigens such as CD117 (the Kit receptor tyrosine kinase) and DOG1 (a membrane antigen that is reasonably specific for GIST) and tumor genotyping via molecular genetics have significantly increased the accuracy of GIST diagnosis in the past decade. Tyrosine kinase inhibitor therapy with imatinib has been approved by the Food and

Drug Administration to decrease the risk of disease recurrence following resection of GISTs with significant potential for relapse. It is important to note that patients with a low risk of relapse have not derived substantive benefits from adjuvant imatinib because they have a very good chance of being cured by expert surgery alone. GIST is therefore a paradigmatic example of a sarcoma in which critical therapy decisions must be made in the context of the proper diagnosis and with access to the latest evidence-based medical information.

For soft tissue sarcomas other than GIST, radiation therapy can play a meaningful role in preventing disease recurrence, especially for lesions that arise in the extremities. Radiation therapy can also provide significant palliation of unresectable disease, and it can be surprisingly effective in certain tumors such as desmoid tumor. However, radiation-associated sarcomas are increasingly common after therapeutic radiation therapy (e.g., in patients cured of breast cancer with radiation therapy), and an increasing incidence of poorly differentiated sarcomas or vascular sarcomas has been reported in patients following irradiation for other diseases.

As noted earlier, traditional cytotoxic chemotherapy is dramatically effective at increasing disease control and cure rates for certain sarcomas (especially those most prevalent in pediatric patients, such as osteosarcoma, Ewing's sarcoma, and rhabdomyosarcoma). It appears to be somewhat less effective in improving long-term cure rates for patients with most other forms of soft tissue and bone sarcomas, such as liposarcoma, leiomyosarcoma, synovial sarcoma, and other subtypes. Nonetheless, appropriate use of chemotherapy can lead to objective responses in certain patients and can palliate metastatic disease with disease control and prolongation of progression-free survival. Sarcoma experts often disagree about the relative value and toxicity of combination chemotherapy as opposed to sequential single-agent chemotherapy. In patients with very aggressive and highly symptomatic sarcomas, clinicians may wish to "hedge their bets" and choose a combination chemotherapy regimen, even if there is a greater risk of toxicity, to ensure some measure of rapid disease control or even a greater chance of disease regression. In contrast, in patients with asymptomatic metastatic disease (e.g., a sarcoma patient with indolent pulmonary metastases and no symptoms), the optimal choice might be single-agent chemotherapy to avoid toxicity and to maximize the choice of subsequent chemotherapeutic agents after the benefit of the first agent is fully realized. There is no single "best" choice for all patients, and each clinical situation requires individualization based on the specific details of the case and the patient's preferences. There are no definitive data from rigorously conducted and properly powered randomized trials that any chemotherapy for metastatic sarcoma of soft tissue (other than GIST) improves overall survival, yet there is no room for nihilism. All experts agree that owing to the complexity of the trials, the diseases, and the clinical settings, one must allow for variations in interpretations for individual patients. This explains the greatly discordant practice patterns observed across the country based on referrals, provider experience, and patient characteristics and preferences.

PROGNOSIS

As noted earlier, it is relatively meaningless to discuss prognosis for sarcomas overall because they represent such a variety of diseases with widely divergent natural histories. It is estimated that approximately 50% of patients with localized sarcomas can be cured, and the risk of recurrence is related to variables such as tumor grade (low-grade tumors have a lower risk of recurrence or metastasis compared with intermediate- or high-grade tumors), tumor size, and tumor location or depth. For patients with recurrent or metastatic sarcoma, outcome depends on many factors, including the time from initial diagnosis to the first appearance of metastatic disease: a longer disease-free interval is associated with longer survival, probably indicating a slower rate of tumor proliferation. Another factor that may determine outcome is the number of metastatic lesions: it is possible that oligoclonal metastases, with few lesions, can be surgically resected, which itself may be associated with improved survival. Advances in chemotherapy and targeted therapies may also affect survival, as documented by the dramatic improvements in survival and disease control for GIST and other kinase-driven sarcomas, such as dermatofibrosarcoma protuberans, as well as the more recent molecular therapeutic targeting of giant cell tumor of bone, perivascular epithelioid cell–oma (PEComa), and tenosynovial giant cell tumor. The natural history of these diseases will almost certainly be changed by a more complete and mechanistic understanding of the underlying neoplasia-promoting signals that cause the transformation and maintenance of the sarcoma.

The complexities of soft tissue and bone neoplasms and sarcomas are rivaled only by the spectrum of molecular pathways and aberrancies that are at the root of these diseases. Virtually every disease mechanism can be associated with some form of mesenchymal cell neoplasm. Better understanding of sarcoma biology is translating into improvements in sarcoma outcomes, and this is being extrapolated to improved understanding of the pathophysiology of other stromal-mediated diseases, such as pathologic conditions of fibrosis (e.g., interstitial pulmonary fibrosis and fibrocystic diseases such as lymphangioleiomatosis). Expert multidisciplinary management of sarcomas is critical to improving outcomes, and ongoing translational and therapeutic research will provide dividends far beyond the relatively low incidence and prevalence of these mesenchymal cell neoplastic disorders.

MELANOMA AND NONMELANOMA SKIN CANCERS

LYNN SCHUCHTER

MELANOMA

EPIDEMIOLOGY

Current estimates are that 1 out of 39 men and 1 of out of 58 women will be diagnosed with melanoma during their lifetime. Each year in the United States, approximately 62,000 new cases of invasive melanoma are detected, and 8400 patients die of melanoma. The explanation for the rising incidence is thought to be increasing sun exposure, especially early in life. Melanoma is the leading cause of death from cutaneous malignant disease, and it accounts for 1 to 2% of all cancer deaths in the United States. Melanoma affects all age groups; the median age at diagnosis is 50 years. Melanoma is largely a disease of whites, with a very low incidence in African Americans, Asians, and Hispanics.

PATHOBIOLOGY

Exposure to sunlight, and especially ultraviolet (UV) radiation (Chapter 19), has been strongly implicated as a causative factor in the development of melanoma. Melanomas originate from melanocytes, which are located

predominantly in the basal cell layer of the epidermis and use the enzyme tyrosinase to synthesize melanin pigment, which serves to protect against UV damage (Chapter 443). Worldwide, the incidence of melanoma in whites generally correlates inversely with latitude; that is, rates are generally higher closer to the equator and become progressively lower near the poles.

Risk Factors

Risk factors for melanoma include family history of melanoma, prior melanoma or nonmelanoma skin cancer, inherited genetic susceptibility, and sun exposure. Individuals with fair complexion, blond or red hair, blue eye color, and freckles, who have a tendency to burn rather than tan, have higher rates of melanoma. The pattern of sun exposure may also be important; intermittent intense exposure, rather than long-term exposure, may carry a higher risk of melanoma.

Individuals with an increased number of typical or benign moles or atypical moles or dysplastic nevi (Figs. 210-1 and 210-2) also have an increased risk for melanoma. Atypical moles or dysplastic nevi are important precursor lesions of melanoma and also serve as markers for increasing risk. For example, individuals with dysplastic nevi have a 6% lifetime chance of developing melanoma, and this risk increases to as high as 80% in individuals who have dysplastic nevi and a strong family history of melanoma.

Genetics

Approximately 10% of patients with melanoma have a family history of melanoma. Several chromosomal loci determine susceptibility to melanoma, the most important of which is *p16/CDKN2A,* a gene located on chromosome 9p21. This gene is a member of a class of molecules that play a central role in cell cycle regulation. Of the members of melanoma-prone families, 25 to 40% have mutations in this gene. The risk of developing cutaneous melanoma in an individual who is a CDKN2A carrier is between 30 and 90% by age 80 years and varies by geographic location. Testing for mutations in the *p16/CDKN2A* locus is commercially available, but its clinical utility is unclear at this time. Genetic variability in melancortin-1 receptor (MC1R) plays a key role in pigmentation of skin and hair and more recently has been implicated in melanoma predisposition.

Somatic mutations in primary and metastatic melanoma primarily involve the mitogen activated protein kinase pathway. Activating mutations in *B-RAF* can be found in approximately 40% of melanomas, and 10 to 15% of melanomas are associated with a mutation in *N-RAS*. Recent studies have found that melanoma on mucous membranes, acral skin (soles, palms), and skin with chronic sun damage (i.e., lentigo maligna melanoma) have frequent mutations in *c-kit*. Thus, distinct patterns of genetic alterations are found in primary melanomas based on anatomic location and extent of sun exposure. The discovery of somatic mutations in melanoma and associated aberrant signal transduction pathways has provided leads for the development of molecularly targeted therapy for patients with advanced melanoma.

CLINICAL MANIFESTATIONS

Early detection and recognition of melanoma are key to improving survival. The signs of early melanoma are based on the clinical appearance of the pigmented lesion and a change in the shape, color, or surface of an existing mole. Most patients report a preexisting mole at the site of the melanoma. Itching, burning, or pain in a pigmented lesion should increase suspicion, although melanomas often are not associated with local discomfort. Bleeding and ulceration are signs of a more advanced melanoma. Most melanomas are varying shades of brown, but they may be black, blue, or pink. The ABCDEs for the recognition of melanoma are asymmetry, border irregularity, color variation, diameter greater than 6 mm, and evolution or a change in a skin lesion.

Cutaneous melanoma has been divided into four subtypes. Superficial spreading melanoma, which accounts for 70% of all melanomas, can be located on any anatomic site (Fig. 210-3). Lentigo maligna melanoma, which represents 4 to 10% of all melanomas, tends to occur more commonly in chronically sun-exposed skin in older patients, frequently on the head and neck (Fig. 210-4); clinically, it appears as a macular (flat) lesion, arising in a lentigo maligna. Nodular melanoma (Fig. 210-5) accounts for 15 to 30% of melanomas and manifests as a rapidly enlarging elevated or polypoid lesion, often blue or black. The ABCDE rule does not always apply as well to nodular melanomas. Acral lentiginous melanoma manifests as a darkly pigmented, flat to nodular lesion on the palm, on the sole, and subungually; sunlight is not thought to play a causative role in this form of melanoma. Histologic subtype does not directly correlate with clinical behavior. However, recent data suggest that histologic subtype may correlate with specific genetic abnormalities.

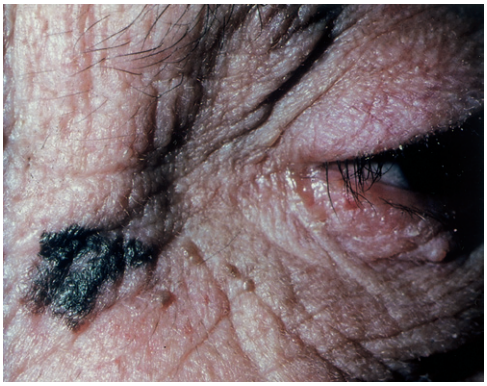

FIGURE 210-4. Lentigo maligna melanoma.

FIGURE 210-5. **Nodular melanoma.** (From Internal Medicine for Clerkship Students. American College of Physicians, 2006.)

Ocular melanomas arise from the pigmented layer of the eye. Uveal melanoma is the most common intraocular malignancy of adults. Melanomas can also arise from noncutaneous sites, including mucosal epithelium in the gastrointestinal tract, anorectal area, genitourinary tract, and nasal and nasopharyngeal mucosa. Melanomas of the vulva and vagina are relatively rare. In general, mucosal melanomas are diagnosed at a more advanced stage of disease. The mainstay of treatment is surgical.

DIAGNOSIS

Any skin lesion suggestive of melanoma should be sampled using biopsy with complete excision, including a 1- to 2-mm margin of normal skin and some subcutaneous fat. An incisional biopsy may be necessary for lesions too large for complete excision. Shallow shave biopsies, curettage, cryosurgery, laser, and electrodessication are contraindicated in lesions suggestive of melanoma. Other lesions that can be confused with melanoma include blue nevi, pigmented basal cell carcinoma, seborrheic keratosis, and hemangiomas (Table 210-1).

TABLE 210-1 CLINICAL FEATURES OF COMMON NEVI, DSYPLASTIC NEVI, AND MELANOMAS

DISEASE	CHARACTERISTICS
Common acquired nevi (moles)	These tend to be small, flat, and round; the border is regular, smooth, and well defined; the color is homogeneous, usually no more than two shades of brown; any site is affected; lesions are usually <6 mm.
Dysplastic nevi (atypical moles)	These occur predominantly on the trunk; they tend to be large, usually >5 mm, with a flat component; the border is characteristically fuzzy and ill defined. The shape can be round, oval, or misshapen. The color is usually brown but can be mottled with dark brown, pink, and tan. Some individuals have only 1 to 5 moles, others more than 100.
Melanoma	The border is more irregular; lesions tend to be larger, often >6 mm; substantial heterogeneity of color is noted, ranging from tan-brown, dark brown, black, pink, red, gray, blue, or white.

Prognostic Factors

As with most malignancies, the outcome of melanoma is dependent on the stage and extent of disease at presentation. For localized melanoma, the most important prognostic factor is involvement of regional lymph nodes. The most important prognostic factor related to the primary tumor is the depth of invasion (Breslow's thickness) of the melanoma, which is measured in millimeters from the top of the epidermis to the underlying dermis. Increasing thickness is associated with an increased risk for recurrence, regional lymph node involvement, and death from melanoma. Patients whose melanomas are less than 1 mm thick have about an 80 to 90% 10-year survival rate, whereas patients whose melanomas are greater than 4 mm thick have only a 40 to 50% 10-year survival rate. Other poor prognostic factors related to the primary melanoma include the presence of ulceration, an increasing level of invasion (Clark's level), a high mitotic rate, and the presence of microscopic satellites. Regional lymph node involvement (stage III) has a major impact on survival, with 5-year survival rates ranging from 20 to 70%, depending on the number of involved lymph nodes. Melanomas that arise on the extremity tend to have a better prognosis, and women tend to do better than men.

Staging System for Melanoma

Staging and prognosis for melanoma are based on the TNM system, in which T refers to tumor, N to nodes, and M to metastasis, which was updated in 2009 (E-Table 210-1). Stages I and II indicate clinically localized primary melanoma, stage III melanoma indicates regional involvement (lymph nodes or in-transit metastases), and stage IV is metastatic disease beyond the regional lymph nodes (i.e., lung, liver, brain).

Patient Evaluation

The initial evaluation of a patient with melanoma includes a personal history, a family history, a total skin examination, and palpation of regional (draining) lymph nodes. The focus is to identify risk factors, signs or symptoms of metastases, dysplastic nevi, and additional melanomas. A chest radiograph and liver enzyme tests may be performed at the discretion of the physician. Most patients who present with melanoma do not have distant metastatic disease at presentation; therefore, extensive evaluations with computed tomography (CT) to search for distant metastases have an extremely low yield and are not indicated in asymptomatic patients. More extensive staging evaluation with CT or positron emission tomography (PET) can be considered in patients with high-risk disease (primary melanoma >4 mm thick or node-positive disease), in whom the risk of distant metastatic disease is higher.

TREATMENT

Primary Melanoma

Once melanoma is diagnosed, the standard treatment is surgical excision. Several prospective randomized trials have been conducted to define the optimal surgery for primary melanoma.[1] The extent of the surgery depends on the thickness of the primary melanoma. Large surgical excisions are no longer required, and most wide excisions can be performed with primary closure. For melanoma in situ, excision with a 0.5-cm border of clinically normal skin is sufficient. For melanomas less than 1 mm thick, a 1-cm margin is recommended. If the thickness is between 1 and 4 mm, a 1- to 2-cm margin is recommended. For melanomas thicker than 4 mm, at least a 2-cm margin should be taken. In cosmetically sensitive areas (face) or anatomically difficult areas (ear, hands), it may be difficult to achieve the desired margin, but at least a 1-cm margin should be obtained whenever possible.

Management of Regional Lymph Nodes

Clinically Normal Regional Lymph Nodes

In approximately 10 to 20% of patients who do not have clinically apparent lymph node involvement, lymph nodes contain occult micrometastases. The risk for occult lymph node involvement rises with increasing tumor thickness. Results from randomized trials fail to show a survival benefit from elective or prophylactic lymph node dissections in patients with clinically negative lymph nodes.

Sentinel lymph node biopsy (SLNB) is a technique that accurately evaluates whether microscopic melanoma cells involve regional lymph nodes. The technique relies on the concept that specific regions of the skin drain specifically to an initial lymph node within the regional nodal basin through an organized pathway of afferent lymphatic channels. This technique is performed by injecting the primary melanoma site with blue dye (isosulfan blue) or radiolabeled colloid, or both. When both modalities are used in combination, a sentinel node can be identified in 98% of patients; biopsy of the node accurately determines whether melanoma cells have metastasized to that specific lymph node basin. The sentinel node technique also promotes a more comprehensive histologic examination of lymph nodes because limited amounts of pathologic material are submitted.

SLNB allows earlier identification of metastases and earlier lymphadenectomy.[2] The likelihood of detecting melanoma in SLNB increases with thickness of the primary lesion providing the rationale for determining which patients may benefit from the procedure. SLNB is recommended to patients with melanoma 1 mm thick or thicker. The use of this technique for patients with thinner melanomas, that is, less than 1 mm thick, is controversial. The SLNB is generally performed at the same time as the wide excision of the primary tumor. If the SLNB is negative for melanoma, no further lymph node surgery is required. If melanoma is detected by the SLNB, complete lymph node dissection remains the standard of care. SLNB is a useful staging tool; however, its impact on the overall survival of patients is uncertain.

Clinically Apparent Regional Lymph Nodes

Surgical (therapeutic) lymphadenectomy is the preferred treatment of cytologically (fine-needle aspiration) positive or pathologically proven regional lymph node involvement with melanoma. The goal is to provide long-term, disease-free survival and reduce local morbidity of enlarged lymph nodes.

Adjuvant Therapy

Postsurgical adjuvant therapy can be considered for patients at high risk for recurrence (melanomas ≥4 mm thick or node-positive disease). These patients have at least a 25 to 75% chance of dying of melanoma. Adjuvant treatment options include interferon-α (IFN-α), enrollment in a clinical trial, or observation. High-dose IFN-α is the only U.S. Food and Drug Administration (FDA)-approved adjuvant therapy for patients with melanoma. Randomized clinical trials have shown that therapy with IFN-α can prolong disease-free survival but has not improved overall survival.[3] The treatment is given for 1 year and is associated with considerable side effects, which require close monitoring. Intermediate and low doses of IFN-α as well as pegylated IFN-α have also been evaluated in a series of clinical trials. These regimens are not considered standard in the United States but are offered in Europe. Numerous vaccine studies are ongoing but are considered experimental at present.

Treatment and Course of Advanced Melanoma (Stage IV)

The treatment of a patient with metastatic melanoma emphasizes palliation. No evidence indicates that treatment of metastatic melanoma has any impact on survival, which ranges from 5 to 11 months, with a median of 8.5 months. Treatment options include surgery for resection of solitary metastases, single-agent chemotherapy such as dacarbazine, temozolomide (an oral version of dacarbazine), combination chemotherapy, immunotherapy (vaccines, interleukin-2, interferon), or combined immunotherapy. Melanoma can metastasize to virtually any organ, especially the lung, skin, liver, and brain.

The discovery of somatic genetic mutations in melanoma has provided leads for the development of molecularly targeted therapies. The MAP kinase pathway, which is activated in most melanomas due to mutations in *BRAF*, *NRAS*, and *c-kit*, has been the focus of most clinical investigations of signal transduction (kinase) inhibitors. Recent results of a phase I study of PLX4032, a potent and specific BRAF inhibitor in patients with metastatic melanoma whose tumors harbor the V600E BRAF mutation demonstrated a response rate of almost 80% and an estimated median progression free survival of at least 7 months. Recent and preliminary results also show that imatinib can induce regression in patients whose melanoma is driven by *KIT* mutations.

New immunotherapy approaches are being tested in patients with advanced melanoma. Encouraging results have been reported with ipilimumab, which blocks cytotoxic T-lymphocyte antigen 4 (CTLA-4) in patients with metastatic melanoma.[4]

Surveillance and Follow-up

Patients should be educated on the clinical characteristics of melanoma, the importance of safe sun strategies, and the performance of monthly self-examinations of the skin. Patients should be followed regularly for evidence of local or regional recurrence, distant metastatic disease, and a second primary melanoma. The intensity of the surveillance and the extent of the investigation is influenced by risk for recurrence with more frequent follow-up visits in patients who have thicker tumors or node-positive disease because these patients are at greater risk for recurrence.

For patients with low-risk melanoma (≤1 mm), visits are recommended every 6 months for 2 years and then annually. The surveillance guidelines for patients with high-risk melanoma include evaluation every 3 to 4 months for 2 years, then every 6 months for 3 years. After 5 years, patients are seen once a year. Patients are generally followed for 10 years. However, lifelong dermatologic examination is recommended, particularly for patients with dysplastic nevi or a family history of melanoma. In general, a history and physical examination are performed at each visit. Periodic chest radiographs, laboratory studies, and other imaging studies are performed at the discretion of the treating physician. The physical examination should include a thorough skin examination, because at least 3% of patients develop an additional primary cutaneous melanoma within 3 years. Regional lymph nodes should be thoroughly examined, especially in patients without prior nodal surgery. For the remainder of the examination, one should keep in mind the frequency of metastases to lung, liver, and brain. Follow-up studies may include a complete blood cell count and chemistry studies, including liver enzyme tests. An elevated lactate dehydrogenase level suggests metastatic melanoma.

PREVENTION

The most important measures to prevent melanoma are to reduce excessive sun exposure, particularly to the midday sun, and to avoid sunburns. Sunscreen products with a sun protection factor of 15 or greater and protective clothing are recommended, and one randomized trial found that regular sunscreen use reduced incident melanoma by 50% and invasive melanoma by 75%.[5] Sunscreens block primarily UVB rays, which are considered to be the major causative agent of cutaneous cancers. Newer sunscreen products also block UVA rays, which may contribute to the risk of melanoma.

Screening for skin cancer, whether by self-examination or by a health care provider, is controversial (Chapter 14). Many public health experts do not recommend screening for adults in the general population, but some organizations do. On the basis of the type and number of nevi, family history of melanoma, prior melanoma, and history of severe sunburns, clinicians can identify patients who are at high risk for melanoma and who may benefit from screening programs. In several population studies, screening has detected melanomas at an earlier, curable stage. Physicians, other health care providers, and the public should be educated regarding the early signs of melanoma and the need for prompt biopsy of a suspicious pigmented lesion.

Patients with clinically atypical nevi (see Fig. 210-2), particularly if they have a family history of melanoma, require a regular dermatologic surveillance program. Regular skin examinations should be performed every 6 to 12 months, preferably assisted by the use of serial photography.

Recent studies have focused on the impact of vitamin D levels on the risk for melanoma, and results have been conflicting. The potential health benefits of vitamin D continue to be evaluated, both in terms of melanoma prevention and risk.

BASAL AND SQUAMOUS CELL SKIN CANCER

Nonmelanoma skin cancer (basal cell cancer [BCC] and squamous cell skin cancer [SCC]) is the most common malignant disease in the United States. Although national statistics are imprecise, an estimated 900,000 to 1,200,000 of nonmelanoma skin cancers are diagnosed annually in the United States. SCC accounts for 20%, and most of the remainder are BCC. SCC is

associated with a higher absolute mortality rate; most of the 2300 annual deaths from nonmelanoma skin cancer in the United States arise from this tumor.

EPIDEMIOLOGY

Overall, skin cancer incidence rates are rising because of increased recreational sun exposure, longer life expectancy, and depletion of the ozone layer. More than 99% of nonmelanoma skin cancers occur in whites. These skin cancers are most commonly seen in elderly persons, especially those with fair skin and long-standing sun exposure. However, nonmelanoma skin cancers are increasingly being seen in people in their 30s and 40s. The lifetime risk of developing BCC is 30%.

PATHOBIOLOGY

BCC arises from a pluripotential stem cell within the skin. Acquired mutations in the patched gene 1 *(PTCH1),* a tumor suppressor gene in the hedgehog signaling pathway, have been identified in cases of sporadic BCC. Sporadic BCC are also associated with mutations in the genes encoding p53 and ras.

SCC of the skin is a malignant disease of epidermal keratinocytes. Many such carcinomas are derived from actinic keratoses, a precursor that appears as a rough, scaly, often erythematous papule, which often is more apparent on palpation than on visual examination. Estimates of the likelihood of progression of actinic keratoses to squamous cell carcinoma range from 0.025% to as high as 20%. Mutations in the gene encoding the p53 protein and in the *RAS* oncogene have been found in both actinic keratoses and squamous cell carcinomas. Mutations in *p16* have also been reported in squamous cell carcinomas.

Risk Factors

The most important risk factor is exposure to UV radiation from sunlight. The most clearly established association is with UVB radiation, but increasing evidence suggests that UVA is probably carcinogenic as well (Chapter 19). The timing and pattern of sun exposure are associated with different types of skin cancer. In general, SCC is associated with cumulative sun exposure and occurs most frequently in areas maximally exposed to the sun (e.g., the face, back of hands, and forearms). Intermittent, intense exposure to the sun, particularly in childhood, is associated with an increased risk for BCC. Individuals who have fair skin, light-colored eyes, red hair, a tendency to burn rather than tan, and a history of severe sunburns are at increased risk for nonmelanoma skin cancers. Other risk factors, primarily for SCC, include chronic arsenic exposure, therapeutic radiation, chronic inflammatory skin conditions, psoralen plus UVA (PUVA) treatment for psoriasis and other diseases, and immunosuppression. Most cases in African American patients are associated with scarring or burns rather than UV exposure. Human papillomavirus infection (Chapter 381) has also been implicated in some SCCs, particularly in the autosomal dominant disorder epidermodysplasia verruciformis.

BCC can be seen in association with several conditions, including the basal cell nevus syndrome (also called nevoid basal cell carcinoma syndrome or Gorlin's syndrome), albinism, and xeroderma pigmentosum. The basal cell nevus syndrome is a rare autosomal dominant disorder caused by germline mutations in the patched gene *(PTCH).*

CLINICAL MANIFESTATIONS

Basal Cell Carcinoma

Approximately 90% of BCCs occur on sun-exposed areas such as the face, neck, ears, scalp, and arms. The nose is the most common site. Typical BCC appears as slowly growing, shiny, skin-colored to pink translucent papules with telangiectasia and a "pearly" rolled border (Fig. 210-6). As the tumor grows, the center may become ulcerated and bleed, although there is usually no associated pain or tenderness. BCC rarely metastasizes and is usually curable with a variety of treatments. Although the mortality rate is low, these cancers may result in significant morbidity owing to invasive local growth with potential disfigurement and destruction of skin, bone, and cartilage. Clinical trials with inhibitors of the hedgehog pathway for patients with advanced BCC are under way, with very encouraging clinical activity demonstrated.

Squamous Cell Carcinoma

This type of skin cancer usually appears on areas of skin that are heavily damaged by sun exposure. The most common sites include the head or neck, back, forearms, and dorsum of the hand. Clinically, SCC occurs as a discrete scaly erythematous papule on an indurated base that can develop on normal-appearing skin or on an actinic keratosis (Fig. 210-7). The lesion may grow over time and may become ulcerated, itchy, painful, or bleeding. Keratoacanthoma is a variant that is characterized by rapid growth and a crateriform appearance with a central plug. Bowen's disease, or squamous cell carcinoma in situ, manifests as an erythematous, scaly, sharply defined plaque.

FIGURE 210-6. Basal cell carcinoma.

FIGURE 210-7. Squamous cell carcinoma of the skin.

Untreated SCC may cause significant local destruction. However, unlike BCC, SCC carries a 0.5 to 5% risk for metastasis. Higher-risk lesions are those that are larger than 2 cm, are moderately or poorly differentiated, have perineural involvement, or are located on the ear or the lip, arise in scars, or occur in immunosuppressed patients. Most metastases develop in regional lymph nodes, although metastases may also occur in lung, liver, brain, skin, or bone. For patients with lymph node metastases, the 5-year survival rate is less than 50%.

DIAGNOSIS

The diagnosis of BCC and SCC is frequently suspected by inspection alone, but histologic confirmation is usually indicated. Either a shave or a punch biopsy technique is acceptable (Chapter 444). Care should be taken to include the base of the lesion if a shave biopsy technique is used.

TREATMENT

Basal Cell Carcinoma

BCCs are classified as low or high risk, based on their clinical features, location, and histology. Treatment options includes cryotherapy (liquid nitrogen), electrosurgery (i.e., curettage and electrodessication), topical treatment (i.e., 5-fluorouracil, photodynamic therapy, or imiquimod), surgical excision, Mohs' surgery, or radiation therapy. Mohs' microsurgery should be considered when treating recurrent cases; microscopically aggressive forms, such as the morpheaform subtype; lesions greater than 2 cm in greatest diameter; and tumors of the ears, eyelids, nose, nasolabial folds, and lips. Cure rates for BCC range between 90 and 99%.

Squamous Cell Carcinoma

As with BCC, SCC can also be cured by traditional surgical excision or Mohs' surgery, cryotherapy, topical therapies, and radiation therapy. Topical 5-fluorouracil, photodynamic therapy, or imiquimod have a role in the management of in situ squamous cell cancers. The optimal approach for a specific patient requires consideration of likelihood of the lesion recurring or metastatic potential, cosmetic factors, and the expertise of the treating physicians.

Mohs' micrographic surgery provides the lowest recurrence rate, with cure rates greater than 90%. Mohs' microsurgery is especially useful for recurrent tumors or lesions that have an increased risk of metastasis.

Follow-up

Patients with BCC and SCC require ongoing follow-up to detect local recurrences and to recognize new skin cancers. The likelihood of developing a second basal cell carcinoma or squamous cell carcinoma has been estimated to be 15% over 3 years. In addition, these patients have an increased risk of developing cutaneous melanoma. Patient education regarding modification of risk factors (i.e., sun exposure) is an important component of follow-up.

PREVENTION

Primary prevention strategies are aimed at reducing long-term sun exposure. Public education and patient education should encourage the regular use of sunscreens with a sun protection factor of 15 or greater, especially in childhood, and sun-protective clothing (e.g., a broad-brimmed hat). Avoidance of tanning parlors and minimizing of total sun exposure, especially to the midday sun, is recommended. The thinning of the ozone layer has been linked to increased UV radiation and increases in the incidence of nonmelanoma skin cancers. Currently, no evidence indicates that total body skin examination is effective at reducing mortality or morbidity from nonmelanoma skin cancer.

CANCER OF UNKNOWN PRIMARY ORIGIN

JOHN D. HAINSWORTH AND F. ANTHONY GRECO

DEFINITION

The first signs or symptoms of cancer are frequently the result of metastases to visceral or nodal sites. In most such patients, routine clinical evaluation with a comprehensive history, physical examination, complete blood cell count, screening chemistries, and directed radiologic studies based on specific symptoms or signs identifies the primary tumor. Patients who have no primary tumor located after this routine clinical evaluation are defined as having cancer of unknown primary origin. Further clinical and pathologic evaluation identifies the primary site in only a few patients, and approximately 80% never have a primary site identified during their subsequent clinical course.

EPIDEMIOLOGY

In patients whose primary site of cancer remains undetectable, the primary site has presumably remained small or, less likely, regressed spontaneously. Before the routine use of computed tomography (CT) or magnetic resonance imaging (MRI) for diagnosis, large autopsy series identified small primary sites of cancer in 85% of patients with previously unidentified primary tumors, usually in the pancreas, lung, and various other gastrointestinal sites; with the use of CT and MRI for diagnosis, however, primary sites are identified at autopsy in only 50 to 70% of patients.

Approximately 3% of all patients with cancer have metastatic disease without a known primary site; the annual incidence is approximately 50,000 to 60,000 cases in the United States. Cancer of unknown primary site occurs with approximately equal frequency in men and women, and it increases in incidence with advancing age.

DIAGNOSIS

The initial clinical and pathologic evaluation should focus on identifying a primary site, when possible, and on identifying patients for whom specific treatment is indicated. In most patients with cancer of unknown primary site, the diagnosis of advanced cancer is strongly suspected after the initial history and physical examination. A brief additional evaluation, including complete blood cell counts, chemistry profile, and CT of the chest and abdomen, should be performed. Any specific symptoms or signs should be evaluated with appropriate radiologic and endoscopic studies.

Biopsy

The diagnosis of metastatic cancer should be confirmed by biopsy of the most accessible metastatic lesion. Fine-needle aspiration may or may not provide sufficient material for optimal histologic examination and special pathologic procedures. If tissue is inadequate, a larger biopsy sample should be obtained so that all necessary stains and special studies can be performed.

The initial light microscopic evaluation identifies adenocarcinoma in approximately 60% of patients with cancer of unknown primary site. Other diagnoses obtained by initial light microscopy include poorly differentiated carcinoma (25%), squamous carcinoma (10%), and poorly differentiated neoplasm (inability to distinguish among carcinoma, lymphoma, melanoma, and sarcoma; 5%).

In patients with adenocarcinoma, it is seldom possible for the pathologist to determine a primary site by light microscopic characteristics or with additional pathologic techniques. Specific exceptions include immunoperoxidase staining for prostate-specific antigen (PSA), which is relatively specific for adenocarcinoma of the prostate (Chapter 207); for estrogen and progesterone receptors, which are suggestive of breast cancer (Chapter 204); and for leukocyte common antigen, which can identify non-Hodgkin's lymphoma (Chapter 191) as the primary tumor in up to 50% of patients with poorly differentiated neoplasms. Other diagnoses suggested by immunoperoxidase staining include neuroendocrine carcinomas, melanomas (Chapter 210), and sarcomas (Chapter 209). Electron microscopy should be considered when light microscopy and immunoperoxidase staining fail to identify the tumor, especially in young patients with anaplastic tumors; specific ultrastructural features may suggest neuroendocrine carcinoma (neurosecretory granules), melanoma (premelanosomes), and certain sarcomas.

Occasionally, detection of a tumor-specific chromosomal abnormality can provide a definitive diagnosis. Cancers with recognized specific chromosomal abnormalities include germ cell tumors (i12p; Chapter 206), peripheral neuroepithelioma and Ewing's tumor (t11;22; Chapter 208), and non-Hodgkin's lymphoma (Chapter 191). Chromosomal analysis should therefore be considered, especially in young men who have poorly differentiated mediastinal or retroperitoneal tumors and in whom other pathologic studies have been inconclusive.

Recently, specific gene expression profiles based on the tissue of origin have been identified for many tumor types. Several currently available multigene assays have 80 to 90% accuracy in determining the tissue of origin when performed on metastatic tissue in patients with tumors of known origin. The contribution of molecular profiling to the diagnosis and management of carcinoma of unknown primary site is still being defined; however, it is likely to

TABLE 211-1 RECOMMENDED EVALUATION FOLLOWING INITIAL LIGHT MICROSCOPIC DIAGNOSIS

DIAGNOSIS	CLINICAL EVALUATION*	SPECIAL PATHOLOGIC STUDIES
Adenocarcinoma (or poorly differentiated adenocarcinoma)	PET CT of chest, abdomen Men: serum PSA Women: mammogram Additional directed radiologic or endoscopic studies to evaluate abnormal symptoms, signs, laboratory values	Men: PSA stain Women: estrogen and progesterone receptor stains (if clinical features suggest metastatic breast cancer)
Poorly differentiated carcinoma	PET CT of chest, abdomen Serum hCG, AFP Additional directed radiologic or endoscopic studies to evaluate abnormal symptoms, signs, laboratory values	Immunoperoxidase staining Electron microscopy (if immunoperoxidase stains indeterminate)
Squamous carcinoma, cervical nodes	PET Direct laryngoscopy with visualization; biopsy of nasopharynx, pharynx, hypopharynx, larynx Fiberoptic bronchoscopy (if laryngoscopy is negative)	—
Squamous carcinoma, inguinal nodes	PET Complete examination of perineal area (including pelvic examination) Anoscopy Cystoscopy	—

*In addition to a history, physical examination, complete blood cell counts, chemistry profile, and chest radiograph.
AFP = α-fetoprotein; CT = computed tomography; hCG = human chorionic gonadotropin; PET = positron emission tomography; PSA = prostate-specific antigen.

have an important role in the future both in diagnosing the site of tumor origin and in allowing more site-specific therapy.

Search for the Primary Site

After completion of the brief, directed initial evaluation outlined previously, further diagnostic studies should be limited (Table 211-1). Positron emission tomography (PET) identifies a primary site and guides therapy in about one third of patients, so it should be obtained in all patients with an initially unknown primary tumor. By comparison, other routine radiologic and endoscopic evaluations of asymptomatic areas are not useful in identifying a primary site and therefore are not recommended. Levels of serum tumor markers, including carcinoembryonic antigen, CA-125, CA-19-9, and CA-15-3, are frequently increased in patients with carcinoma of unknown primary site; however, these elevations are nonspecific and should not be used to infer a primary site, even though they can be useful in monitoring response to treatment.

In all men with metastatic adenocarcinoma, serum PSA should be measured. Mammograms and breast MRI should be considered in women with metastatic adenocarcinoma, particularly if clinical features are consistent with metastatic breast cancer (e.g., axillary node involvement, pleural effusion, lytic or blastic bone metastases). In patients younger than 50 years with poorly differentiated carcinoma, serum human chorionic gonadotropin and α-fetoprotein levels should be measured. Patients with metastatic squamous carcinoma involving cervical lymph nodes should have a thorough endoscopic evaluation of the head and neck, including visualization of the structures from the nasopharynx to the larynx and biopsy of any suspicious areas (Chapter 196). Fiberoptic bronchoscopy should also be considered in patients who have low cervical adenopathy and in whom no head or neck primary site is established by endoscopic examination. In patients with metastatic squamous carcinoma involving inguinal lymph nodes, all perineal structures should be carefully inspected, including anoscopy, a urologic evaluation, and a pelvic examination in women.

TREATMENT

Rx

Management of Specific Treatable Subsets

Because patients with cancer of unknown primary site have advanced disease, therapeutic nihilism has been common. However, several subsets of patients can benefit from specific treatment, and they can be identified on the basis of clinical and pathologic features (Table 211-2). These patients are important to recognize and treat appropriately, because some individuals in each group have the potential for long-term survival.

Adenocarcinoma

Women with Axillary Lymph Node Metastases

Metastatic breast cancer should be suspected in women who have axillary lymph node involvement with adenocarcinoma, particularly when other metastatic sites are not evident. In these patients, pathologic evaluation of the initial lymph node biopsy should include staining for estrogen and progesterone receptors and for HER-2 expression; elevated levels provide strong evidence for the diagnosis of breast cancer. When no other metastases are identified, these women should be treated as if they had stage II breast cancer, which is potentially curable with appropriate therapy (Chapter 204). Modified radical mastectomy identifies a breast primary site in 44 to 82% of women, even when the breast examination and mammographic findings are normal. Axillary lymph node dissection followed by radiation therapy to the breast appears to give results similar to those of mastectomy, although these two options for primary therapy have not been compared directly. Adjuvant systemic therapy should follow standard guidelines for the treatment of women with stage II breast cancer.

Women with Peritoneal Carcinomatosis

Adenocarcinoma involving the peritoneum in women usually originates from the ovary (Chapter 205), although carcinomas arising in the gastrointestinal tract or breast can occasionally produce this syndrome. However, diffuse peritoneal carcinomatosis occasionally occurs in women who have histologically normal ovaries or who have had previous bilateral oophorectomy. The peritoneum is frequently the only site of tumor involvement, and serum CA-125 levels are usually elevated. When histologic features suggest ovarian cancer, this syndrome has been called *peritoneal papillary serous carcinoma* or *primary extraovarian serous carcinoma.*

Even when the histologic features are not typical, women with adenocarcinoma of unknown primary site involving the peritoneum often have cancers with biologic characteristics similar to those of ovarian cancer (Chapter 205). Treatment of these patients should follow guidelines for stage III ovarian cancer. When feasible, a full laparotomy with maximal surgical cytoreduction should be performed, followed by combination chemotherapy with a taxane/platinum–containing regimen. Measurement of serial serum CA-125 levels provides an accurate assessment of the efficacy of treatment. A few of these patients may have complete responses and long-term survival, particularly when initial surgical cytoreduction leaves minimal residual disease. A similar syndrome of peritoneal carcinomatosis that is responsive to chemotherapy for ovarian cancer has occasionally been reported in men.

Men with Skeletal Metastases and/or Elevated Serum Prostate-Specific Antigen Levels

Metastatic prostate cancer (Chapter 207) should be suspected in men with adenocarcinoma predominantly involving bone, particularly if the metastases are blastic. An elevated serum PSA level or tumor immunostaining for PSA confirms the diagnosis of prostate cancer. Occasionally, men with adenocarcinoma of unknown primary site and patterns of metastasis unusual for prostate cancer (e.g., lung metastases, mediastinal lymph node metastases) are found to have elevated serum PSA levels. These patients should be treated according to guidelines for advanced prostate cancer. Androgen ablation produces excellent responses and substantial palliation in most patients.

Single Metastatic Lesion

Occasionally, a single metastatic lesion containing adenocarcinoma or poorly differentiated carcinoma is identified, and a complete evaluation reveals no other evidence of disease. Such presentations can include a single

TABLE 211-2 SPECIFIC PATIENT SUBSETS AND RECOMMENDED TREATMENT

Subset-Identifying Features		
HISTOLOGIC	**CLINICAL**	**TREATMENT RECOMMENDATIONS**
Adenocarcinoma	Women, isolated axillary adenopathy	Treat as stage II breast cancer
Adenocarcinoma	Women, peritoneal carcinomatosis (Occasionally men?)	Treat as stage III ovarian cancer
Adenocarcinoma	Men, elevated PSA and/or blastic bone metastases	Treat as advanced prostate cancer
Adenocarcinoma, poorly differentiated carcinoma	Single metastatic lesion	Definitive local therapy (resection and/or radiation therapy) with or without chemotherapy
Adenocarcinoma	Colon cancer profile	Treat as metastatic colorectal cancer
Squamous	Cervical adenopathy	Treat as locally advanced head or neck cancer
Squamous	Inguinal adenopathy	Definitive local therapy (node dissection with or without radiation therapy) with or without chemotherapy
Poorly differentiated carcinoma	Young men with midline tumor and/or elevated hCG, AFP	Treat as extragonadal germ cell tumor
Poorly differentiated carcinoma	Diverse clinical features	Empirical chemotherapy with paclitaxel, ,platinum, etoposide
Neuroendocrine carcinoma, poorly differentiated	Diverse clinical presentations	Treat with platinum, etoposide
Neuroendocrine carcinoma, well differentiated	Usually liver metastases	Treat as metastatic carcinoid tumor

AFP = α-fetoprotein; hCG = human chorionic gonadotropin; PSA = prostate-specific antigen.

lymph node or subcutaneous site or single lesions at various visceral sites, including bone, liver, lung, brain, and adrenal gland. The possibility of an unusual primary site mimicking a metastatic lesion should be considered (e.g., a subcutaneous nodule from a primary apocrine or sebaceous carcinoma rather than a metastasis), but this possibility can usually be excluded on the basis of clinical or pathologic features. PET is useful in excluding other metastatic lesions. For patients with only a single identifiable lesion, definitive local therapy is recommended, guided by the site of tumor involvement. Such therapy may include surgical resection, radiation therapy, or a combination of these modalities. Although most of these patients eventually develop other metastatic sites, a significant disease-free interval is often experienced, and local treatment provides substantial palliation. The role of systemic chemotherapy in addition to definitive local therapy is not well defined; younger patients with poorly differentiated carcinoma or poorly differentiated adenocarcinoma are often treated with a short course of a taxane/platinum–based regimen (see Empirical Chemotherapy).

Colon Cancer Profile

The accurate recognition of patients likely to respond to colon cancer regimens has become increasingly important as treatment for this cancer has improved substantially. A "colon cancer profile" has been defined and includes (1) metastases predominantly in the liver and/or peritoneum, (2) adenocarcinoma with histologic features typical of gastrointestinal origin, and (3) typical immunohistochemical staining that is CK20 positive, CK7 negative, and CDX-2 positive. Patients with this profile should be treated according to guidelines for metastatic colorectal cancer (Chapter 199).

Squamous Carcinoma

Cervical Adenopathy

Squamous carcinoma of unknown primary site is relatively uncommon. Most patients with this syndrome have involvement of cervical lymph nodes, usually in the upper or midcervical area. Often, patients with this syndrome are middle-aged or elderly and have a history of substantial tobacco or alcohol use or both. A primary site in the head and neck region should be suspected (Chapter 196); however, complete endoscopic evaluation fails to identify a primary site in approximately 15% of these patients. Even if other tests are negative, PET identifies a primary site in the head and neck region in approximately 25% of such patients and should be part of the initial evaluation.

Even when no primary site is identified, management of these patients should follow standard guidelines for the treatment of locally advanced squamous carcinoma arising in the head and neck. Many reports have documented long-term survival rates of 30 to 60% following definitive local treatment, which should include radiation therapy or combined radiation and cervical lymph node dissection. Outcome of treatment depends on the size and number of involved cervical lymph nodes. Concurrent chemotherapy and radiation therapy are now considered the standard treatment approach for patients with locally advanced head and neck cancers and should be considered in patients with multiple involved lymph nodes or nodes larger than 2 cm in diameter (Chapter 196).

Inguinal Adenopathy

Occasionally, metastatic squamous cancer is found in inguinal lymph nodes. In most of these patients, a primary site can be located in the perineal or anorectal area. For the occasional patient in whom no primary site is identified, long-term survival can result from local therapy with inguinal lymph node dissection, with or without radiation therapy. Recently, combined-modality treatment with concurrent chemotherapy and radiation therapy has improved cure rates in patients with several squamous cancers arising in this region (e.g., cervix, anus, bladder). Although data are incomplete, a reasonable approach is the addition of chemotherapy with a platinum/5-fluorouracil regimen, as described for locally advanced carcinoma of the cervix.

Poorly Differentiated Carcinoma

Extragonadal Germ Cell Cancer Syndrome

Young men with clinical features of extragonadal germ cell tumors, including tumors in the mediastinum or retroperitoneum or those associated with elevated serum levels of human chorionic gonadotropin or α-fetoprotein, should be treated according to guidelines for extragonadal germ cell tumors (Chapter 206). Some of these patients can be proved to have germ cell tumors by identifying an i12p chromosomal abnormality, even when the diagnosis is not possible with other standard pathologic techniques. Approximately 30 to 40% of these patients achieve complete responses and long-term survival following chemotherapy with cisplatin, etoposide, and bleomycin, as used for advanced germ cell tumors.

Anaplastic Lymphoma

An appropriate initial pathologic evaluation should identify most histologically atypical lymphomas. Occasionally, immunoperoxidase staining for leukocyte common antigen is negative or cannot be adequately performed in patients with anaplastic lymphoma. The disease in some of these patients can be recognized using other immunoperoxidase stains (e.g., Ki-1, CD-30) or molecular genetic analysis (detection of immunoglobulin gene rearrangements). All patients with lymphomas identified by special pathologic studies should be treated using standard guidelines for aggressive non-Hodgkin's lymphoma (Chapter 191).

Neuroendocrine Carcinoma

In approximately 10% of poorly differentiated carcinomas, neuroendocrine features are identified by either immunoperoxidase staining or electron microscopy. Treatment of these patients is discussed later (see Neuroendocrine Carcinoma).

Other Poorly Differentiated Carcinomas

In most patients with poorly differentiated carcinoma, there are no clinical or pathologic features that allow their assignment to one of the three preceding subsets. However, this heterogeneous group contains some patients whose carcinomas are highly sensitive to platinum-based chemotherapy. Clinical factors predictive of sensitivity to chemotherapy include site of tumor involvement (lymph nodes as compared with visceral metastases), fewer sites of metastatic disease, and younger age. In selected patients with one or more of these favorable clinical features, treatment with cisplatin-based

chemotherapy can produce a greater than 60% response rate, and approximately 15% of patients remain free of disease more than 8 years after completing treatment. Therefore, a brief trial of empirical chemotherapy (see later) is recommended for all patients with poorly differentiated carcinoma, unless they are extremely debilitated at the time of diagnosis. Patients with highly sensitive tumors can be identified within the first 4 to 6 weeks of treatment, and ineffective treatment can be discontinued in the remainder.

Neuroendocrine Carcinoma

Poorly Differentiated Neuroendocrine Carcinoma or Small Cell Anaplastic Carcinoma

These high-grade neuroendocrine tumors are now reliably identified using widely available immunoperoxidase stains. Although the origin of these tumors remains unknown, they are often highly sensitive to combination chemotherapy; with platinum/etoposide chemotherapy, the overall response rate is about 75%, and 25% of patients have complete responses. In patients with locoregional disease, the addition of radiation therapy following chemotherapy is reasonable.

Low-Grade (Carcinoid-Type) Neuroendocrine Tumors

Occasionally, low-grade neuroendocrine tumors are found at a metastatic site. In almost all cases, the liver is the site of involvement, and the histologic features suggest a carcinoid (Chapter 240) or islet cell tumor of gastrointestinal origin (Chapter 201). Various clinical syndromes caused by the secretion of vasoactive peptides (e.g., serotonin, vasoactive intestinal peptide, gastrin) have been described. Like other carcinoid tumors, these tumors often have indolent biologic characteristics, and patients can frequently survive for several years despite multiple liver metastases. Unlike poorly differentiated neuroendocrine tumors, these tumors are relatively resistant to chemotherapy, and intensive combination regimens should usually be avoided. Management of these patients should follow guidelines for metastatic carcinoid tumors (Chapter 240) and may include the use of somatostatin analogues, local ablative procedures (e.g., surgical resection, radiofrequency ablation, chemoembolization), targeted agents (e.g., sunitinib, everolimus), or fluorouracil-based chemotherapy regimens.

Empirical Chemotherapy

Approximately 60 to 70% of patients with carcinoma of unknown primary site do not fit into any of these defined clinical subsets. In these patients, earlier reports of empirical chemotherapy were discouraging, with overall response rates of only 20 to 25% and short median survival times (5 to 7 months). The combination of paclitaxel (200 mg/m^2 IV on day 1) and carboplatin (AUC 6.0 IV on day 1), with or without etoposide (50 mg alternating with 100 mg PO on days 1 to 10), all repeated every 21 days for four courses, produces objective responses in 30 to 45% of patients, with median survival in the 9- to 12-month range. In addition, a few patients obtain a major benefit from treatment; the 2-year survival rate with taxane-containing regimens is 20 to 25%. Regimens containing gemcitabine and cisplatin have produced similar results. The most effective treatment is unknown because randomized comparisons are lacking in this area.

At present, patients with carcinoma of unknown primary site who have a reasonable performance status should be considered for an empirical trial of combination chemotherapy. Patients with responsive tumors can be identified after 4 to 6 weeks of treatment, and they should continue treatment for a standard 4- to 5-month course. Patients who do not respond to initial combination chemotherapy are unlikely to respond to further treatment; palliative care is appropriate in these patients (Chapter 3). For patients who have a poor performance status at the time of diagnosis, palliative care alone is an appropriate approach.

APPROACH TO INBORN ERRORS OF METABOLISM

LOUIS J. ELSAS II

DEFINITION

Metabolism is a collective term for integrated biochemical processes that enables homeostasis for the organism by maintaining anabolic and catabolic flow of substrates to products. Inborn errors of metabolism refer to single gene disorders producing loss of function of a single protein that results in altered concentrations of linked metabolites in the reaction sequence.

HISTORY

In the early 20th century, Garrod recognized heritable blocks in normal human metabolic flow that conformed to mendelian mechanisms of inheritance. He first coined the term *inborn error of metabolism,* describing four diseases—alkaptonuria, albinism, cystinuria, and pentosuria. Garrod presumed that a patient expressing the full abnormality was homozygous for mutant alleles affecting a specific metabolic flow whereas the parents were heterozygous for this same inherited block but were clinically normal. The enzyme defect in alkaptonuria was not discovered until 50 years later, when homogentisic acid oxidase was found impaired in the liver and kidneys of patients with this disease. Twenty years ago, the gene for homogentisate 1,2-dioxygenase was cloned, and mutations causing altered function were defined.

Over the past two decades, advances in technology such as fast throughput, genome-wide DNA sequencing, tandem mass spectrometry, and bioinformatics have confirmed Garrod's postulate of chemical individuality and resulted in the discovery of more than 1321 catalogued inborn errors of metabolism, as well as vigorous research exploring normal and abnormal inherited variation in human metabolism for common conditions such as obesity and cancer. The implementation of public health–based newborn screening using these modern technologies defined the clinical power of genetics in presymptomatic prediction and prevention of more than 40 inborn errors.

PATHOBIOLOGY

Protein Diversity

Variations in human proteins do not usually produce disease. Heritable diversity in proteins within normal populations is required for optimal health (e.g., the ability of the immune system to produce γ-globulin in response to a wide range of antigenic epitopes). Nucleotide sequence variations in genes may produce different amino acid changes in the primary protein structure without producing a functional change. When no functional change occurs, the alteration is considered a *polymorphism.* The term *single nucleotide polymorphism* (SNP) is now used to define an individual's diversity after scanning the entire human genome. Continued research is trying to link genomic SNPs to regulatory RNA, messenger RNA, and protein and metabolic variations. Chromatographic separation of physiologic fluids followed by tandem mass spectrometry enables identification of the metabolomic effect of a given SNP on a wide range of molecules, including lipids, amino acids, phospholipids, and glycoproteins.

There are many molecular mechanisms producing normal protein diversity. Normal protein variation can occur through gene rearrangements, as exemplified by the formation of immunoglobins, which give rise to required variations in response to foreign antigens. Post-transcriptional, alternative splicing of RNA is another mechanism for protein variation. There are many examples of alternative splicing that provide organ specificity for protein isoforms. Post-translational modification of proteins produces diversity and is important in directing proteins to subcellular organelles, to the cell surface, or for secretion. Glycosylation of proteins directed to plasma membrane receptors is an example of this post-translational mechanism. As an example of the importance of these mechanisms, consider that humans have more than 250,000 functional proteins but less than 35,000 genes predicted from the human genome sequence. Added to this sequence diversity of proteins are recent biophysical observations that proteins undergo conformational plasticity that can alter their function.

TABLE 212-1 CLASSIFICATION OF PROTEIN FUNCTION BY LOCATION IN ORGANISM

Proteins act as follows:

1. Catalyze plasma membrane functions
   a. Substrate transport
   b. Cellular signaling (receptors)
2. Catalyze integrated metabolic pathways in the cytosol, lysosome, peroxisome, mitochondria, nucleus, and endoplasmic reticulum
3. Circulate in blood and provide and maintain various functions (clotting; metal, lipid, and vitamin transport; immunity; oxygen transport; regulation of proteases, hormones, and adhesion proteins)
4. Maintain structural integrity of organs and organelles (collagen, elastin, actin, dystrophin, and fibrillin)

TABLE 212-2 CLASSIC PATHOLOGIC MECHANISMS FOR INBORN ERRORS OF METABOLISM

1. Accumulation of substrates to toxic concentrations in a blocked catabolic reaction. *Examples:* maple syrup urine disease, galactosemia, glucose-galactose malabsorption, Fabry's disease, Gaucher's disease, urea cycle defects
2. Production of toxic byproducts through a normally minor pathway. *Examples:* tyrosinemia type I, adenosine deaminase deficiency
3. Deficiency of an end product in an anabolic pathway. *Examples:* albinism, orotic aciduria, scurvy, plasminogen deficiency
4. Loss of regulation resulting in overproduction of intermediates to toxic levels. *Examples:* congenital adrenal hyperplasia, acute intermittent porphyria, familial hypercholesterolemia

Mutations

The relatively rare circumstance in which a change in a protein impairs function is called a *mutation,* and it may produce an inborn error of metabolism. Naturally occurring mutations that produce pathology also provide insight into the functional role of normal proteins in human metabolism. Inborn errors of metabolism are classified here in accordance with the organ, cell, and subcellular location of normal protein function (Table 212-1) and the abnormal mechanisms that interfere with normal metabolic flow as a result of impaired proteins (Table 212-2).

Current diagnosis and therapy for inborn errors focus on relatively rare mutations in single genes that have major effects on disrupting metabolic flow. Current and future research will provide predictive tools for identifying variations in the genome and metabolome that produce sensitivity to the environment with onset of common illnesses of adults and an opportunity to intervene and prevent them. This concept is called *personalized medicine.*

The correlation of genes that are transcribed and translated approaches only 20% of the genome in any cell or organ. Network perturbation models for essential metabolic pathways are being defined, particularly in the context of drug-induced adverse events, where heritable variations are diagnosed by personalized genomic microarrays before the drug is given and thereby prevent adverse reactions by avoidance. Microarrays for genomic variation in the cytochrome P-450 genes are now commercially available and will assist in predicting some sensitivities to drugs. Similarly, genome microarrays to predict genetic variation producing early-onset heart, liver, eye, lung, and nervous system diseases, including cancers, are in development.

Pathophysiology

One important clinical aspect in defining the genetic component of a metabolic disease is that one can predict, intervene in, and prevent irreversible pathology by a variety of stratagems before irreversible disease is expressed. In general, the severity of an inborn error of metabolism depends on the degree of protein impairment rendered by the genetic mutation and the trauma induced by the environment. A "leaky" mutation may not be expressed until adulthood, whereas a complete block in the same metabolic pathway is lethal in infancy. The age at onset and severity of disease are a result of complex interactions of the gene, environment, or other genes that modify the underlying genetic susceptibility. The pathophysiologic mechanisms outlined in Table 212-2 may occur individually or may combine to produce loss in homeostasis and a disease state. The clinical manifestations are usually

pleiotropic, which means that one blocked enzyme reaction produces multiple dysfunctions at the organ level. An example is galactosemia, which causes cataracts, ovarian failure, liver disease, and central nervous system dysfunction. The phenotype (clinical outcome) is also affected not only by the specific genetic block but also by alternative metabolic pathways that may remove toxic precursors or supply deficient products of a blocked reaction. Outcome may be adversely affected by an alternative pathway that produces a toxic analyte, and a pathophysiologic mechanism may differ among organs. In galactosemia, the accumulation of galactose can produce excess intracellular galactitol through an alternative pathway catalyzed by aldose reductase and, consequently, cell death of optic lens fibers as a result of the osmotic effect of intracellular galactitol. Accumulation of galactitol causes cataracts, whereas accumulation of galactose 1-phosphate produces hepatic cell death, ovarian failure, and cerebellar dysfunction.

ERRORS IN PROTEINS THAT CAUSE DISEASES

Plasma Membrane Transporter Protein Mutations

Defects of Glucose Transporters

Many disorders are produced by mutant proteins that impair the transport of nutrients into and out of cells (Table 212-3). *Familial glucose-galactose malabsorption syndrome* exemplifies defective transporter proteins and results in the accumulation of nontransported glucose in the intestinal lumen with refractory diarrhea secondary to its osmotic effects. Direct evidence for genetic control of intestinal glucose transport in humans was obtained by in vitro studies of jejunal biopsy material from families in which the affected members expressed refractory diarrhea on ingesting D-galactose or D-glucose but not fructose. Pedigree analysis conformed to autosomal recessive inheritance. These data predicted a gene that coded for a stereospecific, sodium- and energy-dependent transporter protein in human jejunal (and proximal renal tubular) microvilli. Expression cloning of active glucose transport has now confirmed the presence of a family of glucose transporter genes, their deduced amino acid sequences, and specific codon changes producing the syndromes of familial glucose-galactose malabsorption and renal glycosuria. There are many inherited defects involving the plasma membrane transport of glucose that are caused by mutations of either active or facilitative glucose transport. Glucose transporters are a family of proteins whose definitions of function evolved after their cloning and molecular genetic analysis (Table 212-4). An insulin-responsive, facilitative glucose transporter (GLUT4) is not Na^+ dependent and is expressed primarily in insulin-responsive tissues (fat cells, skeletal muscle). More than one glucose transporter is expressed by most cells. The jejunal epithelial cell uses sodium-glucose cotransporter protein 1 (SGLT1) to concentrate glucose from its luminal surface into the cytosol, then effluxes glucose at its basal-lateral surfaces through GLUT2. GLUT2 is also involved in regulating the amount of glucose transported into β cells of the pancreas, a process that regulates glucose stimulation of insulin release. Indirect evidence suggests that mutations in the *GLUT2* gene are "sensitivity genes" involved in regulating insulin secretion.

Many other facilitative human glucose transporters have been identified by expressed sequence tags (EST) homology searches (GLUT 5, 6, 7, 8, 9, 10, 11, 12, 13). While GLUT5 and GLUT7 have functional assignments as a fructose transporter and as an exporter of glucose from the endoplasmic reticulum, respectively, the functions of these other glucose transporter isoforms are not clearly defined.

Plasma Membrane Receptor Protein Dysfunction

Parathyroid Hormone Resistance

Many diseases characterized by "hormone resistance" are caused by a family of proteins that function as receptors in the plasma membrane and as postreceptor transmitters of signals located in the cytosol and nucleus. The concept of failure to respond to hormone stimulation originated in the early 1940s with a description of *pseudohypoparathyroidism* (Chapter 253). Heritability of resistance to parathormone was suggested before the existence of parathormone receptors, hormone-sensitive adenylate cyclases, or guanine nucleotide-binding proteins was known.

TABLE 212-3 DISEASES CAUSED BY MUTATIONS IN PLASMA MEMBRANE TRANSPORTER PROTEINS

DISEASE	TISSUE AFFECTED	SUBSTRATE	MODE OF INHERITANCE	CLINICAL EXPRESSION
B_{12} malabsorption	Ileum	Vitamin B_{12}	Autosomal recessive	Pernicious anemia
Blue diaper syndrome	Gut	Tryptophan	Autosomal recessive	Hypercalcemia
Primary carnitine deficiency	Kidney + gut	Carnitine	Autosomal recessive	Hypoglycemia, hypotonia
Congenital chloridorrhea	Gut	Chloride	Autosomal recessive	Diarrhea, alkalosis
Cystic fibrosis	Apical epithelia	Chloride	Autosomal recessive	Lung, intestinal obstruction
Cystinuria	Kidney + gut	Cystine + lysine, arginine, ornithine	Autosomal recessive	Renal lithiasis (cystine)
Familial hypophosphatemic rickets	Kidney + gut	Phosphate	X-linked dominant	Rickets
Folate deficiency	Lymphocyte, erythrocyte	Methyltetrahydrofolate	Autosomal recessive	Aplastic anemia
Glucose-galactose malabsorption	Gut + kidney	Glucose and galactose	Autosomal recessive	Refractory diarrhea
Hartnup's syndrome	Gut + kidney	Neutral amino acids	Autosomal recessive (pellagra)	Nicotinic acid deficiency
Hereditary hypophosphatemic rickets	Kidney	Phosphate	Autosomal dominant	Growth restriction, rickets, phosphaturia
Hereditary renal hypouricemia	Kidney	Uric acid	Autosomal recessive	Urolithiasis (uric acid)
Hereditary spherocytosis	Erythrocyte	Sodium	Autosomal dominant or recessive	Hemolytic anemia
Hyperdibasic aminoaciduria (type I)	Kidney	Lysine, arginine, ornithine	Autosomal dominant	Symptoms of growth restriction?
Iminoglycinuria	Kidney + gut	Glycine, proline, hydroxyproline	Autosomal recessive	Benign? Pancreatitis
Isolated lysinuria	Kidney + gut	Lysine	Autosomal recessive	Growth failure, seizures
Lysinuric protein intolerance (type II)	Kidney, fibroblasts, hepatocytes, gut	Lysine	Autosomal recessive	Growth restriction, hyperammonemia, mental retardation
Methionine malabsorption	Gut	Methionine	Autosomal recessive?	Mental retardation, white hair, failure to thrive
Renal glycosuria	Kidney	Glucose	Autosomal recessive	Benign glycosuria
Renal tubular acidosis (type I)	Distal renal tubule	H^+ secretion, citrate, calcium	Autosomal dominant	Hypokalemia, growth restriction, nephrocalcinosis
Renal tubular acidosis (type II)	Proximal renal tubule	Bicarbonate	"Familial"	Hyperchloremic metabolic acidosis

TABLE 212-4 HUMAN GLUCOSE TRANSPORTERS

PROTEIN	kD (AA)	mRNA SIZE (kb)	CHROMOSOMAL LOCALIZATION	EXPRESSION IN TISSUE AND CELLS	FUNCTION	DISORDER
FACILITATIVE GLUCOSE TRANSPORTERS						
GLUT1	55 (492)	2.8	1p35→p31.3	Blood-brain barrier, erythrocyte, fibroblast	Basal glucose transport across most cells, including the blood-brain barrier	Seizures with low cerebrospinal fluid and normal blood glucose
GLUT2	58 (524)	2.8 3.4 5.4	3q26.1→q26.3	Liver, kidney, intestine, β cell of the pancreas	Low-affinity glucose transport	Defective insulin secretion in diabetes
GLUT3	54 (496)	2.7 4.1	12p13.3	Neurons, fibroblasts, placenta, testes	Basal glucose transport, high affinity	?
GLUT4	55 (509)	2.8 3.5	17p13	Fat, skeletal muscle, heart	Insulin-stimulated glucose transport	Defective insulin-stimulated transport, NIDDM?
CONCENTRATIVE GLUCOSE TRANSPORTERS						
SLGT1	75 (664)	2.2 2.6 4.8	22q11→qter	Intestine, kidney (medulla)	Intestinal absorption, renal reabsorption, high affinity (2 Na: 1 glucose)	Glucose-galactose malabsorption
SLGT2	76 (672)	2.4 3.0 3.5 4.5	16p11.2	Kidney (cortex)	Low affinity, high capacity (1 Na: 1 glucose)	Renal glycosuria

AA = amino acids; NIDDM = non-insulin-dependent diabetes mellitus.

In *Albright's hereditary osteodystrophy,* or *pseudohypoparathyroidism* (Chapter 253), a heterogeneous group of mutations affect the gene for the parathormone receptor's guanine nucleotide-binding protein ($G_{s\alpha}$), which links the receptor to adenylate cyclase and stimulates cyclic adenosine monophosphate when the receptor is occupied by parathormone. The gene for $G_{s\alpha}$ is located on chromosome 20q13, and deletions and missense mutations that produce Albright's hereditary osteodystrophy have been defined. Somatic mutations in arginine 201 of the same gene turn the $G_{s\alpha}$ protein constitutively "on" and produce another disease, McCune-Albright-Sternberg syndrome. Cells are mosaic for the mutation, and the syndrome includes nonossifying bone tumors and premature puberty.

Growth Hormone Resistance

Diseases caused by defective transmembrane binding and signaling include *Laron dwarfism,* which results from growth hormone receptor (GHR) defects (Chapter 231). The phenotypic characteristics are *proportionate dwarfism,* hypoglycemia, craniofacial dysmorphology with a doll-like face, balding, frontal bossing, truncal obesity, and wrinkled skin. In this disorder, the growth hormone concentration in blood is elevated, peripheral tissue responses are decreased, and insulin-like growth factor I concentrations in blood are low. An autosomal recessive mode of inheritance has been defined. Dominant or polygenic symmetrical growth restriction may result from mutations in nuclear transproteins, hypothalamic pituitary trophic proteins, growth hormone, GHR, and postreceptor signaling. The *GHR* gene is found on chromosome 5p13-p12, and many different mutations in this gene account for disorders of stature.

Familial Hypercholesterolemia

Familial hypercholesterolemia defines a phenotype of autosomal dominant hypercholesterolemia and early-onset heart disease (Chapter 213). This disorder affects an estimated 1 in 500 individuals in the general population. An autosomal dominant mode of inheritance for early-onset adult heart disease is caused by many different mutations in the trafficking and function of low-density lipoprotein (LDL) cholesterol receptors. Dysfunction of LDL receptors results in a loss of the cell's ability to downregulate endogenous cholesterol synthesis and incorporate LDL cholesterol into cells. Increased intravascular accumulation of LDL cholesterol results in atherosclerosis and heart disease before the sixth decade of life (see Table 212-2).

Errors of Insulin Resistance

Leprechaunism

Leprechaunism has become a prototypical inborn error of severe insulin resistance and loss of cellular signal transduction through the insulin receptor. Affected infants have low birthweight, acanthosis nigricans, cystic changes in organs, and loss of glucose homeostasis. Affected patients have remarkably elevated plasma insulin concentrations greater than 500 mIU/mL. Specific impairment in iodine-125-labeled insulin binding is evident in cells cultured from patients, and a spectrum of mutations produces a variety of severe insulin-resistant syndromes (leprechaunism, Rabson-Mendenhall syndrome, and type A diabetes with acanthosis nigricans). Obligate heterozygotes (parents) of patients with leprechaunism have partially impaired insulin binding and glucose tolerance curves suggesting type 2 diabetes mellitus. The insulin receptor transduces its signal by phosphotransfer to the insulin receptor signal protein 1 (IRS-1), and a cascade of downstream phosphorylations occurs, leading to stimulation of glucose transport.

Impaired Cytosolic Enzymes

Inborn errors affecting proteins of the cytosolic compartment within a cell are the more "traditional" inborn errors of metabolism (Table 212-5). They impair the catalytic reactions of anabolic or catabolic pathways and are usually classified by the class of biochemical involved, such as impairment of glucose, lipid, fatty acid, amino acid, purine, organic acid, vitamin, or drug metabolism.

Phenylketonuria

Phenylalanine is essential for growth, and its anabolic products include tyrosine, thyroid hormone, adrenergic neurotransmitters, and melanin. *Phenylketonuria* (PKU) is caused by mutations in the gene encoding phenylalanine hydroxylase, the first enzyme in this anabolic flow that catalyzes tyrosine production. PKU may also occur if coenzymes are deficient in this reaction, such as dihydropteridine reductase or enzymes involved in biopterin biosynthesis.

Albinism

Albinism is an example of an inborn error in an anabolic pathway in which the pathophysiologic mechanism is related directly to the lack of an end product (see mechanism 3, Table 212-2). Tyrosine is converted by the action of a cytosolic tyrosinase first to dopa and then to dopamine. Dopamine can be converted either to the red-yellow pigment pheomelanin or to the black-brown pigment eumelanin. These reactions occur in the melanosomes produced in melanocytes and exported to keratinocytes. Color of skin is an inherited factor that depends on many genes (polygenic) and is a function of the intensity of the pigment in the skin and not the number of melanocytes, which is constant for all humans. Although skin color is a polygenic trait, single genes can have a profound effect on this color, as evidenced by the albino phenotype. In humans, *oculocutaneous albinism* (OCA) is inherited as an autosomal recessive trait. X-linked forms of *ocular albinism* also exist. Individuals with OCA are classified as tyrosinase negative or positive for tyrosine activity in hair bulbs. Tyrosinase-negative individuals form no pigment. The gene for tyrosinase has been localized to chromosome 11q14, and many mutations have been defined. A tyrosine-positive OCA has been associated

TABLE 212-5 SOME DISEASES CAUSED BY IMPAIRED CYTOSOLIC ENZYMES

DISORDER	ENZYME DEFECT	PHENOTYPE	INHERITANCE
CARBOHYDRATES			
Fructosuria	Fructokinase	Benign	Autosomal recessive
Hereditary fructose intolerance	Fructose 1-phosphate aldolase	Liver dysfunction, early death	Autosomal recessive
Galactosemia	Galactose 1-phosphate uridyltransferase	Liver dysfunction, cataracts, sepsis, mental retardation, death	Autosomal recessive
Hereditary fructose-1,6-*bis*-phosphate deficiency	Fructose-1,6-*bis*-phosphatase	Apnea, ketosis, lactic acidosis	Autosomal recessive
AMINO ACIDS			
Phenylketonuria	*p*-Hydroxyphenylalanine hydroxylase	Mental retardation (teratogenic)	Autosomal recessive
Tyrosinemia Type II Type I	 Tyrosine aminotransferase Fumarylacetoacetate hydrolase	 Palmar bullae, corneal lesions Succinyl acetone accumulation	 Autosomal recessive Autosomal recessive
Homocystinuria	Cystathionine β-synthase	Marfanoid habitus, arterial thrombosis, lens dislocation, mental retardation	Autosomal recessive
Hyperornithinemia	Ornithine aminotransferase	Gyrate atrophy of the retina	Autosomal recessive
Lesch-Nyhan syndrome	Hypoxanthine phosphoribosyltransferase	Neurologic dysfunction with self-destructive tendency	X-linked

with an autosomal recessive gene located on chromosome 15q11-13 (the P gene), and X-linked ocular albinism is caused by *OCA1* gene mutations. Wide variation in the phenotypic expression of albinism, ranging from severe neurologic deficiency with ocular and sarcomatous skin cancers to mild cosmetic problems, has been reported. Therapy requires total body skin protection and eye avoidance of ultraviolet light.

Errors of the Urea Cycle (Cytosol and Mitochondrial Interaction)

Inborn errors of the urea cycle are represented by defects in the integration of anabolic and catabolic pathways and the distribution of catalytic proteins between mitochondria and cytosol. The role of the urea cycle is to convert ammonia, a byproduct of protein breakdown, to urea and to synthesize arginine and ornithine. Reactions to complete this anabolic cycle require mitochondrial enzymes, cytosolic enzymes, and mitochondrial transporter proteins. Inherited disorders affecting the function of these proteins are known. Individuals with defects in any of the enzymes have varying degrees of hyperammonemia caused by protein ingestion or a nutritional state in which muscle is catabolized. With the exception of the gene for ornithine transcarbamylase found on the short arm of chromosome X, the other proteins are encoded on autosomes, and defects are inherited as autosomal recessive traits. Many principles of diagnosis and therapy for inborn errors of metabolism are exemplified by disorders of the urea cycle.

Errors in Mitochondrial Proteins

A group of inborn errors of metabolism are caused by mutations in both mitochondrial and nuclear genes that encode mitochondrial proteins. Collectively, they are considered disorders of organic acid metabolism (Table 212-6). Branched-chain α-ketoacid dehydrogenase is a multienzyme complex located on the matrix side of the mitochondrial inner membrane in all tissues. When any of these proteins is impaired, the autosomal recessive disorder *maple syrup urine disease* may result. In addition to nuclear-encoded genes, 13 proteins of mitochondrial complexes involved in oxidative phosphorylation are encoded in the mitochondrial DNA genome. Only complex II is encoded entirely by the nuclear genome. A wide range of disorders affecting the eye, brain, and muscle are caused by mutations in mitochondrial DNA that impair oxidative phosphorylation. The inheritance pattern of disorders encoded by the mitochondrial genome is distinguished from disorders caused by mutations in nuclear DNA by being transmitted through an affected mother to all of her offspring. Males do not transmit mitochondrial mutations to their offspring, hence the term *maternal inheritance.* Because there are about 10,000 mitochondrial genomes per cell, variation in disease expression is caused by differences in the ratio of mutant to normal mitochondrial genomes *(heteroplasmy)* and the environment.

Lysosomal Disorders

Another group of inborn errors of metabolism are collectively categorized as *lysosomal disorders* (Chapter 215) to indicate the subcellular localization of these enzymes that function in this acidic environment. Most of these enzymes are involved in the breakdown of endocytosed membrane components, and when defective, their nondegraded substrates accumulate in the lysosomes and macrophages of affected organs. Enzyme replacement therapy and substrate deprivation therapy are available interventions for some of these disorders.

TABLE 212-6 ORGANIC ACIDEMIAS: DISORDERS OF METABOLISM BY MITOCHONDRIAL PROTEINS

DISORDER	ENZYME DEFECT	INHERITANCE
Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	Autosomal recessive
Methylcrotonic aciduria	3-Methylcrotonyl-CoA carboxylase	Autosomal recessive
Glutaconic aciduria	3-Methylglutaconyl-CoA hydratase	Autosomal recessive
Glutaric aciduria (1)	3-Hydroxy-3-methylglutaryl-CoA lyase	Autosomal recessive
Mevalonic aciduria	Mevalonate kinase	Autosomal recessive
Thiolase deficiency	2-Methylacetoacetyl-CoA thiolase	Autosomal recessive
Isobutyric aciduria	3-Hydroxyisobutyryl-CoA deacylase	Autosomal recessive
Propionic aciduria	Propionyl-CoA carboxylase	Autosomal recessive
Methylmalonic aciduria	Methylmalonyl-CoA mutase	Autosomal recessive
Lactic acidosis	Pyruvate carboxylase Pyruvate dehydrogenase	Autosomal recessive
Acyl-CoA dehydrogenase deficiencies	Short-, medium-, and long-chain fatty acyl-CoA dehydrogenase	Autosomal recessive
Branched-chain α-ketoacidemia	Branched-chain α-ketoacid dehydrogenase	Autosomal recessive
Glutaric acidemia type II	Electron transfer factor deficiency	Autosomal recessive
Leber's optic atrophy	Mitochondrial oxidative phosphorylation complexes	Maternal
Myoclonic epilepsy and ragged red fibers	Mitochondrial oxidative phosphorylation complexes	Maternal
Leigh's disease	Mitochondrial oxidative phosphorylation complexes	Maternal

I-Cell Disease

I-cell disease is an inborn error of post-translational processing of proteins directed to the lysosome. Clarification of this pathophysiology led to an understanding of the mechanisms by which lysosomal enzymes are trafficked

and polarized through phosphorylation to remain in the acidic lysosomes. Patients with I-cell disease have inherited defects in the recognition markers required to direct enzymes to the endocytic receptor of the plasma membrane and to their capture in the acidic milieu of the lysosome. Patients lack all cellular lysosomal enzymes. Instead, empty lysosomes look like inclusion bodies ("I cell"). The misdirected lysosomal enzymes are secreted and are present in excess in plasma but are missing from cells. These extracellular enzymes were found to lack mannose 6-phosphate residues, and this observation led to an understanding of the post-translational mechanisms by which enzymes are directed to the lysosome and recaptured into endosomes by adding phosphorylated mannose to their protein structure. Individuals with I-cell disease lack this phosphotransferase activity.

Disorders of Mucopolysaccharides and Gangliosides

Inborn errors affecting single enzymes in the degradative pathway for mucopolysaccharides and gangliosides helped define the steps required for the breakdown of these complex macromolecules. Disorders of mucopolysaccharide metabolism include Hurler's syndrome; Scheie's syndrome; Hunter's syndrome; Sanfilippo's syndrome types A, B, C, and D; Morquio's syndrome types A and B; and Sly's syndrome (Chapter 268). Disorders of ganglioside metabolism include Fabry's disease, Gaucher's disease, Niemann-Pick disease (Chapter 215), Tay-Sachs disease, I-cell disease, fucosidosis, mannosidosis, sialidosis, and aspartylglycosaminuria.

Peroxisomal Diseases

Another group of inborn errors of metabolism defined by altered organelle function are *peroxisomal diseases* (Table 212-7). Peroxisomes are radiodense organelles, 0.5 to 1 nm in diameter, bounded by a single trilaminar membrane. Anabolic and catabolic reactions occur in this organelle. Primary pathways synthesize plasmalogens (unique fatty acids containing vinyl ethers), cholesterol, and bile acids. Other biosynthetic reactions include gluconeogenesis from amino acids and the formation of oxalic acid by the action of alanine-glyoxylate aminotransferase. Catabolic reactions include breakdown of hydrogen peroxide by peroxisomal catalase, a traditional protein of the peroxisome; polyamine oxidation; purine breakdown; ethanol oxidation; hydroxylation of phytanic acid; and degradation of pipecolic acid. A major function of the peroxisome is β-oxidation of very-long-chain fatty acids (>24 carbons). Diagnosis of these disorders entails finding an excess of very-long-chain fatty acids but reduced plasmalogen in blood.

An understanding of the importance of many reactions that occur in the peroxisome has come from identifying patients with either defects in individual biochemical pathways or lack of peroxisomes. The targeting signal for peroxisomal proteins may lie in their carboxyl-terminal end, and mutations in alanine-glyoxylate aminotransferase have resulted in mistargeting of this enzyme to mitochondria with consequent *familial hyperoxaluria*.

TABLE 212-7 INBORN ERRORS OF PEROXISOMES

NAME	GENE DEFECT	ABNORMAL ANALYTES
DISORDERS OF BIOGENESIS		
Zellweger's spectrum	*PEX* 1, 2, 3, 5, 6, 10, 12, 13, 14, 16, 19, 26 *DLP1*	Increased plasma very-long-chain fatty acids; bile acids intermediates, phytanic and pipecolic acids Decreased erythrocyte plasmalogen
Rhizomelic chondrodysplasia punctata, type I	*PEX* 7	Increased plasma phytanic acid Decreased erythrocyte plasmalogen
DISORDERS OF β-OXIDATION		
X-linked adrenoleukodystrophy Acyl CoA oxidase deficiency Methylacyl CoA racemase deficiency	*ABCD1* *ACOX1* *AMACR*	Increased plasma very-long-chain fatty acids Increased plasma very-long-chain fatty acids Increased plasma bile acid intermediates phytanic and pristanic acids
DISORDER OF PLASMALOGEN BIOSYNTHESIS		
Dihydroxyacetone phosphate acyltransferase deficiency	*GNPAT*	Decreased erythrocyte plasmalogen
DISORDER OF α-OXIDATION		
Refsum's disease	*PHYH*	Increased plasma phytanic acid only
DISORDER OF GLYOXALATE METABOLISM		
Hyperoxaluria, type I (alanine glyoxylate aminotransferase misplacement)	*AGXT*	Oxaluria

Errors In Nuclear Proteins

Several inborn errors are caused by abnormalities in proteins that function in the nucleus and are involved in gene expression or DNA repair (see class 2, Table 212-1). Patients expressing these inherited disorders carry a high risk for the development of cancer. Among these inborn errors of DNA repair are rare disorders, such as *xeroderma pigmentosum, Bloom's syndrome, ataxia-telangiectasia,* and *Fanconi's anemia;* diseases associated with early aging, such as *progeria, Cockayne's syndrome,* and *Werner's syndrome;* and more common adult-onset *nonpolyposis colon cancer.* Collectively, the disorders show increased sensitivity and delayed repair of DNA damaged as a result of ultraviolet, x-ray, or alkylating cross-link mechanisms. Disorders of nucleotide expansion of repeating elements such as -CGG- in the promoter region of the fragile-X protein (FMR1) result in cytosine methylation that turns off FMR1 protein expression with consequent dysregulation of the RNAs to which FMR1 binds.

Errors in Blood-Circulating Proteins

Many inborn errors involve proteins that circulate in blood (see class 3, Table 212-1). Stable circulating proteins in blood perform a variety of functions, including immunologic, hemostatic, regulatory, hormonal, and interorgan transport of trace metals, lipids, and other nutrients. Some inherited disorders affecting circulating proteins are tabulated in Table 212-8. Proteins involved in oxygen transport, coagulation, and immunity are detailed in other chapters, but the pathophysiologic mechanisms and genetic approaches of screening, diagnosis, and intervention to restore homeostasis and prevent an expected disease state make them appropriate to consider here as inborn errors of metabolism.

Abnormal Matrix Proteins

Abnormal matrix proteins produce inborn errors, such as Marfan syndrome (fibrillin), osteogenesis imperfecta (collagen type I) (Chapter 268), spondyloepiphyseal dysplasia (collagen type II), and Sachs' disease (collagen type III). These disorders exemplify class 4 of inborn errors of metabolism (see Table 212-1). The enzymes involved in post-translational processing of these proteins can also cause these syndromes. An example is Ehlers-Danlos syndrome (Chapter 268) type VI, in which procollagen lysyl hydroxylase

TABLE 212-8 SOME INBORN ERRORS OF PROTEINS THAT CIRCULATE IN BLOOD

FUNCTIONAL CLASS	PROTEIN	PHENOTYPE
Transport	Ceruloplasmin Albumin Hemoglobin α-Lipoprotein β-Lipoprotein Transcobalamin II	Wilson's disease Analbuminemia Hemoglobinopathies Analphalipoproteinemia Abetalipoproteinemia Megaloblastic anemia
Hormones	Growth hormone Insulin Somatomedin	Pituitary dwarfism Diabetes mellitus (insulin dependent) Pituitary dwarfism
Coagulation	Factors I-XIII Kininogen Prekallikrein	Coagulopathies Kininogen deficiency Prekallikrein deficiency
Immune system	Complement components Immunoglobulins	Hypocomplementemias Hypogammaglobulinemias
Inhibitors	α_1-Antitrypsin C1 esterase inhibitor	Pulmonary emphysema and/or cirrhosis Angioneurotic edema
Drugs	Pseudocholinesterase	Prolonged paralysis after succinylcholine (Anectine) exposure

TABLE 212-9 APPROACHES TO TREATING INBORN ERRORS OF METABOLISM

Genetic counseling: prospective therapy
Diagnosis, recurrence risk assessment, informational transfer, support for resource allocation, identification of and intervention for "at-risk" relatives

Reproductive alternatives
Contraception, abstinence, artificial insemination, in vitro fertilization, risk taking with or without prenatal monitoring

Environmental engineering
Avoiding the offending agent
Supplemental physical, speech, occupational therapy

Metabolic management
Promote anabolism
Limit precursor of toxic substrate
Detoxify through alternative metabolic route
Provide feedback inhibitor
Provide supraphysiologic amounts of vitamin precursor

Molecular management
Provide gene expression and protein production
Provide stop codon read-through
Provide chaperone for misfolded protein

Protein and enzyme replacement
Infuse engineered enzyme
Provide clotting factors and peptide hormones
Transplantation
- Organ transplantation
- Bone marrow transplantation
- Stem cell transplantation (adult, hematopoietic, embryonic, nuclear transfer)

Genetic engineering
Somatic gene therapy
- Random insertion
- Homologous recombination (site specific)

Germline therapy

deficiency produces poorly hydroxylated lysyl residues in collagen. Inborn errors of matrix proteins are exemplified by disorders of collagen metabolism. More than 20 different genes dispersed on nine chromosomes are currently known to code for more than 13 different types of collagen. Abnormal proteins of matrix such as fibrillin 1 in the aorta may cause aberrant transforming growth factor-β signaling, inflammation, and consequent cystic medial necrosis with aortic dissection.

TREATMENT

Rx

Because the metabolic diseases considered in this chapter have in common causation by genes of large effect that disrupt normal homeostasis, we can consider a general approach to their treatment, as outlined in Table 212-9. The level at which therapy is rendered depends on the level of understanding of the pathophysiologic mechanisms producing disease and the interventional methods available.

Genetic Counseling

Genetic counseling is a unique and fundamental aspect of the management of inherited metabolic diseases and is used for all inherited diseases, even those whose mechanisms are not yet understood and for which no other treatment is available. Patients, their parents, and relatives usually ask questions such as the following: Why did this disease occur? Will this disease happen to me or my children? Can it be cured or prevented? Genetic counseling tries to answer these questions through processes involving probabilities derived from pedigree analysis. One cannot overemphasize the importance of an accurate family history, clinical diagnosis, and prognosis. A genetic discriminant is necessary for other family members before entering into formal genetic counseling. The genetic discriminant can be at the clinical, histologic, biochemical, or molecular level and must define whether an individual family member has or has not inherited the mutant allele or alleles. Transferring information about the burden of the phenotype, variation of clinical outcome including genotype-phenotype associations, and recurrence risks are important components of genetic counseling.

Environmental Engineering

Environmental engineering is the most commonly used approach to preventing disease in patients affected by inherited metabolic disease. Environmental factors (nutritional intake, exposure to toxins, sun, stress, climatic variation, and drug therapy) may produce a disease state in individuals who have inherited single genes or polygenic susceptibility to specific environmental stress. Newborn screening for galactose 1-phosphate uridyltransferase deficiency identifies infants susceptible to accumulation of galactose 1-phosphate, if they ingest human or cow milk. Restriction and replacement of lactose with sucrose save the lives of infants with galactosemia. Pharmacogenetic disorders exemplify the simple treatment of *avoidance* when the genetic susceptibility is identified. Health can be viewed as a continual adaptation between the genes and the environment. Environmental engineering is a form of genetic therapy in which individual genetic susceptibility is identified and the environment is altered to provide optimal health for the individual's unique genetic constitution. The frequency of diseases caused by genetic susceptibility to the environment varies from rare to 100%. *Scurvy* develops in all humans unless ascorbate is provided in the diet because we are unable to convert glucuronic acid to glucuronolactone and ascorbate. Humans and primates lost this anabolic pathway during evolution. By contrast, humans can usually synthesize tetrahydrobiopterin, a cofactor in many hydroxylase reactions, including phenylalanine hydroxylase. In some rare diseases (about 1 in 500,000) of increased blood phenylalanine and severe neurodegeneration, biopterin is not synthesized. Tetrahydrobiopterin can be provided to ameliorate this decreased product from the metabolic block.

Medical Therapy

Nutritional management and chemoprevention involve correction of the metabolic imbalance and return of the patient to homeostasis through diet manipulation and drug therapy. Many of the diseases mentioned in this chapter are amenable to several concurrent therapeutic approaches listed in Table 212-9.

For example, in disorders of the urea cycle, protein intake is limited, and anabolism is encouraged to reduce accumulation of ammonia from either protein intake or catabolism of lean body mass. Arginine is supplemented to provide deficient product of the blocked reaction, and alternative pathways are induced for nitrogen excretion. The latter therapy is made possible by a ubiquitous enzyme, *N*-glycine-acylase, that forms adducts with benzoic acid and glycine to produce hippuric acid, which is excreted, thereby eliminating one nitrogen molecule. Phenylacetylglutamine transferase is also used by giving phenylacetate to produce and excrete two nitrogen molecules as phenylacetylglutamine. Orotic aciduria is caused by mutations in the bifunctional enzyme orotate phosphoribosyltransferase-orotidine-5′-monophosphate decarboxylase. The disease process, which includes severe anemia and immune deficiency, is caused by a deficient end product, uridine, and is treated by replacing 100 to 200 mg/kg/day of uridine, up to 1 g three times daily (orally). Feedback inhibition of pituitary adrenocorticotropic hormone production is important in treating congenital adrenal hypertrophy with replacement doses of hydrocortisone to prevent virilization from overproduction of testosterone.

Vitamin dependency disorders require supraphysiologic amounts of a specific vitamin as the precursor for an active cofactor required for holoenzyme function. Many vitamin-dependent metabolic disorders are known and include pyridoxine (vitamin B_6)–dependent homocystinuria (Chapter 216) and vitamin C–dependent Ehlers-Danlos syndrome type VI (Chapter 268). In vitamin B_6–dependent homocystinuria, mutant cystathionine β-synthase is stabilized to biologic degradation when saturated with pyridoxal phosphate. Others include vitamin B_{12}–dependent methylmalonic aciduria, thiamine-dependent maple syrup urine disease, biotin-dependent multiple carboxylase deficiency, and biopterin-dependent hyperphenylalaninemia. Some blocked metabolic reactions can be augmented by inducing transcription of their gene. Phenobarbital and several other drugs induce hepatic uridine diphosphate glucuronyl transferase gene expression and reduce the accumulation of unconjugated bilirubin in Gilbert's syndrome (Chapter 149). In tyrosinemia type I, the drug NTBC blocks the catabolic pathway by which tyrosine produces the toxin, succinylacetone, when fumarylacetoacetate hydrolase is defective, and successfully prevents hepatic and renal dysfunction.

If the specific protein or enzyme has been purified and engineered to function in its specified organ or subcellular organelle, it can be used to treat an inherited metabolic disease. One good example is glucocerebrosidase, the enzyme that is impaired in Gaucher's disease (Chapter 215). This enzyme has been purified in large quantities from the placenta and from recombinant mammalian cells. The secreted enzyme is biochemically engineered to contain the mannose recognition site for cellular uptake by macrophages into lysosomal compartments. It has been used successfully to prevent and reverse the hypersplenism, pancytopenia, and bone disease of type I Gaucher's disease (Chapter 215). Many proteins are now made through recombinant techniques to treat metabolic disease. Enzymes now include glucocerebrosidase, factor VIII for hemophilia type A, growth hormone for growth hormone deficiency, α-galactosidase to treat Fabry's disease, iduronidase for Hurler-Scheie syndrome, and acid maltase for Pompe's disease. Several other engineered proteins used to treat inherited metabolic disease include 1-deamino-8-D-arginine vasopressin to treat X-linked recessive diabetes insipidus and recombinant α_1-antitrypsin made stable by inactivating methionine-385 for the treatment of α_1-antitrypsin deficiency. Some enzymes, such as adenosine deaminase, have been modified with polyethylene glycol to reduce immunogenicity and

prolong their biologic half-life in blood. It is used to treat severe combined immunodeficiency. Chemoprevention is being developed for heritable cancers. Cyclooxygenase-2 inhibitors may prevent progression of colon polyps to adenocarcinoma, and estrogen receptor inhibitors may ameliorate some forms of breast cancer.

Treatment using chaperones and substrate reduction therapy represent novel approaches for lysosomal disorders in which substrate accumulation in brain cannot be reduced by intravenous therapy of bulky enzymes that do not cross the blood-brain barrier. Small molecules that inhibit ceramide glucosyltransferase reduce the rate of glucosylceramide accumulation in Gaucher's disease types II and III as well as glycosphingolipids that accumulate in the brain of patients with Niemann-Pick disease type C (Chapter 215). Rhodamine B inhibits glucosamine-glycans accumulation in mucopolysaccharidosis. Chaperones are used to protect misfolded enzymes that will otherwise be destroyed before reaching their lysosomal compartment. Structural analogues of substrates for genetically misfolded α-galactosidase (Fabry's disease) (Chapter 215) are in trial as chaperones for missense mutations. Future use of "read-through molecules" for mutations producing stop codons are in trial. For example, gentamicin will read through stop codons in *CFTR* (cystic fibrosis) and dystrophin (Duchenne muscular dystrophy) genes.

Surgical Therapy

Surgical intervention may be a useful adjunct for treating heritable disorders. Stabilization of hypoplastic cervical vertebrae may prevent quadriparesis or death in a variety of chondrodysplasias and mucopolysaccharidoses accompanied by hypoplasia of the odontoid process or atlantoaxial instability. In Marfan syndrome (Chapter 268), careful monitoring of aortic root diameter with surgical removal of the aorta and prosthesis may prevent lethal aortic dissection. Losartan therapy may prevent the inflammatory response to mutant fibrillin and mitigate the need for this surgery. Evaluation of polyps and early colectomy may prevent disseminated adenocarcinoma in families with the autosomal dominant forms of familial polyposis coli. Molecular diagnosis of mutations in the *APC* gene helps identify at-risk family members and reassure members who did not inherit the mutant allele. Preventing heritable cancer by surveillance and early surgical excision is therapeutic for medullary thyroid carcinoma, Wilms' tumors, and the neurofibromas of von Recklinghausen's disease. Other examples of the benefit of preventive surgery for inborn errors include splenectomy for hemolytic anemias associated with spherocytosis, pyloroplasty for pyloric stenosis, and mastectomy and oophorectomy for patients with *BRCA1* or *BRCA2* mutations.

Transplantation

Organ transplantation (Chapter 48) for metabolic disorders that are lethal and have no other available therapy may be life-saving. Liver transplantation is an option in the long-term treatment of patients with urea cycle defects. Stem cells from cord blood (Chapter 181) are being used to treat neurodegenerative disorders in early childhood. Cloned embryonic cells or stem cells that are still naïve to adult antigens and adult bone marrow are promising therapeutic agents in research. Adult stem cells from differentiated organs are proving useful in improving myocardial function after heart failure from infarction.

Several principles are required for successful treatment of an inherited metabolic disorder by organ transplantation: (1) the normal enzyme, protein, or function must be provided by the transplanted organ or adult stem cell; (2) the pathogenesis must be understood to decide whether the affected organ should be removed; and (3) the host must be immunologically tolerant to the gene product being introduced, in addition to the transplanted organ itself. These principles are particularly relevant when displacement bone marrow transplantation is used. In the latter, normal donor stem cells differentiate and provide their enzymes to the recipient's reticuloendothelial system. Diseases associated with accumulation of products in the central nervous system are not yet ameliorated by bone marrow transplantation, although accumulation in bone, liver, and spleen is reduced. In one group of metabolic diseases, stem cell bone marrow transplantation is performed to prevent leukemia caused by inherited syndromes that are associated with defective DNA repair, such as Fanconi's anemia, Bloom's syndrome, and ataxia-telangiectasia. Liver or kidney transplantation can reverse growth and developmental delay in type I glycogen storage disease, cystinosis, acute intermittent porphyria, type I tyrosinemia, Fabry's disease, oxalosis, and non-neuronotropic lysosomal storage diseases. Lung transplantation has been successful for cystic fibrosis and α_1-antitrypsin deficiency, and prophylactic aortic transplantation has prevented aortic dissection in patients with Marfan syndrome.

Somatic Gene Therapy

Somatic cell gene therapy (Chapter 43) to treat patients with genetic disease continues in the arena of clinical research. Numerous laboratories throughout the world are actively designing strategies by which exogenous DNA can be incorporated into the genomic DNA of specific organs to provide a missing gene function and its protein product. Somatic gene therapy for many inherited metabolic diseases continues to be a goal of the future and awaits a nontoxic, stable vector with which to transfer normally transcribed genes.

DISORDERS OF LIPID METABOLISM

CLAY F. SEMENKOVICH

Despite considerable progress, morbidity and mortality from vascular diseases are substantial and are likely to increase, given the epidemic of lipid-associated diseases such as obesity and diabetes, as well as the export of Western habits to the developing world. Recently discovered mediators of lipid metabolism continue to provide new insight into the mechanisms causing abnormal levels of cholesterol and triglycerides, among the most common problems encountered by practicing physicians.

COMPONENTS OF LIPID TRANSPORT

Cholesterol and Triglycerides

Cholesterol is a critical constituent of eukaryotic cell membranes and the precursor for the synthesis of steroid hormones such as cortisol, vitamin D, progestins, estradiol, and testosterone. Triglycerides carry fatty acids, nutrients that are used preferentially by muscle tissue and are especially important as an energy source in the fasting state. Because both cholesterol and triglycerides are essentially insoluble in water, the lipid transport system evolved to transport fats from one site to another through an aqueous environment.

Lipoproteins

Cholesterol and triglycerides are transported in lipoproteins (Table 213-1), spherical particles that differ in size and composition, depending on their site of origin. Each particle is composed of a central core consisting of cholesteryl esters (the product of an esterification reaction between the polar cholesterol molecule and a fatty acid) and triglycerides, both nonpolar compounds. Free cholesterol, phospholipids, and apolipoproteins are found on the particle surface.

Chylomicrons and their remnants are the largest lipoproteins. Produced by the intestine, these particles carry fats that are absorbed from the diet. Their residence time in the circulation after a meal is short, on the order of minutes in healthy people. Chylomicrons are large and light; that is, their density is low. Because fat floats on water, particles with high fat and low protein content have lower density. Very low density lipoprotein (VLDL) is a triglyceride-rich particle produced by the liver. The removal of triglycerides from VLDL converts this particle to intermediate-density lipoprotein (IDL), which is subsequently metabolized to yield low-density lipoprotein (LDL, popularly known as "bad cholesterol"). A covalent modification of the apolipoprotein (apo) in LDL, apo B100, results in the formation of lipoprotein (a). High-density lipoprotein (HDL, or "good cholesterol") is formed in the blood as a byproduct of the metabolism of triglyceride-rich lipoproteins and the acquisition of esterified cholesterol from peripheral tissues.

Apolipoproteins

Apolipoproteins are amphipathic molecules capable of interacting with both the lipids of the lipoprotein core and the aqueous environment of the plasma. They function as biochemical keys, allowing lipoprotein particles access to specific sites for the delivery, acceptance, or modification of lipids. Major apolipoproteins, their chromosomal locations with sequence accession numbers, and functions are shown in Table 213-2. Serum measurements of apolipoproteins may have clinical utility. For example, increased levels of apo B and decreased levels of apo AI are associated with vascular disease. Apo B48, specific for gut-derived particles, derives its name from the fact that it

TABLE 213-1 LIPOPROTEIN CHARACTERISTICS

LIPOPROTEIN	APOLIPOPROTEIN CONTENT	MAJOR LIPIDS	SIZE (NM DIAMETER)	DENSITY (G/ML)
Chylomicrons, chylomicron remnants	Apo B48, apo E, apo AI, apo AII, apo AIV, apo CII, apo CIII	Triglycerides from diet	80-500	<<1.006
VLDL	Apo B100, apo E, apo CII, apo CIII	Triglycerides from liver	30-80	<1.006
IDL	Apo B100, apo E	Cholesteryl esters, triglycerides	25-35	1.006-1.019
LDL	Apo B100	Cholesteryl esters	18-25	1.019-1.063
HDL	Apo AI, apo AII, apo AV	Cholesteryl esters, phospholipids	5-12	1.063-1.210
Lp(a)	Apo B100, apo(a)	Cholesteryl esters	~30	1.055-1.085

Apo = apolipoprotein; HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; Lp(a) = lipoprotein (a); VLDL = very low density lipoprotein.

TABLE 213-2 MAJOR APOLIPOPROTEINS

APOLIPOPROTEIN	CHROMOSOMAL LOCATION, GENBANK SEQUENCE IDENTIFICATION	FUNCTIONS
Apo B100	2p24-p23, M14162	Structural component of atherogenic lipoproteins (VLDL, IDL, LDL), VLDL secretion, ligand for LDL receptor, elevated levels associated with vascular disease
Apo B48	Same as apo B100	Chylomicron secretion from intestine
Apo E	19q13.31, K00396	Ligand for binding of triglyceride-rich particles to LDL receptor and LRP, potential roles in Alzheimer's disease and neuronal injury
Apo AI	11q23-q24, X02162	Structural component of HDL, activates LCAT, elevated levels associated with protection from vascular disease
Apo AII	1q21-Q23, NM_001643	Genetically and biochemically associated with familial combined hyperlipidemia
Apo AIV	11q23-qter, NM_000482	Potential role in regulating food intake
Apo AV	11q23, AF202889	Required for normal lipolysis of triglyceride-rich lipoproteins
Apo CII	19q13.2, X00568	Activator of LPL
Apo CIII	11q23-qter, X01388	Inhibitor of LPL
Apo (a)	6q26-q27, X06290	Covalent bond with apo B100 forms Lp(a) and renders particle resistant to uptake by LDL receptor

Apo = apolipoprotein; HDL = high-density lipoprotein; IDL = intermediate-density lipoprotein; LCAT = lecithin-cholesterol acyltransferase; LDL = low-density lipoprotein; Lp(a) = lipoprotein (a); LPL = lipoprotein lipase; LRP = LDL receptor–related protein; VLDL = very low density lipoprotein.

TABLE 213-3 IMPORTANT RECEPTORS AND PROTEINS IN LIPID TRANSPORT

PROTEIN	CHROMOSOMAL LOCATION, GENBANK SEQUENCE IDENTIFICATION	FUNCTIONS
LDL receptor	19p13.3, AY114155	Clearance of apo B100 and apo E–containing lipoproteins, activity increased by statin drugs, deficiency causes familial hypercholesterolemia
LDL receptor–related protein (LRP)	12Q13-Q14, NM_000014	Clearance of apo E–containing lipoproteins
Scavenger receptor B1 (SR-B1)	12q24.32, Z22555	HDL receptor
Lipoprotein lipase (LPL)	8p22, NM_000237	Rate limiting for triglyceride metabolism, deficiency causes chylomicronemia syndrome
Lecithin-cholesterol acyltransferase (LCAT)	16q22.1, NM_000229	Esterifies cholesterol in HDL to increase HDL cholesterol levels, deficiency decreases HDL levels
Cholesteryl ester transfer protein (CETP)	16q13, NM_000078	Exchanges cholesteryl ester in HDL for triglycerides in apo B–containing lipoproteins, deficiency increases HDL levels
ABCA1	9q31, AJ12376	Transfers cholesterol in tissues to nascent HDL particles, deficiency causes Tangier disease
PCSK9	1p32.3, NC_000001.10	Degrades LDL receptor, deficiency decreases LDL levels

ABCA1 = ATP binding cassette A1; apo = apolipoprotein; HDL = high-density lipoprotein; LDL = low-density lipoprotein; PCSK9 = proprotein convertase subtilisin-like/kexin type 9.

is about 48% of the size of apo B100. Apo B100 and apo B48 are products of the same gene, with B48 resulting from the post-transcriptional introduction of a premature stop codon in the apo B messenger RNA by apobec1, a cytidine deaminase. Genetic variants in apolipoproteins can be associated with well-defined clinical syndromes.

Receptors and Proteins

Several receptors and proteins required for normal lipid transport are listed in Table 213-3.

Low-Density Lipoprotein Receptor

The LDL receptor mediates the removal of LDL as well as some VLDL and IDL particles by binding to apo B100 and apo E. The most important site of LDL receptor expression is the liver, where its regulation is mediated by sterol regulatory element-binding proteins (SREBPs). SREBPs are found in inactive forms in the endoplasmic reticulum (ER). When cellular cholesterol levels rise after the delivery of cholesterol by the LDL receptor, increased ER sterol content causes cholesterol to bind to Scap, a protein that promotes the migration of SREBPs from the ER to the Golgi. In the Golgi, SREBPs undergo proteolytic conversion to active forms that move to the nucleus and stimulate the expression of genes involved in cholesterol synthesis. The binding of cholesterol to Scap induces a conformational change that causes it to bind to Insigs, ER anchor proteins. However, when intracellular cholesterol levels are high, the Scap/SREBP complex does not move to the Golgi, SREBPs are not processed, and cholesterol synthesis stops. When cholesterol levels are low, Scap is released from Insigs, the Scap/SREBP complex moves to the Golgi,

SREBPs are converted to active forms, and genes important for cholesterol synthesis and acquisition (such as the LDL receptor) are transcribed. Statin drugs effectively lower cholesterol. They inhibit 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase, the rate-limiting enzyme in cholesterol synthesis. Cholesterol levels fall, Scap is free to shepherd SREBPs to the Golgi for activation, an active SREBP stimulates transcription of the LDL receptor gene, and increased levels of the LDL receptor protein on the surface of the hepatocyte bind and remove LDL particles from the circulation.

Low-Density Lipoprotein Receptor–Related Protein

The LDL receptor–related protein (LRP), also called the chylomicron remnant receptor, participates in the removal of intestine-derived lipoproteins by interacting with apo E. Chylomicron remnants carry apo B48, which is missing the LDL receptor binding domain, but these particles are also cleared by the LDL receptor through apo E binding.

Scavenger Receptor B1

Scavenger receptor B1 (SR-B1) is a protein expressed in liver that binds HDL. Unlike the LDL receptor that endocytoses LDL particles, SR-B1 does not appear to internalize HDL particles but instead facilitates the transfer of cholesteryl ester from HDL to the liver. Its genetic manipulation in mice has raised clinically relevant questions regarding the significance of elevated HDL levels. Inactivation of SR-B1 elevates HDL cholesterol levels but promotes atherosclerosis, presumably because of disruption of the transport of cholesterol from peripheral cells, where it can cause disease, to the liver, where it is excreted. These results suggest that it is not the level of HDL per se but the flux of cholesterol through HDL that affords protection from vascular disease.

Lipoprotein Lipase

Lipoprotein lipase (LPL) is rate limiting for the metabolism of triglyceride-rich lipoproteins and is required for the generation of HDL particles because HDL is absent from LPL-deficient mice. Deficient LPL activity thus provides a physiologic explanation for the common association between high triglyceride levels and low HDL cholesterol.

Lecithin-Cholesterol Acyltransferase

Another protein important in HDL metabolism is lecithin-cholesterol acyltransferase (LCAT). LCAT is associated with HDL in the circulation, where it esterifies free cholesterol to form cholesteryl esters that are easily stored in the nonpolar core of the lipoprotein. LCAT deficiency, a rare disorder, is characterized by low HDL as well as anemia and renal failure, clinical features probably related to disruption of the normal membrane function by the accumulation of excessive amounts of unesterified cholesterol.

Cholesteryl Ester Transfer Protein

Cholesteryl ester transfer protein (CETP) exchanges one molecule of cholesteryl ester in HDL for one molecule of triglyceride in apo B–containing particles such as VLDL. The resulting HDL particle is triglyceride enriched, enhancing its clearance (especially by an enzyme related to LPL, hepatic lipase) and lowering HDL. Inhibition of CETP activity increases HDL levels.

ATP Binding Cassette A1

ATP binding cassette A1 (ABCA1) is a cell membrane protein that mediates the transfer of cholesterol and phospholipids from cells to lipid-poor apo AI, a process that promotes HDL formation. ABCA1 in the liver contributes to the genesis of HDL, and overexpression of ABCA1 in macrophages may diminish atherosclerosis. Heterozygous ABCA1 deficiency is responsible for isolated low HDL cholesterol levels that occur in some kindreds (also known as familial hypoalphalipoproteinemia, based on an older term for HDL). Rare homozygotes for ABCA1 mutations have Tangier disease, characterized by the accumulation of cholesteryl esters in macrophages and resulting in distinctive features, including orange-yellow tonsils, neuropathy, and hepatosplenomegaly. HDL is very low to absent. Atherosclerosis is probably increased in these patients, but its extent may be moderated by concomitant low LDL levels.

Proprotein Convertase Subtilisin–Like/Kexin Type 9

Proprotein convertase subtilisin–like/kexin type 9 (PCSK9) is a secreted enzyme that promotes the degradation of the LDL receptor. Its overexpression decreases the LDL receptor, resulting in hyperlipidemia. PCSK9 deficiency in humans is associated with low LDL levels and less atherosclerosis. Pharmacologic inhibition of PCSK9 would be predicted to have similar effects.

EXOGENOUS LIPID METABOLISM

Animal products containing cholesterol and triglycerides are eaten regularly by most people. Dietary fats are broken down in the gut to free cholesterol and fatty acids, which are then transported across cell membranes into the enterocyte. There, they are re-esterified into cholesteryl ester and triglycerides and then packaged onto apo B48. These particles gain access to the plasma through the thoracic duct and acquire other apolipoproteins in part by transfer from HDL. These mature chylomicrons circulate to peripheral tissues. LPL, bound to the capillary endothelium in tissues such as adipose tissue and muscle, is activated by apo CII on chylomicrons, and fatty acids hydrolyzed from triglycerides by LPL are released and transported into adipose tissue for storage or into muscle for energy. This process also requires apo AV, an apolipoprotein transported in HDL that appears to facilitate the interaction between LPL and triglyceride-rich lipoproteins, as well as glycosylphosphatidylinositol-anchored high-density lipoprotein–binding protein 1 (GPIHBP1), a recently discovered protein that forms a platform for triglyceride metabolism at the endothelium.

Progressive hydrolysis of triglyceride converts chylomicrons into chylomicron remnants, which are relatively enriched in cholesteryl esters. Chylomicron remnants are removed in the liver by species that bind apo E: LRP, the LDL receptor, and cell surface glycosaminoglycans. Chylomicrons are large, and it is unlikely that they contribute to atherosclerosis. Chylomicron remnants are enriched in cholesteryl esters, the major lipid component of the atherosclerotic lesion, and small enough to enter the subendothelial space, where they are taken up by macrophages. Remnants are atherogenic, consistent with the idea that the progression of atherosclerotic lesions can occur in the postprandial state, a potential contributor to morbidity that is not assessed by current practices, which focus on the measurement of fasting lipoproteins.

Chylomicrons are not soluble. Their presence causes the "tomato soup" appearance of blood drawn after a fatty meal. Because they are mostly triglycerides, they float to the top of serum that is refrigerated overnight, leaving a layer of "cream" on top of the sample. The detection of chylomicrons in fasting serum has clinical relevance because it indicates a risk for pancreatitis and other elements of the chylomicronemia syndrome.

ENDOGENOUS LIPID METABOLISM

Fats deposited in the liver are further metabolized into component lipid species, re-esterified as cholesteryl ester and triglycerides, and either stored in hepatocytes or exported as lipoproteins (Fig. 213-1). The liver produces the triglyceride-rich VLDL. Its rate of production appears to depend on the availability of triglycerides. Apo B100 is the major apolipoprotein of VLDL, but under normal conditions, regulation of the apo B gene does not appear to play an appreciable role in the control of VLDL synthesis. Production of the apo B100 protein depends on its cotranslational stabilization. As the message is translated into protein, the presence of triglyceride stabilizes the peptide and allows the continued addition of amino acids. In the absence of triglycerides, the apo B molecule is degraded. The transfer of triglycerides to the growing apo B peptide is mediated by microsomal transfer protein (MTP). Mutations in MTP cause abetalipoproteinemia, a rare disease characterized by the absence of circulating apo B. In the absence of apo B, the metabolism of fat-soluble vitamins (normally carried in lipoproteins) is disrupted, and patients with abetalipoproteinemia suffer from multisystem defects, including severe neurologic dysfunction and retinopathy that are presumably caused by deficiency of vitamins E and A. Drugs that interfere with MTP function lower lipids but, not surprisingly, cause the accumulation of triglyceride in the liver. The apo B gene is normal in patients with abetalipoproteinemia. Mutations in the apo B gene cause another condition known as hypobetalipoproteinemia, caused by shortened forms of the apo B protein. Subjects with hypobetalipoproteinemia have very low, but not absent, levels of circulating lipids and appear to be healthy.

Nascent VLDL containing one apo B100 molecule per particle is secreted into the plasma, where it acquires apo E, apo CII, and apo CIII. In a process analogous to that occurring with chylomicrons, apo CII on VLDL activates LPL, and fatty acids hydrolyzed from triglycerides by LPL are released in capillary beds and transported into tissues. With continued hydrolysis and the loss of both phospholipids and apolipoproteins to HDL, VLDL is converted to IDL, a cholesteryl ester–rich particle with an apolipoprotein

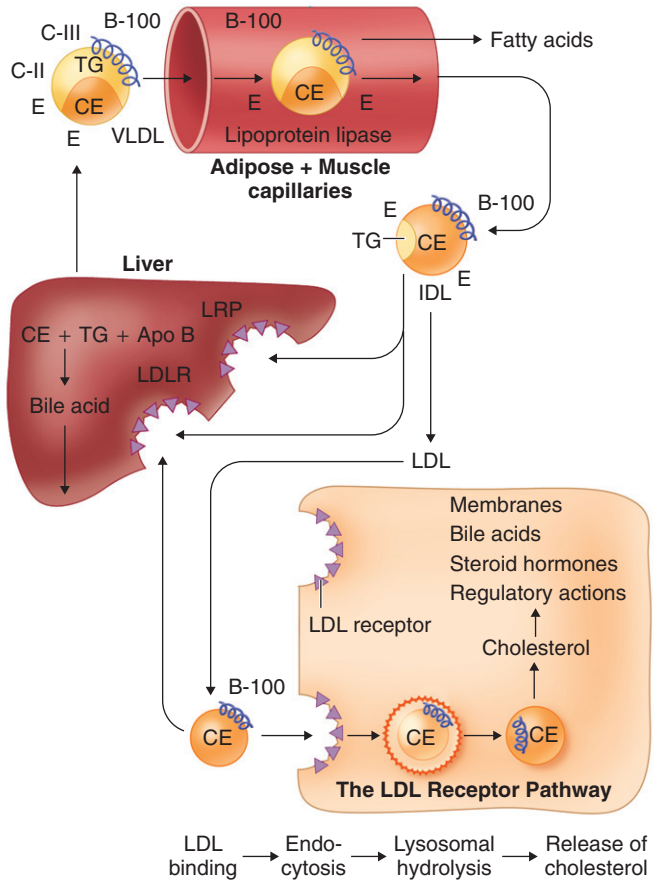

FIGURE 213-1. Endogenous lipid metabolism. In the liver, triglycerides (TG), cholesteryl esters (CE), and apolipoprotein B100 are packaged as very low density lipoprotein (VLDL) particles. TG is hydrolyzed by lipoprotein lipase to generate intermediate-density lipoprotein (IDL), which is further metabolized to generate low-density lipoprotein (LDL). This particle can be removed by the liver or by peripheral cells. Cholesterol derived from LDL regulates several processes and can be used for the synthesis of bile acids, steroid hormones, and cell membranes. LDLR = low-density lipoprotein receptor.

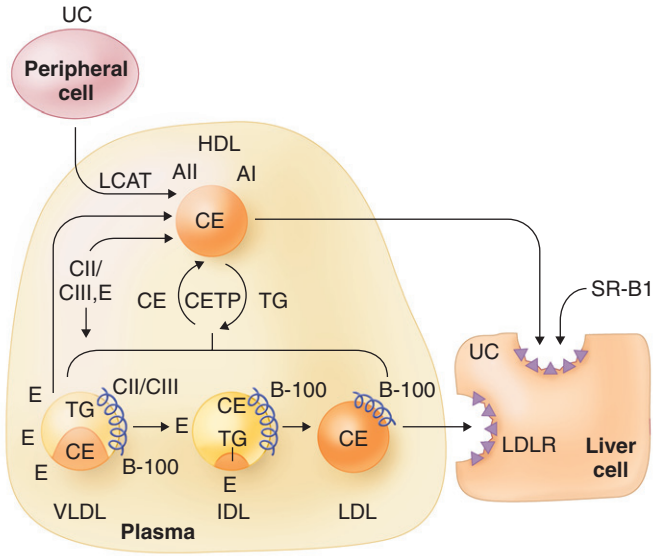

FIGURE 213-2. Reverse cholesterol transport and high-density lipoprotein (HDL) metabolism. Unesterified cholesterol (UC) in peripheral cells can be transferred to HDL and esterified by lecithin-cholesterol acyltransferase (LCAT). This cholesterol ester (CE) in HDL can be transferred to the liver directly through scavenger receptor B1 (SR-B1). Alternatively, it can be transferred to apolipoprotein B100–containing lipoproteins in exchange for triglycerides (TG) through the action of cholesteryl ester transfer protein (CETP). IDL = intermediate-density lipoprotein; LDL = low-density lipoprotein; LDLR = low-density lipoprotein receptor; VLDL = very low density lipoprotein.

complement of only apo B and apo E. These particles, like chylomicron remnants, are thought to have high atherogenic potential. Unlike chylomicron remnants, IDLs are included in current management schemes because reporting of LDL cholesterol levels by most clinical laboratories includes IDL. IDL can be taken up by either the LRP or the LDL receptor in the liver. In the presence of a normal apo E molecule, IDLs are converted to LDL, consisting of one molecule of apo B100 per particle and a cholesteryl ester with essentially no triglycerides. About 75% of LDL is removed from the plasma by the LDL receptor pathway, and most of this takes place in the liver. The uptake of LDL results in the migration of LDL particles to lysosomes, where cholesterol is released for (depending on the cell type) plasma membrane localization, bile acid synthesis, steroid hormone synthesis, and interaction with Scap for the control of SREBP activation. A minority of LDL enters the subendothelial space of the vascular wall, where its modification by oxidation or other processes promotes its uptake by macrophages in atherosclerotic lesions.

Most VLDL particles are large and are not thought to promote vascular disease. However, some small VLDL particles as well as IDL and LDL are atherogenic. Because the majority of VLDL is triglyceride, most patients with elevated levels of fasting triglyceride have either increased numbers of VLDL particles or an increased triglyceride content in each VLDL. LDL has a plasma half-life of 2 to 5 days. The detection of elevated levels of fasting cholesterol usually reflects the presence of either increased numbers of LDL particles or increased cholesteryl ester in each LDL. LDL also exists in a range of sizes. Small, dense LDL tends to occur in the setting of concomitant hypertriglyceridemia. This type of lipoprotein is thought to have greater atherogenic potential than larger LDL species, perhaps because of easy access to the vascular wall and greater susceptibility to oxidative modification. Lipoprotein particle size and number can be quantified by nuclear magnetic resonance techniques, but it is not clear that these data provide diagnostic advantages beyond the determination of total cholesterol, triglycerides, LDL cholesterol, and HDL cholesterol.

REVERSE CHOLESTEROL TRANSPORT AND HIGH-DENSITY LIPOPROTEIN METABOLISM

Lipid metabolism is dynamic. At the same time lipoproteins are being processed to modify their nonpolar lipids, particles are interacting with one another, exchanging surface materials, apolipoproteins, and nonpolar lipids. HDL is an important reservoir for components cast off during the metabolism of other lipoproteins as well as lipids discarded by cells. Nascent HDL is generated by the liver and intestine as a phospholipid disc containing apo AI and apo AII. It accepts unesterified (free) cholesterol (UC in Fig. 213-2) and phospholipids shed from cells. This unesterified cholesterol is converted to cholesteryl ester by the action of LCAT and stored in the center of the disc, allowing it to become a spherical particle. The particle is further modified as a consequence of the action of LPL on triglycerides in apo B–containing lipoproteins. As the core triglycerides of VLDL are metabolized, the particle collapses, leaving redundant surface lipids (phospholipid in the form of lecithin and unesterified cholesterol) and excess apolipoproteins such as apo CII, apo CIII, and apo E, which are transferred to HDL. LCAT again esterifies the cholesterol to increase the content of cholesteryl ester in the HDL.

Reverse cholesterol transport is the beneficial process by which cholesterol present in peripheral cells, such as foam cells in a growing atherosclerotic lesion, is transported back to the liver for excretion. There are at least two well-defined pathways mediating this transfer. First, after accepting cholesterol from peripheral cells and esterifying it through the action of LCAT, HDL can interact directly with the liver by binding to SR-B1 and transferring cholesteryl ester to the hepatocyte. Second, HDL can transfer cholesteryl ester to apo B100–containing lipoproteins such as VLDL (see bottom of Fig. 213-2) through the action of CETP. This cholesteryl ester can ultimately be transported to the liver after conversion of VLDL to IDL to LDL and uptake by the LDL receptor (LDLR in Fig. 213-2). This pathway is not direct because the transfer of cholesteryl ester to apo B–containing lipoproteins results in cholesterol-enriched particles that may be taken up by foam cells in atherosclerotic plaques before being cleared by the liver. Humans with genetic defects in CETP have high HDL levels and appear to be healthy. An inhibitor of CETP, torcetrapib, increases HDL cholesterol but also increases adverse events, perhaps in part related to its adverse effects on blood pressure. The benefits of raising HDL with medications are uncertain; a meta-analysis of more than 100 randomized trials showed no reduction in coronary heart disease events by simply increasing HDL.■

LIPID-ACTIVATED NUCLEAR RECEPTORS AND LIPID METABOLISM

Nuclear receptors are transcription factors that are activated by ligand binding to increase the expression of specific sets of genes. Several nuclear receptors are activated by lipids, play important roles in systemic lipid metabolism, and are current or potential targets of medications for altering lipids in patients.

Peroxisome proliferator-activated receptors (PPARs, so named because their activation increases peroxisomes in rodents) are thought to be activated by fatty acids or their derivatives, such as phospholipids. There are at least three types: PPARα, PPARγ, and PPARδ. PPARα appears to be particularly important in liver and muscle. It stimulates the expression of genes mediating fatty acid oxidation as well as those promoting the formation of HDL. Fibrate drugs such as gemfibrozil and fenofibrate work by activating PPARα. They lower triglycerides by accelerating the oxidation of fatty acids in the liver, so that less lipid is available for stabilizing apo B100 in VLDL secretion, and they elevate HDL by increasing the expression of apo AI, LPL, and other genes. PPARγ is expressed mostly in adipose tissue and macrophages, but it also has measurable effects in other tissues, such as muscle. It increases the expression of genes promoting the development of fat tissue and appears to suppress chronic inflammation. Thiazolidinedione drugs such as pioglitazone and rosiglitazone work by activating PPARγ. They lower blood glucose in people with diabetes by decreasing insulin resistance, a complex process that also results in multiple lipid effects, including lower triglycerides and higher HDL (expected to be beneficial) and higher LDL (expected to be detrimental). Their use is complicated by volume expansion and an increased risk of heart failure. Combined PPARα-PPARγ agonists are in development. PPARδ is expressed widely; has multiple potential effects, including increased fatty acid oxidation; and is the subject of intense pharmacologic investigation.

Two other nuclear receptors are activated by lipids and modulate lipid physiology. Liver X receptors (LXRα and LXRβ) are activated by oxidized derivatives of cholesterol. In the liver, they promote the synthesis of fatty acids and triglycerides in addition to stimulating both the conversion of cholesterol into bile acids and the excretion of bile acids into the gut. In the intestine, they suppress the absorption of cholesterol. The farnesoid X receptor (FXR) is activated by bile acids. FXR stimulates the secretion of bile acids into bile as well as the reabsorption of bile acids from the intestine.

Together, these receptors help orchestrate two important, futile cycles in lipid metabolism. In one, fatty acids exported from the liver (in the form of triglycerides within VLDL) and from the intestine (in chylomicron triglycerides) are released to peripheral tissues by the action of LPL. Some are taken up by muscle, where their activation of PPARα accelerates their oxidation in mitochondria, yielding adenosine triphosphate. Others enter adipose tissue, where they are re-esterified into triglycerides. From there, fatty acids are released in a process stimulated by catecholamines and glucagon. This process is complicated, involving hormone-sensitive lipase, a recently discovered enzyme known as adipose triglyceride lipase, and the remodeling of proteins that coat lipid droplets to alter their accessibility to lipases. Following lipolysis, fatty acids bind to albumin and return to the liver, where they can fuel the production of more VLDL particles. Nicotinic acid improves lipids in part by blocking the release of fatty acids from adipose tissue. A G protein–coupled receptor for nicotinic acid has been identified.

In another futile cycle, bile acids (formed from cholesterol and constituting the major pathway for the excretion of cholesterol from the body) are secreted into the intestine through events stimulated by LXR and FXR. Bile acids are reabsorbed in the terminal ileum. Treatment with bile acid sequestrants such as colesevelam interrupts this enterohepatic circulation, and the increased excretion of cholesterol (in the form of bile acids) depletes cholesterol content in the liver, leading to the induction of LDL receptors and thereby lowering circulating levels of LDL. This treatment also tends to elevate triglyceride levels, the result of de-repression of several processes mediated by FXR that decrease fatty acids and triglycerides. Through effects likely involving both LXR and FXR, colesevelam lowers blood glucose in people with type 2 diabetes.

IMPORTANT CLINICAL DISORDERS OF LIPID METABOLISM

Familial Hypercholesterolemia

EPIDEMIOLOGY

Familial hypercholesterolemia (FH) is an autosomal dominant form of hypercholesterolemia caused by defects in LDL receptor activity. The vast majority of affected patients have mutations in the LDL receptor gene. Heterozygotes for LDL receptor mutations occur at a frequency of perhaps 1 in 500 in the population, but they account for up to 5% of premature myocardial infarctions (those occurring in males younger than 55 and females younger than 65).

PATHOBIOLOGY

In addition to defects in the LDL receptor gene, other mutations can cause autosomal dominant hypercholesterolemia that is clinically indistinguishable from FH. These include familial defective apo B, caused by mutations that interfere with the ability of LDL to bind the LDL receptor, and variants in PCSK9.

CLINICAL MANIFESTATIONS

Total cholesterol levels are usually greater than 300 mg/dL, with LDL cholesterol levels greater than 200 mg/dL. Triglycerides are generally normal. Clinical features include thickening of the Achilles tendon as well as xanthomas at the extensor tendons of the knees and hands, reflecting the infiltration of lipid-laden macrophages at these sites. There is evidence that clinically apparent tendon xanthomas occur in a minority of patients with FH. Arthralgias are common, perhaps because of the presence of macrophage-mediated inflammation; these tend to improve with cholesterol lowering. Other features include xanthelasmas and corneal arcus, although the latter is also seen in elderly people and certain ethnic populations independent of cholesterol levels. Homozygotes (about 1 in 1 million) have total cholesterol levels in the range 800 to 1000 mg/dL and usually do not survive to adulthood without liver transplantation to provide LDL receptors. Children and adolescents with this disease may develop aortic valve disease because of macrophage infiltration at the aortic origin.

The penetrance of cardiovascular events in heterozygous FH is variable, with some subjects presenting with sudden death or accelerated disease in their 20s and others (generally women without other risk factors) surviving beyond menopause without clinically evident disease.

TREATMENT Rx

Treatment should address any associated risk factors for vascular disease, such as smoking, hypertension, and diabetes. Patients should be instructed in maintaining a diet low in saturated fat and cholesterol, and most require more than one cholesterol-lowering medication to achieve goals. The National Cholesterol Education Program provides periodic updates on the approach to screening and treating hyperlipidemia (Fig. 213-3). It is not uncommon for FH patients to be treated with a statin drug, a bile acid sequestrant such as colesevelam, and nicotinic acid. Some with aggressive disease require LDL apheresis, which involves perfusing blood through a column that extracts apo B–containing lipoproteins.

Familial Combined Hyperlipidemia

EPIDEMIOLOGY

Familial combined hyperlipidemia is an autosomal dominant form of hyperlipidemia that is present in up to 2% of the general population. It accounts for as many as 20% of cases of premature coronary artery disease.

PATHOBIOLOGY

The specific molecular defect is uncertain. Familial combined hyperlipidemia also appears to be associated with the metabolic syndrome (Chapter 237). The disorder is characterized by the primary overproduction of apo B. VLDLs secreted by the liver are small. Small, dense LDLs, thought to be particularly atherogenic, accumulate. For a given concentration of LDL cholesterol, patients with familial combined hyperlipidemia have greater numbers of LDL particles and an increased apo B concentration.

DIAGNOSIS

The diagnosis is made in the setting of a family history of premature coronary disease with different lipid phenotypes combined in the same family. Affected family members may have elevated triglycerides, elevated LDL cholesterol, or both, or they may have hypertriglyceridemia with low HDL cholesterol. Lipid phenotypes commonly change over time.

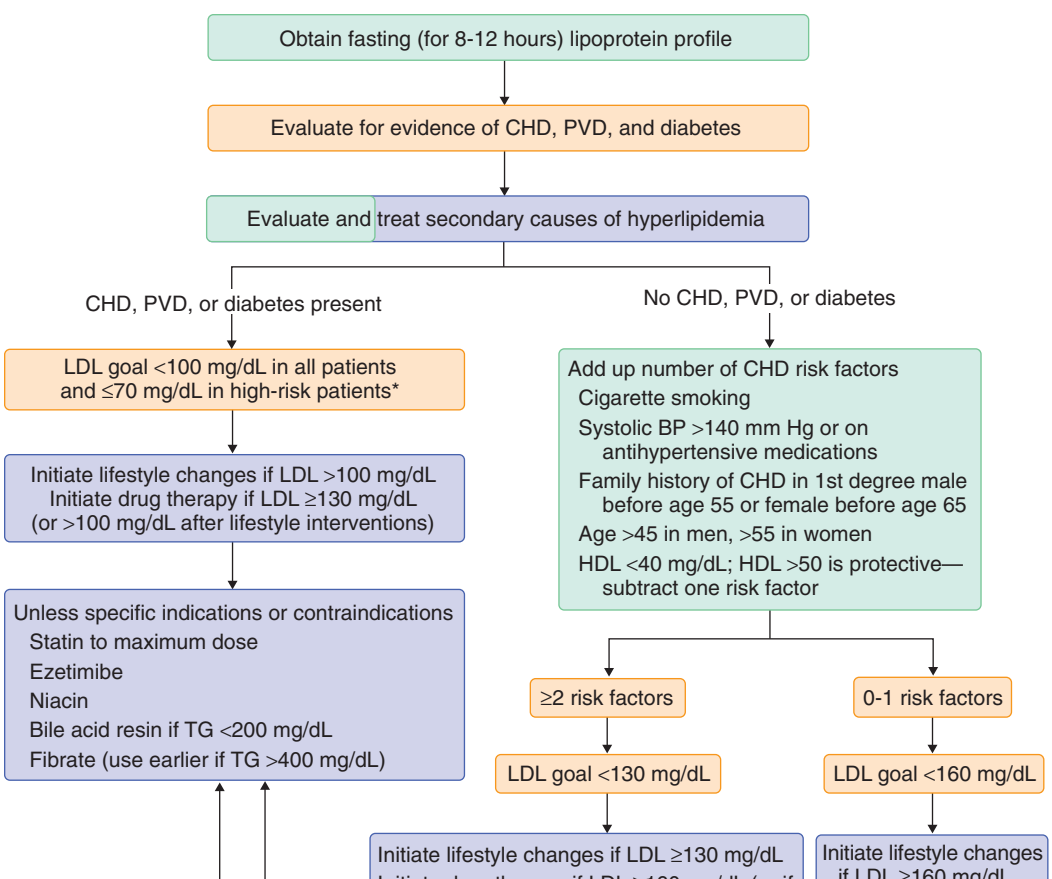

FIGURE 213-3. Approach to lipid screening and treatment. BP = blood pressure; CHD = coronary heart disease; HDL = high-density lipoprotein; LDL = low-density lipoprotein; PVD = peripheral vascular disease; TG = triglycerides. * >20% 10-year risk of cardiovascular events. (Based on recommendations from Executive summary of the third report of the National Cholesterol Education Program [NCEP] expert panel on detection, evaluation, and treatment of high blood cholesterol in adults [Adult Treatment Panel III]. *JAMA*. 2001;285:2486-2497.)

Familial Hypertriglyceridemia

Familial hypertriglyceridemia is also a common autosomal dominant disorder, occurring in 1 to 2% of the general population. Affected family members have isolated elevated triglycerides. A unifying molecular mechanism is lacking. The phenotype is stable, with affected family members consistently showing isolated hypertriglyceridemia on repeated analyses. The disorder is characterized by primary overproduction of triglyceride. Lipoprotein particles tend to be large, consisting of increased amounts of triglyceride relative to apo B. For a given level of cholesterol, these patients have lower numbers of lipoprotein particles and a decreased apo B concentration. The relationship between this disorder and cardiovascular risk is uncertain. Affected kindreds do not appear to have a propensity for premature vascular disease, but these individuals are at risk for the chylomicronemia syndrome when an additional stimulus for hypertriglyceridemia, such as uncontrolled diabetes, is present.

Chylomicronemia Syndrome

PATHOBIOLOGY

This syndrome occurs when triglycerides are extremely elevated, usually greater than 2000 mg/dL. Individuals with homozygous defects in the LPL gene can present with the syndrome in infancy, although the penetrance of clinical sequelae is extremely variable. Some individuals suffer repeated episodes of the syndrome throughout life, whereas others with triglycerides consistently above 2000 mg/dL remain completely asymptomatic. The basis for the wide spectrum of symptoms despite similar degrees of severe hypertriglyceridemia is unknown. Other molecular defects responsible for the syndrome include mutations in apo CII and apo AV.

Although defects in LPL, apo CII, and apo AV can cause the syndrome, the disorder is most likely to occur when patients with a common predisposition to hypertriglyceridemia (familial combined hyperlipidemia or familial hypertriglyceridemia) develop another defect associated with elevated triglycerides (such as uncontrolled diabetes, obesity, and treatment with glucocorticoids, estrogens, or other drugs).

CLINICAL MANIFESTATIONS

Clinical features include eruptive xanthomas on the back, buttocks, knees, and elbows; lipemia retinalis (a white appearance of retinal blood vessels, usually seen with triglycerides >4000 mg/dL); severe abdominal pain and pancreatitis (which can be life threatening); hepatosplenomegaly; dyspnea; lymphadenopathy; and neurologic dysfunction, such as memory loss and peripheral neuropathy.

DIAGNOSIS

Evaluation can be complicated by the presence of extreme hypertriglyceridemia, which interferes with the determination of amylase (pancreatic lipase should be measured when pancreatitis is suspected) and artifactually lowers serum glucose, sodium, and other analytes.

TREATMENT Rx

Treatment consist of intravenous hydration and other supportive care for pancreatitis, complete elimination of dietary fat (which usually causes striking decreases in lipids within 24 to 48 hours), and appropriate blood glucose control with insulin in the setting of diabetes.

Dysbetalipoproteinemia

This rare disorder is caused by a mutation in apo E. There are three common variants of the apo E protein: E2, E3 (considered normal), and E4. Subjects with one or more E4 alleles are at risk for Alzheimer's disease. Subjects with two E2 alleles are at risk for dysbetalipoproteinemia. The frequency of this genotype is about 1% in the general population, but dysbetalipoproteinemia is rare, requiring an additional poorly defined factor. Hypothyroidism is known to precipitate the disorder. Subjects classically present with equal elevations of triglycerides and cholesterol in the range of about 300 to

600 mg/dL and xanthomas, especially in the palmar creases of the hands. They are at substantial risk for coronary artery disease. Unlike patients with FH, patients with dysbetalipoproteinemia are also at risk for severe peripheral vascular disease. Atherosclerosis occurs in part because of the presence of elevated concentrations of chylomicron remnants, which are not removed normally because of the presence of apo E2, and IDL particles, which are not converted normally to LDL in the presence of apo E2. It is unknown why the remnants that accumulate in dysbetalipoproteinemia cause both peripheral vascular disease and coronary disease, whereas the LDL particles that accumulate in FH tend to cause only coronary disease.

Diabetic Dyslipidemia

PATHOBIOLOGY

Insulin is a critical regulator of lipid metabolism, and because diabetes represents impaired insulin signaling, lipid disorders are common in both type 1 and type 2 diabetes (Chapters 236 and 237). Hypertriglyceridemia is the hallmark of diabetic dyslipidemia. This is driven by two mechanisms. First, LPL is insulin dependent. In the absence of insulin or in the presence of insulin resistance, LPL enzyme activity is deficient, and triglyceride-rich lipoproteins cannot be metabolized appropriately. Second, insulin suppresses the release of free fatty acids from adipose tissue stores. Insulin deficiency or resistance results in unabated release of free fatty acids, and these return to the liver, where they stabilize apo B synthesis and increase VLDL production.

TREATMENT

Rx

The lack of insulin in patients with type 1 diabetes causes diabetic ketoacidosis, in which elevated triglycerides can be severe and are corrected by reinstitution of insulin therapy (Chapter 236). Intensive insulin therapy in type 1 diabetes decreases triglycerides, LDL, and often lipoprotein (a). Patients gain weight with intensive insulin therapy, and increased adiposity tends to lower HDL levels, which may explain why HDL does not always increase in intensively treated type 1 patients. Patients with type 2 diabetes usually have increased triglycerides and decreased HDL. These abnormalities improve but seldom normalize with better glycemic control. Most of the improvement occurs with initial pharmacologic glucose-lowering therapy, regardless of its mechanism of action.

Diabetes is frequently classified as a secondary cause of lipid disorders. However, lipid abnormalities are intrinsic to diabetes, and people with diabetes who lack clinical evidence of vascular disease have the same risk for cardiovascular events as those with established coronary disease. Therefore, every person with diabetes should be evaluated for lipid disorders, and adequate control of lipid levels often requires treatment with a statin drug. In patients with diabetes, cholesterol-lowering therapy reduces vascular mortality. This intervention should not be delayed while glycemic control is optimized.

TABLE 213-4 SECONDARY CAUSES OF LIPID DISORDERS

CONDITION/MEDICATION	COMMENTS
Diabetes	Common contributor to dyslipidemia; abnormal lipids are seldom normalized by glycemic control alone
Hypothyroidism	Thyroid hormone regulates multiple steps in lipid metabolism, including LDL receptor expression and LPL activity
Alcohol	Can cause hypertriglyceridemia in susceptible patients, but mild intake linked to decreased risk of vascular disease
Renal disease	Increased LDL in nephrotic syndrome, hypertriglyceridemia in end-stage renal disease
Obstructive liver disease	Can be associated with very high cholesterol levels; some evidence that diseases such as primary biliary cirrhosis are not associated with increased vascular events despite dyslipidemia
Diuretics	Increased LDL with high doses; current practice of using low doses of thiazides decreases vascular events and has minimal effect on lipids
β-Adrenergic receptor blockers	Increased triglycerides and decreased HDL, probably by inhibiting LPL
Anabolic steroids	Can result in very low HDL (<10 mg/dL)
Estrogens	Exacerbate hypertriglyceridemia when given orally; this effect is not seen with topical estrogen therapy
Protease inhibitors	Increased triglycerides and decreased HDL especially in the setting of HIV-associated lipodystrophy
Glucocorticoid excess	Increased triglycerides and decreased HDL, probably related to exacerbation of insulin resistance
Antipsychotics	Increased triglycerides and decreased HDL, probably related to increased adiposity and insulin resistance
Retinoids	Increased triglycerides
Systemic lupus erythematosus	Chronic inflammation may increase risk of vascular disease independent of effects on lipid metabolism
Acute intermittent porphyria	Many agents used to treat lipid disorders reported to provoke episodes of abdominal pain

HDL = high-density lipoprotein; HIV = human immunodeficiency virus; LDL = low-density lipoprotein; LPL = lipoprotein lipase.

EVALUATION AND THERAPY OF LIPID DISORDERS

Diagnosis

The initial evaluation should include a complete history and physical examination, with careful attention to potential secondary causes of lipid disorders (Table 213-4). Diabetes, hypothyroidism, and excess alcohol intake are probably the most common secondary contributors to abnormal lipid metabolism.

Among prescription medications, β-adrenergic blocking agents are frequent contributors to abnormal lipid profiles. These agents have proven beneficial effects after myocardial infarction but also tend to promote weight gain, elevate triglycerides, and decrease HDL. Many clinicians are using lower doses of these agents and relying on more lipid-neutral drugs (angiotensin-converting enzyme inhibitors and angiotensin receptor blockers) for blood pressure control.
